TRANSACTIONS

OF THE

AMERICAN INSTITUTE

OF

ELECTRICAL ENGINEERS

JANUARY TO SEPTEMBER 1927.

VOL. XLVI

PUBLISHED BY THE
AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS
33 WEST THIRTY-NINTH STREET
NEW YORK, N. Y., U. S. A.
1927

Press of McIlroy & Smith, Inc., 22 Thames Street, New York

Preface

This is the forty-sixth and last annual volume of the TRANSACTIONS of the American Institute of Electrical Engineers. It consists of the complete papers and accompanying discussions presented at the two conventions and three regional meetings of the Institute prior to September 1927. The January 1928 Quarterly TRANSACTIONS contains the papers from the two succeeding meetings in 1927. The annual report of the Board of Directors for the fiscal year ending April 30, 1927, and a list of the officers, committeemen, and Section and Branch officers for that period, are included in this volume. The index of subjects has been made as complete as possible, with ample cross references. The authors' index contains as well the names of all those contributing to the discussions. In addition to the papers published in this volume, the index lists certain articles of more transitory interest, which were printed only in the JOURNAL.

In 1928, with Volume 47, the Institute inaugurates its new policy under which the JOURNAL consists of abridged papers, while the Quarterly TRANSACTIONS will contain the papers and discussions in full.

Synchronous Machines—III

Torque-Angle Characteristics Under Transient Conditions

BY R. E. DOHERTY* and C. A. NICKLE*

Associate, A. I. E. E. Associate, A. I. E. E.

Synopsis.—This is the third part of a series of papers on the subject of synchronous machines. The first two were:

I. An Extension of Blondel's Two-Reaction Theory,

II. Steady State Power-Angle Characteristics.

The present paper deals with the power-angle, or torque-angle, characteristics under transient conditions, namely,

A. Cyclic variation of impressed torque,

B. Sudden angular displacement,

C. Synchronizing out of phase.

It is shown, as in Fig. 6, that although the slope of the torque-angle characteristic (which is an important factor in the determination of the resonant frequency) under the oscillatory condition is greater over a large range of values of the average angle δ' than under steady operation, nevertheless in the range of normal operation, i. e., from $\delta' = 0$ to $\delta' = 25$ deg., the two slopes, in the case of salient-pole machines, are practically the same. Hence, it is only in rather rare, special cases that a correction in the slope for the oscillatory condition is necessary. For such cases, Equation 27 gives the correction.

Referring to condition B, Fig. 13 shows the steady state torque-angle characteristic and also the characteristics for the condition of sudden angular displacement, the latter occurring from various given points on the steady state curve. The slopes indicated by dotted line segments in Fig. 6 merely correspond to parts of the complete characteristics shown in Fig. 13. The latter are calculated from Equation 46.

It is fairly well known that synchronizing out of phase gives rise to much larger torque than would exist at the same angular displacement under steady operation. The difference between these two torques is shown in Fig. 17 for a steam turbine type generator. The steady state torque is calculated from Equation 26; the transient torque from Equation 61.

IN certain applications of synchronous machines it is required to determine the relation between the torque and the displacement angle under transient conditions. For instance, when such a machine is direct-coupled to a reciprocating engine or compressor, there is, of course, a resultant alternating component of torque which causes an angular oscillation of the machine. This produces current pulsations in the line which are a function of the torque-angle characteristic,—that is, of the "synchronizing torque." Such an oscillation induces currents in the field winding, thus affecting the values of synchronizing torque, and therefore must properly be treated as a transient phenomenon. The present treatment, on this basis, however, shows that although there may be special cases where the effect of the oscillation on synchronizing torque is significant, there are nevertheless many practical applications where it is not.

Another instance is sudden angular displacement. If, when operating under a given load condition and angular displacement, the rotor is suddenly displaced to a different angle, the torque at the new angle will be different, under this transient condition, from the value at the same angle under steady operation.

Still another instance is synchronizing an incoming alternator out of phase. In this case, the resulting current and torque are much greater than at the same phase difference under steady operation. There may be danger of overstressing the shaft or coupling in such a case; hence it is important to have means for predetermining such forces.

The problem of steady state operation has already been treated by the authors[1]. It has also been treated more recently by Putman[2], giving the same results for those aspects of steady operation treated by him. His paper also investigated certain conditions of transient operation. The results for the latter, however, differ in certain important respects from the present treatment.[3]

It is the purpose of the present paper to establish mathematically, from what appear to be reasonable and practical premises, the relation between torque and the displacement angle of a synchronous machine under the following conditions:

A. Cyclic variation of impressed torque,

B. Sudden angular displacement,

C. Synchronizing out of phase.

PREMISES

For condition A it is assumed that:

1. *The machine is connected to a relatively large power system,*
2. *The effect of armature resistance is negligible.* This has been justified in a previous paper.[1]
3. *The currents are polyphase, balanced, sine waves (in time).* They can be resolved, therefore, into two complementary polyphase current systems, one in which the current in each individual phase reaches maximum at the instant the axis of the field pole coincides with the axis of magnetization of the phase under consideration—this is termed the *direct* component of current; and another in which the current in the same phase reaches maximum one quarter-cycle later, that is, in time quadrature. This is termed the *quadrature* component[1].
4. *The machine has salient poles.* Cylindrical rotor thus becomes a special case of salient poles in which the synchronous reactances in the *direct* and *quadrature* axes are equal. The transient reactances in the two axes, however, may or may not be equal.

*Both of the General Electric Co., Schenectady, N. Y.

1. All numbered references are to the Bibliography.

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

5. *The machine has a short-circuited rotor winding in the quadrature axis, as well as the main field winding in the direct axis.* The effect of an amortisseur winding may thus be taken into account as a practical approximation.

6. *Saturation is negligible.* While the results apply strictly only to machines in which magnetic saturation is negligible, nevertheless this does not mean that practical calculations, within practical accuracy, can not be thus made when saturation is present. Indeed, they are made, just as many other similar calculations are made, by exercising engineering judgment in shading the constants of the machine with respect to the degree and distribution of the saturation.

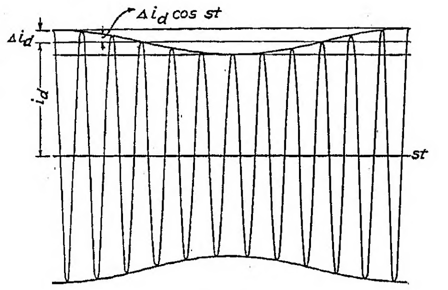

FIG. 1

Such a procedure should be recognized, however, as an approximation and should not be treated, as it sometimes is, as a correct method. The theory of superposition does not apply when saturation is present. Hence a linear relation between field current and nominal voltage can not be combined properly with other equations of armature voltage.

7. *The pulsation in the magnitude of the fundamental component of armature m. m. f. is harmonic.* The pulsation may comprise more than one harmonic, in which case each may be treated separately, and the results superposed.

8. *The frequency of this pulsation is low compared with the normal electrical frequency.* It thus becomes permissible, as a close approximation, to express the current as a vector of harmonically varying amplitude. The modulation frequency, *i. e.*, the frequency of the envelope of the current wave, must be low enough for the polyphase relation of the currents at any instant not to be appreciably disturbed. In still other words, the current wave throughout any cycle of normal frequency is not appreciably changed from a sine wave by the modulation, as indicated in Fig. 1.

For conditions B and C, it is assumed, in addition to the above and excepting 7 and 8, that

9. *The effect of the field circuit resistance is negligible in the first moment.* It is assumed that the time interval in which the displacement occurs is small enough to justify this.

10. *The direct component of the transient armature current is neglected.* This component gives rise to an alternating torque comprising normal frequency and higher harmonics. These rapidly alternating torques do not, as a rule, produce significant motional effects, on account of the relatively large inertia of the rotor with respect to the frequency of the torques. These will be treated in a future paper. The present treatment deals only with that component of torque which is unidirectional for a given displacement and is the component which may throw large stresses on the shaft if a machine is synchronized out of phase.

A. CYCLIC VARIATION OF IMPRESSED TORQUE

When a synchronous machine is direct-coupled to a reciprocating engine or compressor, the impressed torque comprises a steady component with superposed alternating components. The latter may be substantially a single harmonic, or it may comprise a number of significant torque harmonics. Each harmonic may be treated independently.

The problem may therefore be definitely stated as follows: A synchronous machine, operating on a relatively large power system, and carrying a given average mechanical load, experiences also an impressed cyclic, angular oscillation which produces an harmonic modulation of the armature current, as indicated in Fig. 1. This induces, by transformer action, a corresponding alternating component of current in the field winding, thus affecting the power-angle, or torque-angle, characteristic of the machine—that is, changing the slope, as indicated in Fig. 2. Thus, instead of an oscillation above and below the point p, from a to b on the steady state characteristic, as would occur at very low frequency of impressed oscillation, the actual oscillation, for the above reasons, would be from a' to b', *i. e.*, at a different slope. In other words, if the frequency of oscillation is low enough in relation to the resistance of the field circuit, the adjustment of the field flux to the changing armature m. m. f. will be effected without appreciable induced currents in the field. On the other hand, for the same angular oscillations, if the frequency is so high that the field flux cannot change,

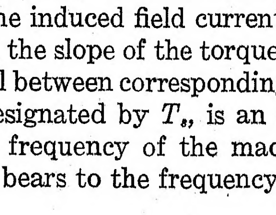

FIG. 2

the maximum induced field current will result—*i. e.*, that which is required to maintain constant flux linkages. Hence the induced field current will be between these limits and the slope of the torque-angle characteristic will also fall between corresponding limits.

The slope, designated by T_s, is an important factor in the *resonant* frequency of the machine. The relation which this bears to the frequency of the *impressed*

oscillation is an important factor in determining the magnitude of the oscillation[4].

The present problem, therefore, is to determine the slope of the torque-angle characteristics at the point p corresponding to the average torque, Fig. 2.

The plan of attack is, first, to determine the rotor current induced by the oscillation. This, added to the average value supplied by the exciter, determines the total nominal voltage as a function of time. From the vector diagram of voltages, the displacement angle of the machine is also expressed as a function of time. Since the torque has been shown[1] to be a function of the nominal voltages and displacement angle, it may also be expressed, from the foregoing relations, as a function of time. The torque thus expressed contains a constant term and an alternating component. The plan is to obtain the complex expression for "motional impedance* by dividing the alternating component of torque by the alternating component of velocity, both expressed as vectors. The two components of the motional impedance give, respectively, the damping coefficient and the resilience coefficient, *i. e.*, synchronizing torque.

The use of motional impedance is convenient because of its analogy with electrical impedance. In the particular convention chosen[5], velocity corresponds to current, torque to voltage, damping constant to resistance, motional reactance to capacity reactance, etc.

Thus, the real term of the motional impedance consumes a torque which is in phase with the velocity (just as resistance consumes a voltage in phase with the current) and therefore represents damping. The imaginary term, the motional reactance, consumes a torque which is in time quadrature with the velocity (just as capacity reactance consumes a voltage in quadrature with the current) and hence in phase with, and proportional to, the displacement—just as the voltage across the condenser is in phase with and proportional to the charge. It therefore represents the synchronizing torque. That is, the change of angular displacement is accompanied by a proportional change in torque. This proportionality factor, *i. e.*, the slope of the torque-angle characteristic, is the objective of the investigation for condition A.

Percentage Representation of Quantities. As in the first two sections of this investigation, already published[1], the various quantities here will be expressed as a percentage (as a fraction) of some definite value, thus avoiding cumbersome conversion factors and other constants. For instance, all armature currents are expressed as fractions of normal current; all voltages, as fractions of normal voltage; etc.

Equations for Condition A. Since the modulation of the armature current produced by the angular oscillation of the machine is assumed to be harmonic, the current wave will be as shown in Fig. 1. The total direct component of current i_d at any time t and expressed in terms of the peak value, is

$$i_d = i_d' + \Delta\, i_d \cos s\, t \qquad (1)$$

where

$\Delta\, i_d$ = the peak value of the low-frequency alternating component which causes the modulation, as shown in Fig. 1,

i_d' = the steady, or average, value of the direct component expressed in terms of the peak value as a fraction of the peak value of normal current,

s = angular velocity corresponding to the frequency of modulation, expressed as a fraction of the angular velocity corresponding to normal electrical frequency,

t = time, expressed as a fraction of the time required, at normal frequency, to pass one electrical radian.

Thus the time angles corresponding to the two frequencies are expressed, respectively, at $s\, t$ and t.

Likewise, the quadrature component is

$$i_q = i_q' + \Delta\, i_q \cos (s\, t + \alpha) \qquad (2)$$

where α = the time phase difference between the low-frequency modulations of the direct and quadrature components of current.

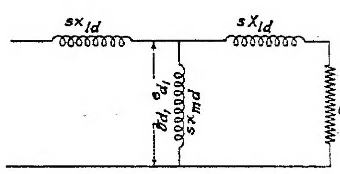

FIG. 3

Zero time can be chosen so that (1) is true, since the total current, and therefore each of the two components, is assumed to be modulated harmonically. But the phase difference α is not known.

The modulation of the polyphase armature currents produces a corresponding low-frequency variation in the otherwise constant magnitude of the armature m. m. f. (space sinusoid), *i. e.*, the armature reaction, which rotates at the same speed with the field poles. That particular component of armature reaction which is directly opposite the pole, that is, the direct component produced by i_d, is impressed on the same magnetic circuit with which the main field winding is linked. Thus, by transformer action, these harmonic variations in armature currents induce corresponding variations in the field winding, the latter being short-circuited through the exciter armature.

The variations in the quadrature component, however, are obviously not short-circuited by the main field winding. If there is an amortisseur winding, or some other short-circuited winding in the quadrature axis, the currents induced therein by the variations of i_q must also be taken into account.

The next step is to determine these induced field currents. Just as the armature reaction can be ex-

*This term has been used by Dr. A. E. Kennelly and others.

pressed in terms of the current of only one phase (because all of the currents are related in phase and magnitude so that this is possible) it is obviously also possible to express in the same way the variation of that armature reaction, within the limits of the premises. Hence the transformer relations may be determined from the well-known equivalent circuit. Thus in Fig. 3,

x_l = armature leakage reactance at normal frequency (see notation). This is taken to be the same for i_d and i_q. See "Reactance," in Bibliography 1.

X_{lda} = field leakage reactance, in armature terms, for the winding in the direct axis—*i. e.*, main field winding.

R_{da} = resistance of main field winding, armature terms.

x_{md} = mutual reactance, direct axis.

x_{d1} = equivalent impedance. See Fig. 3.

e_{d1} = voltage across z_{d1}.

It is shown in Appendix A that the variation in the field current, direct axis, corresponding to $\Delta\, i_d$ is

$$\Delta\, \dot{I}_d = \Delta\, \dot{i}_d\,(a + j\,b) \tag{3}$$

or, as a function of time, from (**1**),

$$\Delta\, I_d = \Delta\, i_d\,(a \cos s\,t - b \sin s\,t) \tag{3a}$$

Likewise

$$\Delta\, \dot{I}_q = \Delta\, \dot{i}_q\,(c + j\,d) \tag{4}$$

and, from (2) and (4),

$$\Delta\, I_q = \Delta\, i_q\,(c \cos \alpha - d \sin \alpha) \cos s\,t - (c \sin \alpha + d \cos \alpha) \sin s\,t \tag{4a}$$

where

$$a = \frac{s^2\, x_{md}^2\,(x_{md} + X_{lda})}{R_{da}^2 + s^2\,(x_{md} + X_{lda})^2}$$

$$b = \frac{s\, x_{md}^2\, R_{da}}{R_{da}^2 + s^2\,(x_{md} + X_{lda})^2}$$

$$c = \frac{s^2\, x_{mq}^2\,(x_{mq} + X_{lqa})}{R_{qa}^2 + s^2\,(x_{mq} + X_{lqa})^2}$$

$$d = \frac{s\, x_{mq}^2\, R_{qa}}{R_{qa}^2 + s^2\,(x_{mq} + X_{lqa})^2}$$

With the alternating components of the field currents thus determined, the nominal voltages, which are proportional to the field currents, may be also determined by adding to the alternating component, the constant term supplied by the exciter. Since both the field current and the nominal voltage are expressed as fractions, they are numerically equal. Thus the peak value of the total nominal voltage, direct axis, at any time is, from (**3a**),

$$\begin{aligned} e_d &= I_d' + \Delta\, I_d \\ &= I_d' + \Delta\, i_d\,(c \cos s\,t - b \sin s\,t) \end{aligned} \tag{5}$$

and, since there is assumed to be no constant excitation in the quadrature axis, the quadrature component is, from (**4a**),

$$\begin{aligned} e_q &= \Delta\, I_q \\ &= \Delta\, i_q (c \cos \alpha - d \sin \alpha) \cos s\,t - (c \sin \alpha + d \cos \alpha) \sin s\,t \end{aligned} \tag{6}$$

The variable displacement angle δ will now be determined as a function of time. From Fig. 4 it is shown in Appendix A that two expressions for this angle can be written: one, as a function of $\Delta\, i_q$, t and α; the other, as a function of $\Delta\, i_d$ and t. These will be identities involving terms of $\sin s\,t$ and $\cos s\,t$. Equating the respective coefficients, as in Appendix A, α is determined. Thus,

$$\cot \alpha = \frac{b\,d + (x_d - a)\,(x_q - c)}{d\,(x_d - a) - b\,(x_q - c)} \tag{7}$$

Also, it is shown by equating the magnitudes (since the expressions represent the same angle) that the ratio of $\Delta\, i_q$ to $\Delta\, i_d$ is

$$\frac{\Delta\, i_q}{\Delta\, i_d} = \sqrt{\frac{(x_d - a)^2 + b^2}{(x_q - c)^2 + d^2}}\, \cot \delta' \tag{8}$$

The variable displacement angle δ comprises the average component δ' plus an alternating component $\Delta\, \delta$.

Thus

$$\delta = \delta' + \Delta\, \delta \tag{9}$$

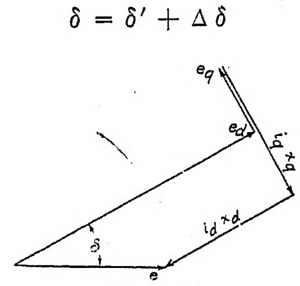

FIG. 4

The alternating component as a function of t and $\Delta\, i_d$ is, as shown in Appendix A,

$$\Delta\, \delta = \frac{\Delta\, i_d\,[(x_d - a) \cos s\,t + b \sin s\,t]}{e \sin \delta'} \tag{10}$$

It has been shown[1] that the torque of a synchronous machine connected to a power system of constant voltage is determined by the nominal voltages e_d and e_q, the terminal voltage e, the synchronous reactances x_d and x_q, and the displacement angle δ. It is

$$T = \frac{e\, e_d}{x_d} \sin \delta + \frac{e\, e_q}{x_q} \cos \delta + \frac{e^2\,(x_d - x_q)}{2\, x_q\, x_d} \sin 2\,\delta \tag{11}$$

This equation gives the torque not merely for steady state conditions, when $\Delta\, \delta = 0$, but for any condition within the limits of the premises, when the actual values of e_d, e_q and δ, existing at the moment under consideration, are substituted.

Substituting in Equation (**11**), e_d from (**5**), e_q from (**6**), δ from (**9**) and (**10**), and $\Delta\, i_q$ from (**8**), the equation for the torque T at any time t is obtained, which contains a constant term T' and an alternating component $\Delta\, T$. Thus

$$T = T' + \Delta T$$

where

$$T' = \frac{e\, e_d'}{x_d} \sin \delta' + \frac{e^2}{2} \frac{(x_d - x_q)}{x_d\, x_q} \sin 2\, \delta' \qquad (12)$$

It is convenient to express the alternating component of torque as a vector. Thus

$$\Delta \underset{\cdot}{T} = \Delta i_d \left\{ \frac{x_d - a}{e \sin \delta'} T_s' + \frac{a\, e \sin \delta'}{x_d} + \frac{e \cos^2 \delta'}{x_q \sin \delta'} (c \cos \alpha - d \sin \alpha) \sqrt{\frac{(x_d - a)^2 + b^2}{(x_q - c)^2 + d^2}} \right\}$$
$$+ j\, \Delta i_d \left\{ - \frac{b}{e \sin \delta'} T_s' + \frac{b\, e \sin \delta'}{x_d} + \frac{e \cos^2 \delta'}{x_q \sin \delta'} (c \sin \alpha + d \cos \alpha) \sqrt{\frac{(x_d - a)^2 + b^2}{(x_q - c)^2 + d^2}} \right\} \qquad (13)$$

where T_s' is the synchronizing torque, given by Equation (26), corresponding to steady state operation.

The next step is to obtain the vector expression for the alternating component of velocity. Dividing (13) by this velocity will give the motional impedance. The velocity of oscillation is given by the rate of change of δ with respect to time. Thus, substituting (10) in (9) and differentiating, the velocity is

$$\Omega = \frac{d\, \delta}{d\, t} = \frac{d\, \Delta\, \delta}{d\, t} = \frac{s\, \Delta\, i_d}{e \sin \delta'} \left[- (x_d - a) \sin s\, t + b \cos s\, t \right] \qquad (14)$$

Taking the cos $s\,t$ term as reference vector, as before, (14) becomes

$$\underset{\cdot}{\Omega} = \frac{s\, \Delta\, i_d}{e \sin \delta'} \left[b + j\, (x_d - a) \right] \qquad (15)$$

Consider further the meaning of motional impedance. The well-known equation for torque consumed in any mechanical system involving inertial reaction, damping, and resilience is, for rotation,

$$T = I \frac{d\, \Omega}{d\, t} + T_d\, \Omega + T_s \int \Omega\, d\, t \qquad (16)$$

where

Ω = angular velocity
I = moment of inertia
T_s = resilience coefficient
T_d = damping coefficient

This is exactly analgous to the expression for voltage consumed in an electrical circuit containing inductance, resistance, and capacity. The familiar equation is

$$E = L \frac{d\, i}{d\, t} + R\, i + \frac{1}{C} \int i\, d\, t \qquad (17)$$

Now if the current in (17) is a sine wave, it can be expressed of course as a vector by the following familiar method. Let

$$\frac{d}{d\, t} = j\, \omega$$

where ω = the angular velocity corresponding to the frequency of the current.

Then Equation (17) becomes

$$\underset{\cdot}{E} = \underset{\cdot}{i} \left(j\, \omega\, L + R + \frac{1}{j\, \omega\, C} \right)$$

or

$$\underset{\cdot}{i} = \frac{\underset{\cdot}{E}}{R + j \left(\omega\, L - \frac{1}{\omega\, C} \right)} \qquad (18)$$

Similarly, in Equation (16), if the total consumed torque is a sine wave, the velocity is

$$\underset{\cdot}{\Omega} = \frac{\underset{\cdot}{T}}{T_d + j \left(s\, I - \frac{T_s}{s} \right)} \qquad (19)$$

Since in the present problem the purpose is to study the character of the electromagnetic torques only as affected by the oscillatory motion, the inertial reaction does not enter the equations. In the present case it

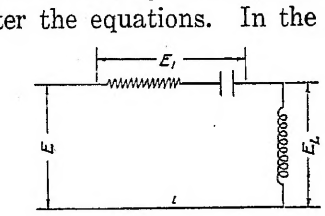

FIG. 5

is as if, in Fig. 5, the total voltage $\underset{\cdot}{E}$ were a sine wave, thus giving a sine wave current, and as if only the component $\underset{\cdot}{E}_1$ of the consumed voltage were to be investigated. The impedance which consumes the voltage E_1 would be

$$Z_1 = \frac{\underset{\cdot}{E}_1}{\underset{\cdot}{i}} = R - j \frac{1}{\omega\, C} \qquad (20)$$

and, similarly, in the present problem the impedance to the oscillatory motion, *i. e.*, to the velocity of oscillation, offered by the electromagnetic reactions of the machines is, by (19),

$$Z_m = \frac{\Delta \underset{\cdot}{T}}{\underset{\cdot}{\Omega}} = \mathcal{R} + j\, X = T_d - \frac{j\, T_s}{s} \qquad (21)$$

Thus, the motional resistance, due to damping, is

$$\mathcal{R} = T_d \qquad (22)$$

and the motional reactance, due to the synchronizing torque, is

$$X = - \frac{T_s}{s} \qquad (23)$$

and

$$T_s = - s\, X$$

Dividing (**13**) by (**15**), and equating to (**21**),

$$T_d = \frac{b\, e^2 \sin^2 \delta' + \dfrac{e^2 \cos^2 \delta'}{x_q} \sqrt{\dfrac{(x_d - a)^2 + b^2}{(x_q - c)^2 + d^2}}\, [(c \cos \alpha - d \sin \alpha)\, b + (x_d - a)\,(c \sin \alpha + d \cos \alpha)]}{s\,[b^2 + (x_d - a)^2]} \qquad \textbf{(24)}$$

and

$$T_s = T_s' + \frac{e^2 \sin^2 \delta'}{x_d} \left[\frac{a\,(x_d - a) - b^2}{(x_d - a)^2 + b^2}\right] + \frac{e^2 \cos^2 \delta'}{x_q}\, \frac{[(x_d - a)\,(c \cos \alpha - d \sin \alpha) - b\,(c \sin \alpha + d \cos \alpha)]}{\sqrt{[b^2 + (x_d - a)^2]\,[d^2 + (x_q - c)^2]}} \qquad \textbf{(25)}$$

It is thus seen that the synchronizing torque, *i. e.*, the slope of the torque-angle characteristic, is equal to the steady state value T_s' plus an increment which is a function of the frequency of the oscillation and the average displacement angle δ'.

T_s' is obtained by differentiating (**11**) with respect to δ, and substituting δ' for δ. Omitting the second term, since there is no constant excitation in the quadrature axis,

$$T_s' = \frac{e\, e_d'}{x_d} \cos \delta' + e^2 \frac{(x_d - x_q)}{x_d\, x_q} \cos 2\,\delta' \qquad \textbf{(26)}$$

Equations (**24**) and (**25**) are general. The type of machine usually found in installations where such oscillations exist, however, is the salient-pole type with an amortisseur winding. For such a winding, calculation shows that the resistance is so high at practical frequencies of oscillation that the winding has a negligible effect on the synchronizing torque. That is, c and d may be assumed to be zero in (**25**). For such cases,

$$T_s = T_s' + \frac{e^2 \sin^2 \delta'}{x_d} \left[\frac{a\,(x_d - a) - b^2}{(x_d - a)^2 + b^2}\right] \qquad \textbf{(27)}$$

The main field winding and the amortisseur winding do produce damping, as given by (**24**). That is, c and d cannot be neglected in (**24**), although they are negligible in (**25**).

Consider a few special cases. When the resistance of the main field winding is very small compared to the leakage reactance, b becomes zero and, as shown in Appendix A,

$$a = x_d - x_d' \qquad \textbf{(28)}$$

where x_d' = transient reactance, direct axis. Thus

$$T_s = T_s' + e^2 \frac{(x_d - x_d') \sin 2\,\delta'}{x_d\, x_d'} \qquad \textbf{(29)}$$

Substituting (**26**),

$$T_s = \frac{e\, e_d'}{x_d} \cos \delta' + e^2 \frac{(x_d - x_q)}{x_d\, x_q} \cos 2\,\delta' + e^2 \frac{(x_d - x_d')}{x_d\, x_d'} \sin^2 \delta' \qquad \textbf{(30)}$$

This condition—*i. e.*, zero field resistance, $b = 0$—gives the maximum synchronizing torque which can be obtained for the given average nominal voltage e_d' and terminal voltage e, at any oscillating frequency which is low enough to make c and $d = 0$. For more rapid oscillations c becomes significant, as shown later in Equation (**32**).

When the oscillations are very slow, so that the induced field currents are practically zero, a and b are zero, and

$$T_s = T_s' \qquad \textbf{(31)}$$

That is, the oscillation occurs on the slope of the steady state angle-torque curve.

Another interesting case is the condition of very rapid oscillation in which the resistances of the direct axis winding and the quadrature axis winding are zero, that is,

$$R_{da} \text{ and } R_{qa} = 0$$

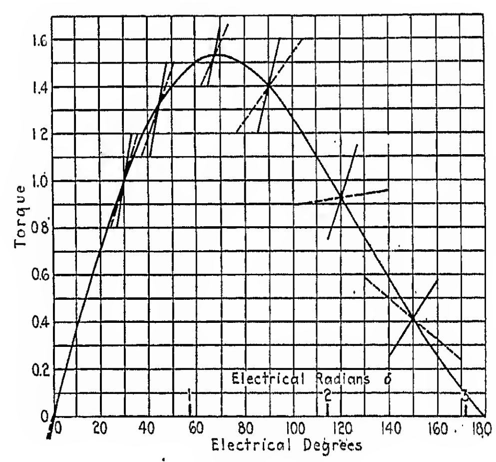

Fig. 6

Then, as shown in Appendix A,

$$a = \frac{x_{md}^2}{x_{md} + X_{lda}} = x_d = x_d'$$

$$b = 0$$

$$c = \frac{x_{mq}^2}{x_{mq} + X_q} = (x_q - x_q')$$

$$d = 0$$

Substituting these expressions in (**25**),

$$T_s = T_s' + e^2 \left[\frac{x_d - x_d'}{x_d\, x_d'} \sin^2 \delta' + \frac{x_q - x_q'}{x_q\, x_q'} \cos^2 \delta'\right] \qquad \textbf{(32)}$$

Numerical Examples. a. The following constants are representative of a low-speed synchronous motor, say 300 kv-a. at 120 rev. per. min.:

$x_d = 1.0$, $x_q = 0.6$, $x_d' = 0.4$, $e = 1.0$, $e_d' = 1.4$, $e_q = 0$

The torque-angle characteristic for steady state operation, calculated from equation (**11**), is shown in Fig. 6. The slope of this characteristic at any angle δ is the synchronizing torque, as given by Equation (**26**). The synchronizing torque for oscillatory operation under the assumption that $b = c = d = 0$, is shown at different angles by the dotted line segments, as calculated for Equation (**30**).

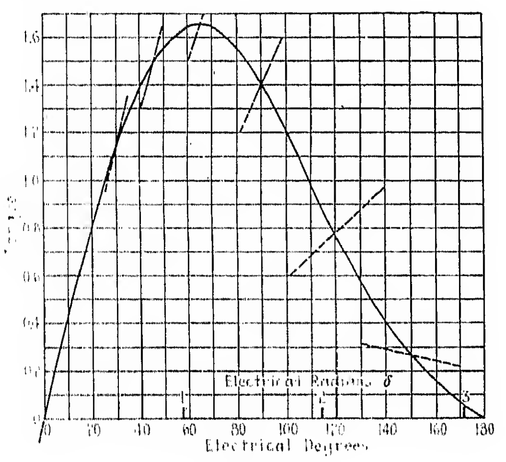

Fig. 7

If an amortisseur winding were added to the machine, the constants would be modified somewhat as follows: $x_d = 1.0$, $x_q = 0.6$, $x_d' = 0.25$, $x_q' = 0.3$, $e = 1.0$, $e_d = 1.4$.

Under the assumption that $b = d = 0$, the synchronizing torque, as calculated from (**32**), is shown by the full line segments in Fig. 6.

b. In Fig. 7 the characteristics are shown for $b = c = d = 0$, and for a higher speed machine with a somewhat lower transient reactance x_d' and a relatively smaller pole arc:

$x_d = 1.0$, $x_q = 0.5$, $x_d' = 0.3$, $e = 1.0$, $e_d' = 1.4$.

c. Fig. 8 shows the characteristics of a laminated cylindrical rotor machine: $x_d = 1.0$, $x\pi = 1.0$, $x_d' = 0.15$, $e = 1.0$, $e_d' = 1.45$.

These curves bring out some very interesting and important facts:

1. The synchronizing torque T_s under the oscillatory condition (indicated by the slope of the dotted lines) is exactly the same* as T_s' for steady state operation at $\delta = 0$ (*i. e.*, at no load, neglecting armature resistance); and departs only slightly from the steady state slope up to $\delta = 30$ electrical deg., which may be considered the practical operating range. Moreover, the dotted lines are the *maximum* slopes, neglecting the field resistance. The slope T_s for the transient condition, therefore, will be more nearly the same as the steady state slope T_s' than shown.

2. The practical approximation which has been used for some years by the authors is to divide full load torque by full load angle, which corresponds to the slope of a line through zero and the full load point on the curve. This, it will be noted, falls between the steady state slope and the dotted line, and is probably nearer the correct value in most practical applications than either of those limits, particularly for salient-pole machines.

3. It will be observed that the slope of the dotted line is still positive beyond the maximum power point of stable, steady state operation. This means that if a machine were operating beyond the angle corresponding to maximum, steady state power, say at 100 electrical deg., the machine would be stable under sudden changes, although the steady state characteristics at that point indicate instability.

4. Comparison of Figs. 6 and 7 with Fig. 8 shows that the difference between T_s' and the maximum slope T_s, indicated by the dotted lines, is much greater for cylindrical rotor machines than for those of salient-pole construction. An inspection of Equations (**29**) and (**30**) shows that the correction term for transient condition is the same in either case. The difference is in the middle term of (**30**), *i. e.*, the reaction torque term due to salient poles. When this is zero, as for cylindrical rotors, the correction term merely becomes a larger percentage of the total.

5. The addition of the effect of the quadrature axis winding, which comes into full play for very rapid oscillations, is shown in the full line segments, Fig. 6. It will be noted that the slope is steeper, and remains positive throughout the range between $\delta' = 0$ and $\delta' = \pi$.

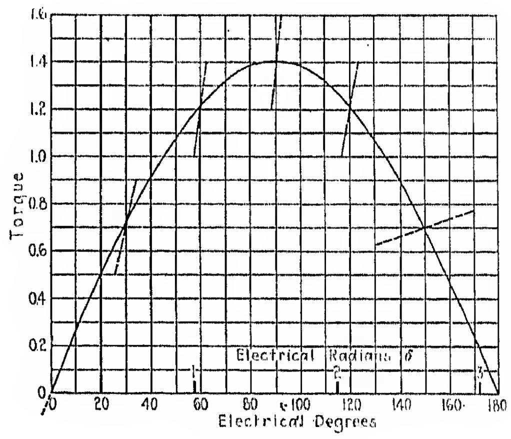

Fig. 8

B. Sudden Angular Displacement

A synchronous machine operating at a constant terminal voltage e, nominal voltage e_d', armature currents i_d and i_q, and an angular displacement δ', is suddenly displaced by an angle $\Delta\,\delta$ giving a total displacement δ. This will cause increments in the armature currents, so that the total current is

$$i_d = i_d' + \Delta\, i_d \qquad (33)$$

$$i_q = i_q' + \Delta\, i_q \qquad (34)$$

The increments $\Delta\, i_d$ and $\Delta\, i_q$ will induce corre-

*This is also evident from equation 29 for $\delta = 0$.

sponding increments of current in the short-circuited rotor windings in the two axes, and this also gives rise to increments in the nominal voltages. These are, from equations in Appendix A,

$$\Delta e_d = \Delta i_d (x_d - x_d') \tag{35}$$

$$\Delta e_q = \Delta i_q (x_q - x_q') \tag{36}$$

The total nominal voltages are thus

$$e_d = e_d' + \Delta i_d (x_d - x_d') \tag{37}$$

$$e_q = \Delta i_q (x_q - x_q') \tag{38}$$

There is assumed to be no constant component of nominal voltage in the quadrature axis.

The vector diagram for the conditions both before and after the sudden displacement, is shown in Fig. 9, from which the following relations are derived:

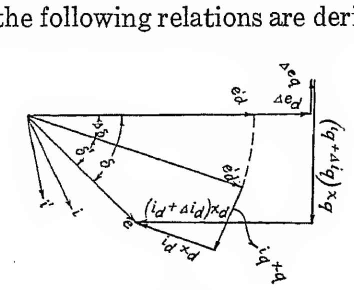

FIG. 9

$$i_d x_d = (i_d' + \Delta i_d) x_d = e_d - e \cos \delta \tag{39}$$

$$i_q x_q = (i_q' + \Delta i_q) x_q = e \sin \delta + e_q \tag{40}$$

Solving for Δi_d and Δi_q, and substituting in (37) and (38), respectively,

$$e_d = \frac{x_d}{x_d'} e_d' - \frac{x_d - x_d'}{x_d'} (e \cos \delta + i_d' x_d) \tag{41}$$

and

$$e_q = \frac{x_q - x_q'}{x_q'} (e \sin \delta - i_q' x_q) \tag{42}$$

Substituting (41) and (42) in (11),

$$T = \frac{e\, e_d'}{x_d'} \sin \delta + \frac{e^2 (x_d' - x_q')}{2\, x_d' x_q'} \sin 2\delta$$

$$- e \frac{x_d - x_d'}{x_d'} i_d' \sin \delta + \frac{x_q - x_q'}{x_q'} i_q' \cos \delta \tag{43}$$

The initial currents i_d' and i_q' are determined from the initial conditions as shown in Fig. 9. Thus

$$i_d' = \frac{e_d' - e \cos \delta'}{x_d} \tag{44}$$

$$i_q' = \frac{e \sin \delta'}{x_q} \tag{45}$$

Substituting these relations in (43),

$$T = \frac{e\, e_d'}{x_d} \sin \delta + e^2 \frac{x_d' - x_q'}{2\, x_d' x_q'} \sin 2\delta$$

$$+ e^2 \frac{x_d - x_d'}{x_d x_d'} \sin \delta \cos \delta' - e^2 \frac{x_q - x_q'}{x_q x_q'} \cos \delta \sin \delta' \tag{46}$$

Equation (46) gives the relation between torque and angle when the rotor is very suddenly shifted from the initial phase angle δ' to the new position δ.

The synchronizing torque T_s is obtained by differentiating (46) with respect to δ. Thus,

$$T_s = \frac{e\, e_d'}{x_d} \cos \delta + e^2 \frac{x_d' - x_q'}{x_d' x_q'} \cos 2\delta$$

$$+ e^2 \frac{x_d - x_d'}{x_d x_d'} \cos \delta \cos \delta' + e^2 \frac{x_q - x_q'}{x_q x_q'} \sin \delta \sin \delta' \tag{47}$$

The value of T_s, for sudden change, at the initial angle $\delta = \delta'$, is

$$T_{s1} = \frac{e\, e_d'}{x_d} \cos \delta' + e^2 \frac{x_d' - x_q'}{x_d' x_q'} \cos 2\delta'$$

$$+ e^2 \frac{x_d - x_d'}{x_d x_d'} \cos^2 \delta' + e^2 \frac{x_q - x_q'}{x_q x_q'} \sin^2 \delta' \tag{48}$$

Equation (48) can be re-written

$$T_{s1} = \frac{e\, e_d'}{x_d} \cos \delta' + e^2 \frac{x_d - x_q}{x_d x_q} \cos 2\delta'$$

$$+ e^2 \frac{x_d - x_d'}{x_d x_d'} \sin^2 \delta' + e^2 \frac{x_q - x_q'}{x_q x_q'} \cos^2 \delta' \tag{49}$$

The first two terms of (49) comprise the synchronizing torque T_s' at the angle δ' under steady state operation, as given by Equation (26). Hence,

$$T_{s1} = T_s' + e^2 \frac{x_d - x_d'}{x_d x_d'} \sin^2 \delta' + \frac{x_q - x_q'}{x_q x_q'} \cos^2 \delta' \tag{50}$$

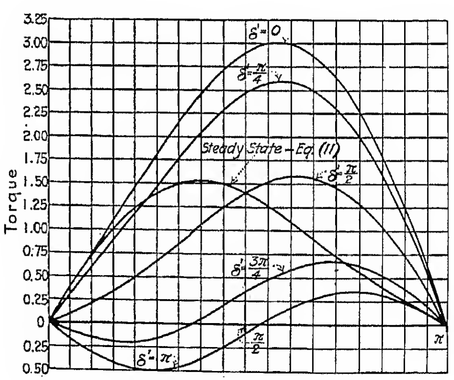

FIG. 10

It is thus seen that the synchronizing torque for very rapid displacements from the initial steady load angle δ' is equal to the steady state value T_s' plus an increment which is independent of the initial excitation and depends only on the terminal voltage, reactances, and the initial angle δ'. It is interesting to note that this equation checks with (32), which was derived, of course, under assumptions which are equivalent to those in Equation (50).

Numerical Examples. Equation (**46**) is applied to four different representative cases:

a. Laminated salient-pole rotor. (Low speed engine or compressor type.)

$x_d = 1.0,\quad x_q = 0.6,\quad x_d' = 0.4,\quad x_q' = 0.6,\quad e = 1.0,$
$e_d' = 1.4,\quad e_q' = 0.$

The torque T is plotted against displacement angle δ in Fig. 10 for various values of initial angle δ', and for the above voltages. Also, for comparison, the steady state torque-angle characteristic is shown, as calculated from Equation (11).

b. Amortisseur winding, salient-pole rotor. (Low speed engine or compressor type.)

$x_d = 1.0,\quad x_q = 0.6,\quad x_d' = 0.25,\quad x_q' = 0.3,\quad e = 1.0,$
$e_d' = 1.4,\quad e_q' = 0.$

The characteristics for this case are plotted in Fig. 11.

c. Laminated cylindrical rotor, Fig. 12. (High speed turbine generator.)

$x_d = 1.0,\quad x_q = 1.0,\quad x_d' = 0.15,\quad x_q' = 1.0,\quad e = 1.0,$
$e_d' = 1.4,\quad e_q' = 0.$

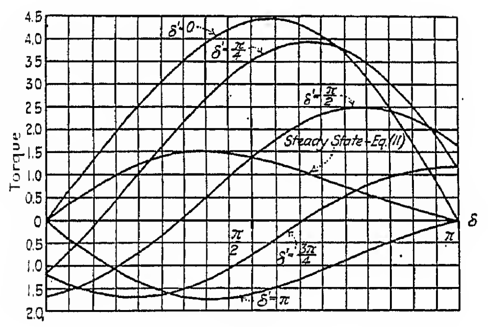

Fig. 11

d. Massive steel cylindrical rotor, Fig. 13. (High speed turbine generator.)

$x_d = 1.0,\quad x_q = 1.0,\quad x_d = 0.15,\quad x_q' = 0.2,\quad e = 1.0,$
$e_d' = 1.4,\quad e_q' = 0.$

These examples bring out some interesting points. In Fig. 10, example a, it is seen that if the machine is operating at a steady load corresponding to $\delta' = \dfrac{\pi}{4}$ (*i. e.*, 45 electrical deg.) and at approximately full load excitation $e_d' = 1.4$, a very sudden angular displacement of the rotor would cause a torque following the characteristic marked $\delta' = \pi/4$. Similar characteristics are also shown for other initial angles δ', but for the same nominal voltage e_d'. It is interesting to note that

1. The slope of these characteristics, that is, the synchronizing torque (which may be computed from Equation (**50**)), at the initial angle δ' corresponds to the dotted line segments in Fig. 6, since in the latter $b = c = d = 0$. That is, the resistance is zero and $x_q = x_q'$, as in the present case. In other words, the dotted lines in Fig. 6 are merely corresponding parts of the complete characteristics shown in Fig. 10.

2. The characteristics reverse between zero angle and δ'.

3. The maximum torque is attained when the initial angle is $\delta' = 0$, in which case it reaches 3.0 times normal torque at about 105 electrical deg. It will be noted also that when $\delta' = 0$, the slope of the transient curve is the same as that of the steady state curve, and continues to be so for 15 or 20 electrical deg.

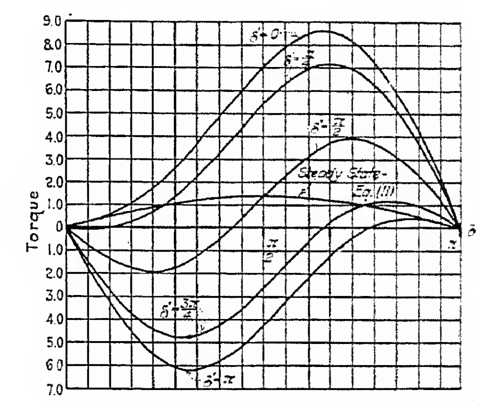

Fig. 12

4. All characteristics are zero at $\delta = 0$ and $\delta = \pi$.

The addition of an amortisseur winding significantly modifies the characteristics. Fig. 11, example b, shows the following points:

1. As in example a, the maximum slope occurs for $\delta' = 0$; unlike a, the slope of the transient characteristic at $\delta' = 0$ is much greater than the slope of the steady state curve at that point.

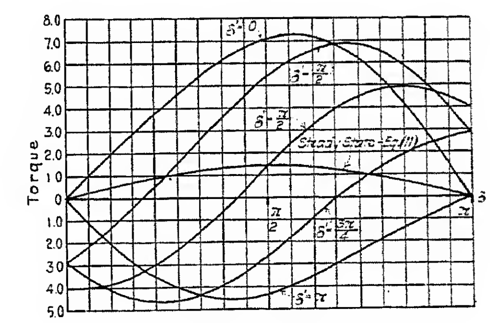

Fig. 13

2. The maximum torque is about 4.5 normal torque.

3. Unlike example a, the characteristics are not all zero at $\delta = 0$ and $\delta = \pi$, but show from 1.0 to 1.65 times normal at these angles, at which the steady state torque is zero.

Figs. 12 and 13 show characteristics for cylindrical rotor machines, examples c and d. The respective characteristics have the same general form as those for the salient-pole machines with the following exceptions:

1. The maximum torque is much greater, due to

the lower reactance. It is of the order of 8.0 times normal torque instead of 3.0 or 4.0 times normal.

2. There is a greater deviation from the steady state curve in the neighborhood of $\delta' = 0$.

C. Synchronizing Out of Phase

Synchronizing out of phase gives rise to problems very similar to those occasioned by sudden angular displacement, as treated under B. The essential difference is that in the latter case the circuit is already closed, and carrying an initial current, when the displacement occurs; whereas in the former, the circuit is open and the current zero until the instant the synchronizing switch is closed. This difference in boundary conditions makes it desirable to treat the cases independently.

If the synchronizing switch is closed when the incoming machine is out of phase with the system by the angle δ, armature currents, of course, suddenly appear. The two components i_d and i_q induce corresponding current increments in the short-circuited windings in the direct and quadrature axes, respectively. The induced increments of rotor currents are, numerically, the increments in nominal voltages e_d and e_q, since both are expressed in per cent.

Thus, by Equations (**35**) and (**36**), the suddenly appearing currents i_d and i_q cause the following induced increments in the nominal voltages:

$$\Delta e_d = i_d (x_d - x_d') \tag{51}$$

$$\Delta e_q = i_q (x_q - x_q') \tag{52}$$

The vector diagram for conditions at the first instant is shown in Fig. 4. From the diagram and Equations (**51**) and (**52**),

$$e \cos \delta + i_d x_d = e_d' + i_d (x_d - x_d') \tag{53}$$

and

$$e \sin \delta + i_q (x_q - x_q') = i_q x_q \tag{54}$$

From these two relations,

$$i_d = \frac{e_d' - e \cos \delta}{x_d'} \tag{55}$$

and

$$i_q = \frac{e \sin \delta}{x_q'} \tag{56}$$

Substituting (**55**) and (**51**) and (**56**) in (**52**),

$$\Delta e_d = \frac{x_d - x_d'}{x_d'} (e_d' - e \cos \delta) \tag{57}$$

and

$$\Delta e_q = \frac{x_q - x_q'}{x_q'} e \sin \delta \tag{58}$$

The total nominal voltage e_d in the direct axis is the sum of the constant component e_d' supplied by the exciter, plus the induced component. Thus,

$$e_d = \frac{x_d}{x_d'} e_d' - \frac{x_d - x_d'}{x_d'} e \cos \delta \tag{59}$$

The total nominal voltage e_q in the quad Δe_q, since there is assumed to be no co nished by the exciter. That is,

$$e_q = \frac{x_q - x_q'}{x_q} e \sin \delta$$

Therefore, substituting (**59**) and (**60**) in E the torque is

$$T = \frac{e\, e_d'}{x_d'} \sin \delta + \frac{e^2}{2} \frac{(x_d' - x_q')}{x_d'\, x_q'}$$

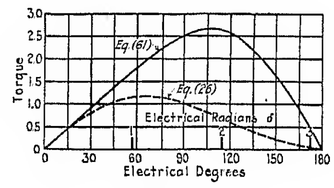

Fig. 14

It is very interesting that Equation (6 under this transient condition is of exac form as (**11**), excepting that in the pre reactances are the *transient reactances*, x_d' is, the total leakage reactances, instead chronous reactances x_d and x_q. It is in that Equation (**61**) comprises the first two *i. e.*, when i_d' and $i_q' = 0$. It is not obvi that the assumption $i_d' = i_q' = 0$ in (**43**) to the open-circuit condition on which (since with the closed circuit and the assu voltage e_d' there would be armature curr

Since the same voltages e and e_d' appea tion (**61**) as in (**11**), but with much lower r torque is correspondingly higher.

Numerical Examples. Four representat be considered. In each case, a curve, Equation (**61**), is shown of the torque w

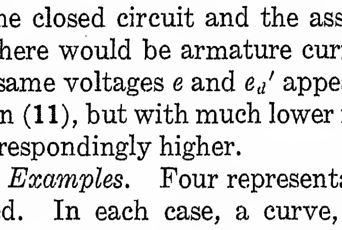

Fig. 15

obtained if the machine were synchronize by any angle δ. For comparison, the torque-angle characteristic, Equation (26

a. Low speed engine or compressor 300 kv-a., 120 rev. per min.

$x_d = 1.0$, $x_d' = 0.4$, $x_q = 0.6$, $x_q' =$
$e_d' = 1.0$.

Characteristics are plotted in Fig. 14.

b. Same as a, but with an amortis

$x_d = 1.0$, $x_d' = 0.25$, $x_q = 0.6$, $x_q' = 0.3$, $e = 1.0$, $e_d' = 1.0$.

Characteristics are plotted in Fig. 15.

c. Medium speed water-wheel type of, say, 5000 kv-a., 300 rev. per. min.

$x_d = 1.0$, $x_d' = 0.27$, $x_q = 0.5$, $x_q' = x_q$, $e = 1.0$, $e_d' = 1.0$.

Characteristics in Fig. 16.

d. High speed steam turbine type generator of about 35,000 kv-a. with massive steel rotor.

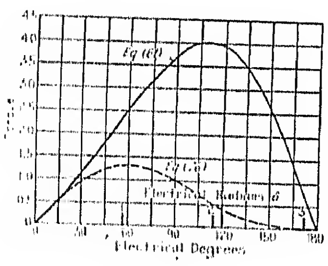

FIG. 16

$x_d = 1.0$, $x_d' = 0.15$, $x_q = 1.0$, $x_q' = 0.2$, $e = 1.0$, $e_d' = 1.0$.

Characteristics in Fig. 17.

It will be noted that these characteristics are of the same general nature as those shown in Figs. 10, 11, 12 and 13. It will be noted that a machine without amortisseur winding effect, *i. e.*, without a short-circuited winding in the quadrature axis, will suffer practically no more torque when it is synchronized at an angle less than, say, 20 deg., than would be exerted by the machine at that angle under steady operation. It

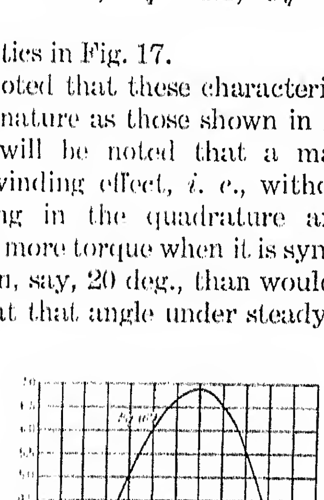

FIG. 17

increases very rapidly, however, above the steady state value for increasing angle, the maximum torque being obtained when the machine is synchronized at about 100 deg.

Referring to Figs. 14 and 15, the addition of a short-circuited rotor winding in the quadrature axis very greatly increases not only the maximum torque but also the difference between the transient characteristic and the steady state curve at small angles.

It should be kept in mind that the torque given by Equation (**61**) is the average value existing in the first moment under the transient condition. There are, in addition, alternating components of normal and higher frequencies which are not taken into account here. While the latter are of large magnitude, nevertheless the frequency is so high that the torque does not have time, except in case of resonance, to produce much displacement, and therefore strain in the shaft. Hence the alternating component is rarely a serious factor. The unidirectional component given by Equation (**61**), however, has time to produce large strain in the shaft and coupling, where the fly-wheel effect on the other end of the shaft is comparable with that of the synchronous machine, as in the case of a turbine driven generator or a motor-generator set.

ACKNOWLEDGMENT

The authors gratefully acknowledge the assistance of Mr. R. O. Brosemer in calculations and in the preparation of curves and data.

Appendix A

When a three-phase system of currents of constant amplitude flows in the winding of a three-phase machine, there exists a uniformly rotating sinusoidal m. m. f. of constant amplitude, this m. m. f. rotating at synchronous speed. This is the speed at which the poles are rotating and by proper time phase of the currents, as at zero power factor, the rotating m. m. f. may be made to exist at every instant directly over the field poles, *i. e.*, the direct axis. If each of the three-phase currents pulsates in amplitude at a frequency, f, the m. m. f. over the field winding will likewise pulsate at the same frequency. The alternating component of this pulsating m. m. f. in acting on the field winding, which is short-circuited through the exciter armature, will induce currents in the field winding and we have essentially a transformer with the secondary short-circuited. The frequency impressed on this transformer is obviously the modulating frequency of the three-phase system of currents.

The equivalent diagram for this transformer is as shown in Fig. 3. In this diagram,

x_l = armature leakage reactance at normal frequency,

X^3_{da} = field leakage reactance, in armature terms, for the winding in the direct axis, *i. e.*, the main field winding,

R_{da} = resistance of the main field winding, in armature terms,

x_{md} = mutual reactance in the direct axis,

Z_{d1} = equivalent impedance,

e_{d1} = voltage across Z_{d1},

s = modulating frequency as a fraction of normal frequency.

Then

$$Z_{d1} = \frac{j\, s\, x_{md}\, (R_{da} + j\, s\, X_{lda})}{R_{da} + j\, s\, (x_{md} + X_{lda})} \qquad \textbf{(1a)}$$

When a current $\Delta\, i_d$ flows through Z_{d1}, the voltage e_{d1} is

$$e_{d1} = \Delta\, i_d\, Z_{d1} \qquad \textbf{(2a)}$$

The current flowing in the field winding will be

$$\Delta I_{da} = \frac{e_{d1}}{R_{da} + j\, s\, X_{lda}} \qquad (3a)$$

Substituting (**1a**) in (**2a**) and (**2a**) in (**3a**), and rationalizing,

$$\Delta I_{da} = \Delta i_d \frac{s^2 x_{md}(x_{md} + X_{lda}) + j\, s\, x_{md} R_{da}}{R_{da}^2 + s^2 (x_{md} + X_{lda})^2} \qquad (4a)$$

The field current ΔI_{da} is here expressed in armature terms; *i. e.*, it is the ampere-turns induced in the field winding as a fraction of normal *armature* ampere turns. The field current in field terms is numerically equal to the per cent nominal voltage which it produces. Since normal armature ampere-turns, existing in the field winding, produce a mutual flux or nominal voltage numerically equal to X_{md}, the current ΔI_{da} will produce a nominal voltage,

$$x_{md}\, \Delta i_{da}{}^*$$

Hence, the field current in field terms is

$$\Delta I_d = \Delta i_d \frac{s^2 x_{md}^2 (x_{md} + X_{lda}) + j\, s\, x_{md}^2 R_{da}}{R_{da}^2 + s^2 (x_{md} + X_{lda})^2} \qquad (5a)$$

If we let

$$\frac{s^2 x_{md}^2 (x_{md} + X_{lda})}{R_{da}^2 + s^2 (x_{md} + X_{lda})^2} = a \qquad (6a)$$

and

$$\frac{s\, x_{md}^2 R_{da}}{R_{da}^2 + s^2 (x_{md} + X_{lda})^2} = b \qquad (7a)$$

$$\Delta I_d = \Delta i_d (a + j\, b) \qquad (8a)$$

If Δi_d is taken as the reference vector, Equation (**8a**), as a function of time, is

$$\Delta I_d = \Delta i_d [a \cos s\, t - b \sin s\, t] \qquad (9a)$$

In the quadrature axis, similar relations may be obtained for such short-circuited rotor windings which exist in this axis. By similar reasoning, we get

$$\Delta I_q = \Delta i_q \frac{s^2 x_{mq}^2 (x_{mq} + X_{lqa}) + j\, s\, x_{mq}^2 R_{qa}}{R_{qa}^2 + s^2 (x_{mq} + X_{lqa})^2} \qquad (10a)$$

If we let

$$\frac{s^2 x_{mq}^2 (x_{mq} + X_{lqa})}{R_{qa}^2 + s^2 (x_{mq} + X_{lqa})^2} = c \qquad (11a)$$

and

$$\frac{s\, x_{mq}^2 R_{qa}}{R_{qa}^2 + s^2 (x_{mq} + X_{lqa})^2} = d \qquad (12a)$$

then

$$\Delta I_q = \Delta i_q (c + j\, d) \qquad (13a)$$

The modulating current Δi_q is not, in general, in time phase with the modulating current, Δi_d. Hence, if Δi_d is assumed to vary as a cosine function of time, *i. e.*, the reference vector, Δi_q must be taken as

$$\Delta i_q \doteq \Delta i_q \cos (s\, t + \alpha) \qquad (14a)$$

Then (**13a**) as a function of time becomes

$$\Delta I_q = \Delta i_q [(c \cos \alpha - d \sin \alpha) \cos s\, t - (c \sin \alpha + d \cos \alpha) \sin s\, t] \qquad (15a)$$

With the alternating components of the field currents thus determined, the nominal voltages which, in per cent, are numerically the same as the field currents, may be determined by adding to the alternating component the constant term supplied by the exciter. Thus the total nominal voltage in the direct axis is

$$e_d = I_d' + \Delta i_d (a \cos s\, t - b \sin s\, t) \qquad (16a)$$

Since there is assumed to be no constant excitation in the quadrature axis, the total nominal voltage in the quadrature axis is

$$e_q = \Delta i_q [(c \cos \alpha - d \sin \alpha) \cos s\, t - (c \sin \alpha + d \cos \alpha) \sin s\, t] \qquad (17a)$$

The displacement angle will now be determined as a function of time. It has been shown[1] that the vector diagram for a synchronous machine connected to a source of voltage e is as shown in Fig. 4. Armature resistance has been neglected since it may be shown to have a negligible effect on power angle characteristics for values of resistance which exist in commercial machines. In the diagram, i_d is the total component of current in the direct axis and is given by

$$i_d = i_d' + \Delta i_d \cos s\, t \qquad (18a)$$

where

i_d' = the average peak value of armature current in the direct axis.

Also, i_q is the total component of current in the quadrature axis and is given by

$$i_q = i_q' + \Delta i_q \cos (s\, t + \alpha) \qquad (19a)$$

where

i_q' = average peak value of the armature current in the quadrature axis.

From Fig. 4, the following relations may be obtained:

$$\begin{aligned} e_d &= e \cos \delta + i_d x_d \\ &= e \cos \delta + i_d' x_d + \Delta i_d x_d \cos s\, t \end{aligned} \qquad (20a)$$

and

$$\begin{aligned} e_q + e \sin \delta &= i_q x_q \\ &= i_q' x_q + \Delta i_q x_q \cos (s\, t + \alpha) \end{aligned} \qquad (21a)$$

The angle δ in these equations comprises two components, an average value δ' and a variation angle $\Delta \delta$. Hence

$$\delta = \delta' + \Delta \delta \qquad (22a)$$

and Equations (**20a**) and (**21a**) become

$$e_d = e \cos (\delta' + \Delta \delta) + i_d' x_d + \Delta i_d x_d \cos s\, t \qquad (23a)$$

and

$$e_q + e \sin (\delta' + \Delta \delta) = i_q' x_q + \Delta i_q x_q \cos (s\, t + \alpha) \qquad (24a)$$

From (**23a**)

$$e \cos (\delta' + \Delta \delta) = e_d - i_d' x_d - \Delta i_d x_d \cos s\, t \qquad (25a)$$

Expanding (**25a**)

$$e \cos \delta' \cos \Delta \delta - e \sin \delta' \sin \Delta \delta = e_d - i_d' x_d - \Delta i_d x_d \cos s\, t \qquad (26a)$$

*Here X_{md} is merely a numeric to change a quantity from one reference to another and the operator j is not required.

For very small values of $\Delta\,\delta$, Equation (26a) may be written

$$e \cos \delta' - e\,\Delta\,\delta \sin \delta' = e_d - i_d'\,x_d - \Delta\,i_d\,x_d \cos s\,t \quad (27a)$$

or

$$\Delta\,\delta = \frac{e \cos \delta' - e_d + i_d'\,x_d + \Delta\,i_d\,x_d \cos s\,t}{e \sin \delta'} \quad (28a)$$

Substituting for e_d from Equation (16a) and placing

$$I_d' = e_d' \quad (29a)$$

we get

$$\Delta\,\delta = \frac{e \cos \delta' - e_d' + i_d'\,x_d + \Delta\,i_d[(x_d - a) \cos s\,t + b \sin s\,t]}{e \sin \delta'} \quad (30a)$$

But $\Delta\,\delta$ is, by definition, alternating with respect to time. Also the bracket quantity on the right hand side is evidently alternating with respect to time. Since the other terms in the numerator are constant with respect to time, their sum must be zero, that is,

$$e \cos \delta' - e_d' + i_d'\,x_d = 0 \quad (31a)$$

Then

$$\Delta\,\delta = \Delta\,i_d \frac{(x_d - a) \cos s\,t + b \sin s\,t}{e \sin \delta'} \quad (32a)$$

From Equation (21a)

$$e \sin \delta = i_q'\,x_q - e_q + \Delta\,i_q\,x_q \cos (s\,t + \alpha) \quad (33a)$$

Substituting (29a) in (33a), and expanding,

$$e \sin \delta' \cos \Delta\,\delta + e \cos \delta' \sin \Delta\,\delta$$
$$= i_q'\,x_q - e_q + \Delta\,i_q\,x_q (\cos \alpha \cos s\,t - \sin \alpha \sin s\,t) \quad (34a)$$

For very small values of $\Delta\,\delta$, Equation (34a) may be written

$$e \sin \delta' + e\,\Delta\,\delta \cos \delta' = i_q'\,x_q - e_q + \Delta\,i_q\,x_q (\cos \alpha \cos s\,t - \sin \alpha \sin s\,t) \quad (35a)$$

Substituting for e_q from Equation (17a) and solving for,

$$\Delta\,\delta = \frac{i_q'\,x_q - e \sin \delta' + \Delta\,i_q\,\{[(x_q - c) \cos \alpha + d \sin \alpha] \cos s\,t - [(x_q - c) \sin \alpha - d \cos \alpha] \sin s\,t\}}{e \cos \delta'} \quad (36a)$$

For reasons following Equation (30a),

$$i_q'\,x_q - e \sin \delta' = 0 \quad (37a)$$

Then

$$\Delta\,\delta = \Delta\,i_q \frac{[(x_q - c) \cos \alpha + d \sin \alpha] \cos s\,t - [(x_q - c) \sin \alpha - d \cos \alpha] \sin s\,t}{e \cos \delta'} \quad (38a)$$

Equations (32a) and (38a) are equations for the same angle. Hence the time phase angles must be the same and also the amplitudes.

From the time phase relations

$$\frac{b}{x_d - a} = \frac{d \cos \alpha - (x_q - c) \sin \alpha}{d \sin \alpha + (x_q - c) \cos \alpha} \quad (39a)$$

and

$$\cot \alpha = \frac{b\,d + (x_d - a)\,(x_q - c)}{d\,(x_d - a) - b\,(x_q - c)} \quad (40a)$$

Equating the amplitudes of (32a) and (38a),

$$\Delta\,i_d \frac{\sqrt{(x_d - a)^2 + b^2}}{e \sin \delta'} = \Delta\,i_q \frac{\sqrt{(x_q - c)^2 + d^2}}{e \cos \delta'} \quad (41a)$$

and

$$\frac{\Delta\,i_q}{\Delta\,i_d} = \sqrt{\frac{(x_d - a)^2 + b^2}{(x_q - c)^2 + d^2}} \cot \delta' \quad (42a)$$

Under certain conditions, the resistance of the field winding may be quite negligible compared with the reactance and it is interesting to examine the limiting case, *i. e.*, when R_{da} is zero. Equations (6a), (7a), (11a) and (12a) are then respectively

$$a = \frac{x_{md}^2}{x_{md} + X_{lda}} \quad (43a)$$

$$b = 0 \quad (44a)$$

$$c = \frac{x_{mq}^2}{x_{mq} + X_{lqa}} \quad (45a)$$

$$d = 0 \quad (46a)$$

When the resistance of the field winding is zero, the total impedance of the equivalent circuit in Fig. 3 at normal frequency is the transient reactance, *i. e.*, $j\,x_d'$. Hence

$$j\,x_d' = j\,x_{ld} + j\,\frac{x_{md}\,X_{lda}}{x_{md} + X_{lda}} \quad (47a)$$

The synchronous reactance is from Fig. 3,

$$j\,x_d = j\,x_{ld} + j\,x_{md} \quad (48a)$$

From (47a) and (48a),

$$x_d - x_d' = \frac{x_{md}^2}{x_{md} + X_{lda}} \quad (49a)$$

By similar reasoning for the quadrature axis we get,

$$x_q - x_q' = \frac{x_{mq}^2}{x_{mq} + X_{lqa}} \quad (50a)$$

Hence, Equations (43a), (44a), (45a) and (46a) become

$$a = x_d - x_d' \quad (51a)$$
$$b = 0$$
$$c = x_q - x_q' \quad (53a)$$
$$d = 0 \quad (54a)$$

Nomenclature

All *armature currents* are expressed as fractions of the peak value (sine wave) of normal current.

All *field currents* are expressed as fractions of the field current corresponding to open circuit, normal voltage (sine wave) at normal frequency.

All *voltages* are expressed as fractions of the peak value (sine wave) of normal voltage.

Frequencies and *angular velocities* are expressed, respectively, as fractions of normal frequency and normal electrical angular velocity.

Angles are expressed as fractions of one radian.

Time is expressed as a fraction of the time corresponding to one electrical radian at normal frequency.

Reactance is expressed in per cent (as a fraction), that is, as a ratio of the voltage drop due to normal current to normal voltage.

e = terminal voltage,
e_d = nominal voltage, due to excitation in the direct axis,
e_q = nominal voltage, due to excitation in the quadrature axis,
I_d = field current, direct axis, in field terms,
I_d' = field current, direct axis, in field terms (average value),
I_q = field current, quadrature axis, in field terms,
I_{da} = field current, direct axis, in armature terms,
I_{qa} = field current, quadrature axis, in armature terms,
i_d = total direct component of armature current at the time t,
i_q = total quadrature component of armature current at the time t,
i_d' = steady, or average, peak value of the direct component of armature current,
i_q' = corresponding value of the quadrature component,
Δi_d = variation of i_d. See Fig. 1.
Δi_q = variation of i_q,
$\mathcal{R}$ = motional resistance, corresponding to the damping constant,
R_{da} = field resistance, direct axis, in armature terms,
R_{qa} = field resistance, quadrature axis, in armature terms,
s = frequency of modulation of armature current,
T = torque expressed as a fraction of that corresponding to the current and voltage (at unity power factor) on which the reactances are based,
T_d = damping constant, torque corresponding to unit electrical angular velocity,
T_s = resilience constant, torque corresponding to unit electrical angle,
T_s' = value of T_s for the synchronous machine at the average angle δ' under steady state operation,
X_{lda} = field leakage reactance, direct axis, in armature terms,
X_{lqa} = field leakage reactance, quadrature axis, in armature terms,
X = motional reactance,
x_d = synchronous reactance, direct axis,
x_q = synchronous reactance, quadrature axis,
x_l = armature leakage reactance, for either direct or quadrature axis,
x_{md} = mutual reactance, direct axis,
x_{mq} = mutual reactance, quadrature axis,
Z_m = motional impedance,
z_{d1} = equivalent impedance, direct axis.
z_{q1} = corresponding impedance, quadratu
α = time phase displacement between lating current in the direct axis an lating current in the quadrature a
δ = displacement angle of the nominal the terminal voltage as a fract electrical angle (electrical radian actual space phase lag or lead of
Ω = angular velocity of mechanical osc fraction of normal rotational veloci

Discussion

J. F. H. Douglas: I wish to ask a question paragraph which reads, "It will be observed that the dotted line is still positive beyond the max point of stable, steady-state operation. This mo machine were operating beyond the angle correspon mum, steady-state power, say at 100 electrical machine would be stable under sudden changes, steady-state characteristics at that point indicate I am somewhat curious to know under what operatin if any, this becomes of interest?

The curve in Fig. 7 involves not only sin δ but that is, it quite obviously contains a second harmoni this is fully recognized in the paper, and I simply attention to the fact that most textbooks do not existence of this second component, and that it is ve that it should be recognized inasmuch as it grea torques in the stable operating range.

R. D. Evans: I was much interested in the qu about the increased power limit obtainable by me matic control of excitation. I interpret the answ Mr. Nickle as giving essentially the same idea as wh porated in the term "artificial stability," a term co Shand in 1924. At that time it was thought impossi operation to obtain a condition of increased power li process.

Subsequently we made tests of a somewhat simil that described by Mr. Nickle. These test results closing discussion[1] on the Evans and Wagner pape Midwinter Convention, were the first experimental of the fact that increased power limits were actually I might liken the condition of increased stability by c excitation to the process of maintaining equilibr *artificial* process of juggling. Up to 90 deg., or ac what less, it is possible to obtain stable operatio Beyond that point, equilibrium may be maintaine but it is necessary to use automatic devices. This co the action of a juggler in making a corrective acti system has started to pull out. This action on a pow possible because of the time required for the system of step.

In the presentation Mr. Nickle described a mechanical system. We, too, have found such a system to be very good for the purpose of visualizing the actions taking place during the transients. Analytically, the actions are quite complicated, but they can be understood by a suitable mechanical model by adding inertia to the vector arms, and a spring connecting them. Mr. Griscom described a system of this general character in an article entitled "A Mechanical Analogy to the Problem of Transmission Stability", *Electric Journal*, May 1926. I notice that Mr. Nickle has described the addition of a dashpot to the arrangement which makes it possible to simulate the condition of the demagnetizing action in a machine, which changes the internal e. m. f. and brings about the change of machine reactance from leakage to synchronous reactance.

W. V. Lyon: Mr. Doherty and Mr. Nickle have presented in this paper an ingenious method for analyzing, what I believe to be, a very difficult problem. They have founded their analysis on what seem to be a reasonable set of premises. These premises have been so well chosen that in the subsequent mathematical work it is necessary to make but one simplifying assumption in order to arrive at a final result that is not unduly complicated. Whether or not this method of analysis produces accurate results can be determined only by laboratory experiment, and it is to be regretted that such data are not available at the present time. In fact we have at the Massachusetts Institute of Technology measured the torque-angle characteristic of a small synchronous motor when the load torque varies cyclicly. To be more exact we measured the power-angle characteristic, although there is but little difference between the two. Unfortunately I have had no opportunity to compare these results with Mr. Doherty's calculations.

In the third part of their paper where they consider the question of synchronizing out of phase, I should much prefer to see them follow the methods that have already been developed for computing the transient currents in a three-phase synchronous generator. The first shock on the machine, coming as it does within the time of one cycle, would probably occur before the rotor has swung more than a negligible amount. The methods to which I refer are based on the differential equations which apply to synchronous machines, whereas Messrs. Doherty's and Nickle's treatment has no such fundamental background. Since, however, the differential equations assume certain ideal conditions that do not exist, it is possible that their method will actually give better results. Here, again, laboratory experience only can decide.

I should like to suggest another method of attacking this problem. The premises upon which it is based are much the same as the authors have chosen. Briefly the assumption is that the vector diagrams which are used to explain the steady-state operation may also be used when the angular velocity of the rotor is not constant. The actual condition of operation can be resolved into two component conditions of operation as follows. First, consider that the armature is short-circuited and that normal excitation voltage is impressed on the field. The determination of the armature and field currents is a simple process even if the angular velocity of the rotor is slowly changing. Next, consider that the field winding is short-circuited and that normal polyphase voltage is impressed on the armature. Here we have an induction motor with an unsymmetrical rotor winding. The determination of the armature and field currents is again a fairly simple process which is well understood. It is only necessary to assume that the currents are determined by the actual angular velocity of the rotor and are not affected by its acceleration. Laboratory experiments alone can determine whether this assumption is reasonable. Under the actual condition of operation both of these components of current exist simultaneously and the resultant torque can be computed without much difficulty. We can then set up the differential equation which equates the electromagnetic torque developed equal to the sum of the torques acting on the shaft and that due to the acceleration of the rotor. Although I have had no opportunity to make this solution in detail I have gone far enough to see that there are no insurmountable difficulties in the path.

H. V. Putman (communicated after adjournment): It would seem that the damping torque calculated by the authors is not the actual damping torque of the motor. Actually, the damping torque is proportional to the rate of change of only that part of the displacement between the pole and the electrical field, while the damping torque calculated by the authors is proportional to the rate of change of the total displacement. Such a radical departure from the accepted ideas about this problem, is at least, worthy of further explanation.

There is another peculiar thing about this damping torque T_d calculated by the authors. It was obtained by substituting in a formula for the synchronizing torque derived under the assumption of steady-state conditions. They state that Equation (**11**) which is the synchronizing torque under steady conditions, gives the torque not merely for the steady state but for any conditions within the premises when the actual values of the nominal voltages and the displacement existing at the moment under consideration, are substituted. Substituting these values for the oscillatory condition in this formula, for the synchronizing torque, gives a vector expression of which one term is the synchronizing torque, and the other, so the authors claim, is the damping torque. It at least seems peculiar that one could obtain a damping torque by substituting in a formula for the synchronizing torque, derived under steady-state conditions and one would be inclined to question the premises which could lead to these conclusions.

If I understand the paper correctly, it seems to me that the fundamental assumption made by the authors, is unjustifiable. They assume that the whole phenomenon discussed in Part A can be handled as the result of two transformer actions, one taking place in line with the pole, and the other in line with the inter-polar space. The armature current has been resolved into two components, one in line with the *average* position of the field pole, the other in line with the *average* position of the inter-polar space. The modulation of these components of current causes the armature reactions produced by them to pulsate in magnitude. So the armature reaction produced by the direct component of current, for instance, pulsates in magnitude in line with the *average* position of the field pole. It is not in line with the field pole at every instant of time, as assumed by the authors, and hence, it would seem that the phenomenon can not be calculated as a simple transformer action if the damping torque is to be obtained correctly. If this assumption is not made, the problem might become more complicated but the damping torque, would, in all probability be found to depend on only that part of the displacement between the pole and the electrical field.

I think that the mathematical work from Equations (**14**) to (**21**) could be much simplified as follows:

ΔT is the pulsating motor torque resulting from an oscillation $\Delta\delta$ which was shown to be a harmonic function of $s t$; that is, $\Delta\delta$ is a function of the type

$$A \sin s\,t + B \cos s\,t \qquad (1)$$

and the total motor torque is of the form

$$\Delta T = T_s\,\Delta\delta + T_d\,\Omega \qquad (2)$$

but since $\Delta\delta$ is an harmonic function of $s\,t$, it is evident that:

$$\Delta\delta = -\frac{j}{s}\frac{d}{d\,t}\Delta\delta \text{ or } \Delta\delta = -\frac{j}{s}\Omega \qquad (3)$$

Substituting (3) in (2) gives $\frac{\Delta\ T}{\Omega} = T_d - \frac{j}{s} T_s$

which is the author's Equation (**21**).

I found the explanation given in the paper for this part of the work, more confusing than clarifying, because of the confusion of the units involved. For instance, the well-known equation

for torque consumed in any mechanical system, which is the authors' Equation (16), involves torque in foot-pounds, and time in seconds and angular velocity in mechanical radians per second. Also Equation (17) involves time in seconds and when one puts $\frac{d}{d\,t} = j\,\omega$, the differentiation is with respect to time in seconds.

I have been much interested in this percentage representation of the time unit, but it seems to me that the use of time expressed as a fraction of the time corresponding to one electrical radian at normal frequency, is actually somewhat cumbersome. For instance, if time is in seconds, one obtains the damping torque in units of torque per radian per second, and one can mark his answer exactly what it is. But how does one express damping torque in the time units used by the authors? They define it as "the damping constant, torque corresponding to unit electrical angular velocity." Unit electrical angular velocity is the angular velocity in electrical radians per second, divided by ω so that when one obtains the damping torque in the units used by the authors, he is rather puzzled as to how it is to be used until it has been transferred into electrical radians per second or some other tangible unit which can be defined.

R. H. Park: Mr. Putman states in his discussion that "Actually, the damping torque is proportional to the rate of change of only that part of the displacement between the pole and the electrical field, while the damping torque calculated by the authors is proportional to the rate of change of the total displacement. Such a radical departure from the accepted ideas about this problem, is at least, worthy of further explanation."

The explanation of this phenomenon is as follows: At any given frequency of motion of the rotor there will exist a harmonic electrical torque on the rotor of the same frequency and proportional to the amplitude of oscillation, the constant of proportionality depending in general on the frequency of oscillation. In general, there will be a difference in the time phase of the torque and the displacement. The total harmonic torque, however, may be broken up into two components, one in time phase and one in time quadrature with the displacement of the rotor. The component in time phase with the total displacement is referred to as the synchronizing component of torque. The component in time quadrature is referred to as the damping component of torque, because it is in time phase with the rate of change of displacement—*i. e.*, in time phase with the velocity. Therefore it is quite clear that at any given frequency of oscillation the electrical torque is capable of being expressed as

(a constant) $\times$ total displacement) + a constant) $\times$ rate of change of total displacement).

It is also true, as shown below, that at any given frequency of oscillation the torque may be expressed as

(a constant) $\times$ (relative displacement of magnetic field and pole) + (a constant) $\times$ (rate of change of relative displacement of magnetic field and pole).

since, at any given frequency the relative displacement of the field and pole is in constant relation to the total displacement of the rotor provided that the oscillations are small as was assumed.

Mr. Putman also raises a question as to the reasonableness of the process by which the synchronizing and damping components of torque were calculated by substituting in the steady-state formula for synchronizing torque. The legitimacy of this method of calculation is explained most simply from the following considerations.

1. The electrical torque on the rotor depends only on the instantaneous distributions of flux and current in the machine.

2. Neglecting armature resistance, the distribution of flux and current in a machine, and therefore also the magnitude of torque, are known uniquely when the magnitude of the direct and quadrature nominal e. m. fs., terminal e. m. f., and the displacement angle between the rotor and the terminal e. m. f. are known. (It is to be noted that nominal voltage is to be interpreted as the percent armature flux linkages due to the direct component of field current, quadrature nominal voltage similarly and terminal voltage as the percent total armature linkages.)

3. Although the formula in question was originally derived in the study of the magnetic torque under steady conditions of operation, and was therefore expressed in terms of the nominal and terminal voltages and the displacement angle, nevertheless, since the torque, at any instant, actually depends only upon the instantaneous values of these quantities, it follows, as stated in the paper, that the formula may be extended in scope so as to cover variable conditions of operation.

Since the formula expressed the electrical torque completely, it must contain all component torques; thus it must contain both synchronizing and damping components. As shown in the paper, this is found to be the case. The correctness of the torque formula employed can, moreover, be demonstrated in a more explicit manner than given above. I propose to give such a demonstration in a paper to be presented before the A. I. E. E. in the near future.

C. F. Wagner (communicated after adjournment): During the discussion of this paper the question of the efficacy of voltage regulators and exciters in increasing the amount of power has arisen. This brings up the question as to whether the improvement so obtained could be attributed to the regulator or to the exciter. It is apparent that both must be sufficiently rapid; a long time lag in either regulator or exciter being approximately equivalent to conditions under hand regulation. It has been the experience of the Westinghouse Company with which I am associated that their standard vibrating voltage regulator, which is used with standard exciters, is sufficiently rapid even for quick-response exciters. This becomes apparent when it is known that the contacts of such a regulator close in a fraction of a cycle (at 60 cycles) under reduced potential. In light of these facts one must conclude that the improvement in power limits is due to improvements in exciters rather than improvements in regulators, the regulators as already developed being sufficiently satisfactory.

C. A. Nickle: Mr. Douglas has asked about the operation of synchronous machines above the steady-state power limit. In answering this question, a simple case with a cylindrical-rotor generator connected to an infinite bus will be considered. If the terminal voltage of the infinite bus is e, and e_1 is the nominal voltage of the generator, the power interchange between the generator and the bus is given by

$$P = \frac{e\,e_1}{x} \sin\delta$$

where x is the synchronous reactance of the machine. Evidently, when e_1, e, and x are constant, this expression has a maximum when $\delta = \pi/2$. If, however, e_1 is caused to vary in such a manner as to become a definite function of δ, the expression for power may have its maximum for values of greater than $\pi/2$ and the maximum power is increased. Operation beyond the steady-state power limit thus depends upon applying the proper excitation at the proper time.

By means of a new voltage regulator which we have developed, such requirements are fulfilled and machines have been caused to operate beyond the steady-state power limit by a considerable amount. To illustrate this, the following test may be cited. Two 435-kv-a. synchronous machines were connected to the same bus, one being driven as a generator and the other running as a motor. The rated voltage of these machines was 4000 volts and since, at this voltage, the possible power transfer would seriously overload the direct-connected, direct-current machines, all tests were run at a reduced voltage; *i. e.*, 2200 volts. The

maximum power obtained in tests where the terminal voltage was held by hand-controlled rheostats and also by standard regulators, was 180 kw. The use of the new regulator increased this power to 480 kw. or almost triple the value which could be obtained by ordinary methods. The angular displacement between the rotors of the two machines when operating at these loads was considerably beyond 90 deg. as was verified by means of stroboscopic observations. The torque-angle characteristics for angular displacements beyond the steady-state limit thus have a physical significance as well as a theoretical one.

R. E. Doherty: Mr. Evans has referred to the term, "artificial stability," coined by Mr. Shand, as applying to operation beyond the "static" stability limit. Why coin a new term, since classical usage has long since specified such a state as "dynamic" stability, in contradistinction to "static" stability? It is the distinction between the stability of a boy riding a tricycle in one case and a bicycle in the other.

He refers also to the discussion which took place at the Philadelphia Convention in 1924[1], regarding power transmission, and states that "at that time it was thought impossible in actual operation to obtain a condition of increased power limits by that process," that is, by dynamic stability. There were a number of opinions expressed at that meeting regarding stability. I remember that I expressed this particular one: that, considering the then present stage of electrical engineering art, and the extent to which the studies under consideration projected beyond the limits of experience, we should "neither gamble that a voltage regulator will be able to insert a supporting prop under an otherwise falling system, nor depend for stability during load transients, upon possible, momentary, favorable conditions due to momentum and field transients. These may add up in the right direction, but engineers had better keep them up their sleeves . . . ." Mr. Nickle's investigation since that time has demonstrated that synchronous operation far beyond the steady-state limit is possible. Thus the mechanical momentum can be utilized in this connection to a much greater degree than was thought possible at that time.

I hope that the importance of Mr. Nickle's tests may not be overlooked. The greatest increase above the steady-state power limit which Mr. Evans and his associates state that they have obtained on test is about 20 per cent. I wish to call attention to the fact that in Mr. Nickle's test, the steady-state limit was 180 kw., and that, by the use of a new regulator which he has developed and which applies excitation not merely quickly, (*i. e.* not merely "high-speed excitation" but at the right time phase), it was possible to raise the power from 180 to 480 kw. And, in my opinion, he has written a new chapter in the story of long-distance power transmission.

Mr. Wagner refers to test results given in the closing discussion of the Evans and Wagner paper at the last Midwinter Convention, both as being "similar" to those mentioned by Mr. Nickle, and as being "the first experimental vertifications that increased power limits were actually obtainable."

How similar? They showed an increase of 20 per cent. Mr. Nickle's test showed an increase of 160 per cent beyond the power corresponding to the steady-state limit—*i. e.*, from 180 to 480 kw.

Over a year before, the paper by Doherty and Dewey, at the Pacific Coast Convention, September, 1925[2], had test results showing a 28 per cent increase in power above the steady state limit.

It is recognized generally that the problem of bringing about a quick change in the exciter voltage is important. The point which does not yet appear to be recognized in Mr. Wagner's discussion, is the very important part which the regulator plays. From his discussion, one is clearly led to the conclusion that his sole criterion regarding the efficacy of the regulator is whether its

1. A. I. E. E. Trans., 1924, p. 71.
2. Trans., A. I. E. E., 1925, p. 972.

contacts close promptly on the occasion of a sudden voltage disturbance. Thoughtful consideration must nevertheless surely indicate that the subsequent behavior of the regulator is of equal importance. However, such questions as he has raised cannot be effectively settled by verbal discussion. Mr. Wagner's view would be immensely more convincing if, instead of submitting the time required for the regulator contacts to close, he had adduced some test results obtained by the use of the standard vibrating regulator which he mentions, such test results showing an increase in power over the steady-state limit comparable with those brought out in Mr. Nickle's and my discussion.

We are pleased to note that Professor Lyon considers the authors' premises to be reasonable; also that M. I. T. expects to make some experiments along these lines. Prof. Lyon mentions another possible method of attack which is interesting, and I hope that he may have an opportunity to carry this through.

Mr. Putman has raised some interesting points which the authors are glad to have the opportunity to clear up. Mr. Park has answered the question regarding the damping torque, and the

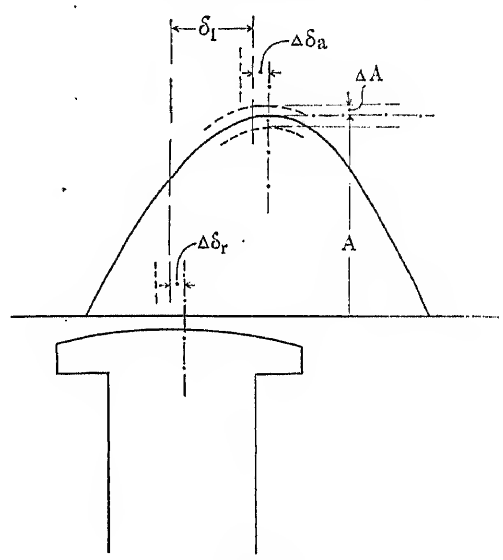

Fig. 1

particular angular velocity on which it depends; also he has shown why the torque formula referred to is applicable in general, and therefore in the present case. The authors acknowledge that there should have been further explanation regarding this point in the paper.

With reference to his proposal to simplify the mathematics, both ways are now available, so the reader may choose to his liking.

Mr. Putman's statement regarding the authors' alleged assumption relating to the reference axes is interesting and requires detailed comment. The basic conception is a synchronous machine connected to an "infinite bus," and experiencing a periodic angular oscillation. Under such conditions the magnitude of the space fundamental component of armature m. m. f. will pulsate periodically. Moreover, on account of the variation of power factor during each oscillation of the rotor, the position of the m. m. f. wave with respect to synchronous space will vary periodically—at the same period as the pulsation in magnitude.

The question is, how shall these phenomena be expressed? One may choose the premises which the authors have actually chosen, or those which Mr. Putman understands that they have chosen, and the result will be the same; that is, one may assume the component of the fundamental m. m. f. wave over the pole (*i. e.* the direct component) and likewise the quadrature component, to vary harmonically; or, as Mr. Putman suggests, that the components in line with the *average* positions of the

pole axis and the quadrature axis, vary harmonically. In the first case it is tacitly assumed by the authors that those variations of the m. m. f. *in line with the pole* other than the harmonic variations, are negligible, being second-order differences under the assumed extremely small oscillations. And it is these negligible differences to which Mr. Putman has apparently assigned an undue importance, as shown in the following:

Referring to the accompanying figure, let δ_1 be the angular displacement between the average position of armature m. m. f. wave and the average position of the direct axis of the rotor, both of which positions are fixed references in synchronous space. Also, let the *total* armature m. m. f. wave vary harmonically in amplitude according to the expression

$$a = A + \Delta A \cos s t$$

and let the position of the m. m. f. wave vary harmonically about its average position according to

$$\Delta \delta_a = \Delta \delta_2 \cos (s t + \beta)$$

The harmonic oscillation of the direct axis about its average position is

$$\Delta \delta_r = \Delta \delta_3 \cos (s t + \beta_1)$$

The total angular displacement between the armature m. m. f. wave and the direct axis of the rotor at any instant is then

$$\delta = \delta_1 + \Delta \delta_2 \cos (s t + \beta) - \Delta \delta_3 \cos (s t + \beta_1)$$

Thus the component of m. m. f. which exists in the direct axis at all instants is

$$A_d = (A + \Delta A \cos s t) \cos [\, \Delta_1 + \Delta \delta_2 \cos (s t + \beta) - \Delta \delta_3 \cos (s t + \beta_1) \,]$$

Expanding, and taking advantage of the close approximation that for small angles

$$\cos x = 1 - \frac{x^2}{2}$$

$$\sin x = x$$

$$A_d = [A + \Delta A \cos s t] \left[\cos \delta_1 \left\{ 1 - \frac{< \Delta \delta_2 \cos (s t + \beta) - \Delta \delta_3 \cos (s t + \beta_1) >^2}{2} \right\} - \sin \delta_1 \left\{ \Delta \delta_2 \cos (s t + \beta) - \Delta \delta_3 \cos (s t + \beta_1) \right\} \right]$$

Neglecting second order terms,

$$A_d = A \cos \delta_1 + [\Delta A \cos \delta_1 \cos s t - A \sin \delta_1 \{ \Delta \delta_2 \cos (s t + \beta) - \Delta \delta_3 \cos (s t + \beta_1) \}]$$

likewise for A_q.

Hence the m. m. f. in the direct axis, that is over the pole, or in the quadrature axis, at all instants comprises a constant term plus a harmonically varying increment—which is the form taken by the authors.

The M. M. F. Wave of Polyphase Windings
With Special Reference to Sub-Synchronous Harmonics

BY QUENTIN GRAHAM[1]
Associate, A. I. E. E.

Synopsis.—The m. m. f. waves of fractional slot windings or other irregular windings are found to contain harmonic components having wavelengths greater than two pole pitches. These are designated as sub-synchronous harmonics since their harmonic order is lower than that of the synchronously rotating wave. They induce currents in the damper windings of synchronous machines which may produce noticeable loss. Some test data concerning losses are included. These harmonics have an effect upon reactance and, under certain conditions, they may cause vibration. An appendix covers the calculation of the m. m. f. of three-phase fractional slot machines.

* * * * *

THE m. m. f. wave shapes of polyphase windings have been investigated by numerous writers.[2] The methods of analysis vary somewhat but the results are essentially the same. It is known, for example, that with the usual three-phase winding, the m. m. f. wave consists of a fundamental sinusoidal wave traveling uniformly at synchronous speed and certain odd multiples of the fundamental. Of these higher harmonic components, it is easily shown that the third or multiples thereof do not exist, and that the 5th, 11th, 17th, etc., travel against rotation while the 7th, 13th, 19th, etc., travel with rotation or in the same direction as the fundamental wave. The speed at which these components of the m. m. f. wave travel is inversely as their harmonic order. Thus the 5th harmonic travels at one-fifth synchronous speed, the 7th harmonic at one-seventh speed and so on. Each component moves through its own wavelength in the same interval of time.

In the present paper, the m. m. f. waves of certain particular types of windings are examined in some detail and it is shown that they possess additional harmonics which may have an important bearing on machine performance. The paper deals chiefly with fractional slot windings.

The term "fractional slot" is applied to machines in which the ratio of the number of slots to the number of poles is not an integral number. In machines of this type the m. m. f. wave varies from pole to pole. Thus when the m. m. f. for the complete armature is plotted and the wave analyzed, it is found to contain harmonic components having a wavelength greater than twice the pole pitch. That is, there are harmonics of lower order than the predominant component which travels at synchronous speed and which is normally spoken of as the fundamental wave. It becomes convenient, then, to use a new rotation in which the complete developed armature is taken as 2π radians and the fundamental component of the m. m. f. is a wave whose length is 2π. The complete m. m. f. wave contains components which are various multiples of this fundamental, one of which is the synchronously rotating wave. The synchronous component, which in usual notation is the fundamental wave, now becomes the $\frac{P}{2}$th harmonic, where P is the number of poles. There may be other component waves having harmonic orders below the $\frac{P}{2}$th or synchronous component and there will always be components of higher order.

The existence of these components of low harmonic order in the m. m. f. wave of fractional slot and other irregular windings has not been noted previously, as far as I am aware.[3] For convenience in distinguishing them from the usual higher harmonic components, I have used the term "sub-synchronous harmonics" since their harmonic order is below that of the synchronous component. This term is not entirely satisfactory since there may be important components whose order is above the synchronous component but which are not multiples thereof. The term "non-synchronous harmonic" may be used to designate any component other than the synchronous and of course is applicable to the 5th, 7th, etc., which occur in integral slot three-phase machines.

It is interesting to examine the sub-synchronous harmonics with reference to their speed of rotation and their direction. It is well known that the usual higher harmonics proceed around the armature at less than synchronous speed, each moving its own wavelength during a cycle of the current. It is not surprising, then, to find that the sub-synchronous harmonics travel at higher speeds, fulfilling the same condition of one wavelength of travel during one cycle of current. The direction is found to be with rotation in some cases

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., Feb. 7-11, 1927.

3. While the present paper was being prepared, the existence of these harmonics was mentioned in a footnote by Doherty and Nickle in their paper, *Synchronous Machines*, presented at the June, 1926, Convention of the A. I. E. E.

and against rotation in others, as will be shown later.

The method of determining the existence of any harmonic and of finding its magnitude will be shown in detail. The fluxes which correspond to the various harmonics will then be considered. The effect of these fluxes in both the stator and rotor will be discussed and it will be shown that they have an influence upon reactance and upon losses.

Determination of M. M. F.

A balanced polyphase winding having an integral number of slots per pole and equal spacing of phase

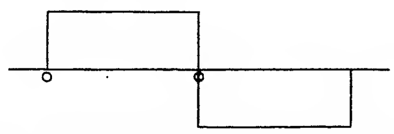

Fig. 1—M. M. F. of Full Pitch Coil

belt: produces an m. m. f. wave in which the space distribution is repeated for every pair of poles. For this type of winding it is sufficient to plot the m. m. f. for two pole pitches and to base all analyses of armature reaction on an equivalent two-pole machine. For the type of windings under consideration, however, the m. m. f. distribution varies from pole to pole around the armature so it becomes necessary to consider the entire winding. The method of analysis used here consists in finding, first, the m. m. f. wave set up by a single coil. This is decomposed into its various harmonic components after which each component is added separately to the corresponding waves of the other coils.

Consider for the moment a developed armature such as is shown in Fig. 1 with a coil having a pitch equal to

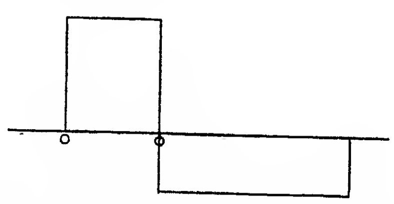

Fig. 2—M. M. F. of Short Throw Coil

half of the developed length. This may be, for example, a two-pole machine with a full pitch coil. The m. m. f. set up by this coil has a space distributed shown by the rectangular wave. It is well known that such a wave can be expressed as

$$a = \frac{4}{\pi}\left(\sin \alpha + \frac{1}{3} \sin 3\,\alpha + \frac{1}{5} \sin 5\,\alpha \;.\;.\;.\; \frac{1}{n} \sin n\,\alpha\right)$$

Suppose now that the throw of the coil is less than half of the developed armature. The m. m. f. form then takes the unsymmetrical rectangular shape shown in Fig. 2. The areas under both halves of this wave are equal and the ratio of the positive to the negative ordinates varies with the angle β which expresses the coil throw. The magnitude of any harmonic component of a wave of this type is shown, in Appendix *A*, to be

$$a_r = \frac{0.45}{n} \sqrt{1 - \cos n\,\beta} \qquad (5)$$

In this case both odd and even harmonics may be present. However, if the armature shown in Fig. 2 is used to represent a two-pole machine with short throw coils and the usual balanced arrangement of slots and phases, the even harmonics will not appear in the final m. m. f. wave due to a cancellation that takes place when the components of all coils are added. This is in agreement with the well-known fact that chording a winding changes the magnitude of the m. m. f. but does not introduce dissymetry.

Let another developed armature be represented by Fig. 3. In this case the complete machine has a large number of poles and the throw of the single coil shown is small compared to the complete developed armature.

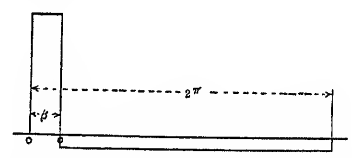

Fig. 3—M. M. F. of Single Coil of a Multipole Machine

For purposes of analysis, however, the coil may be considered just as if it were a coil of extremely short throw on a two-pole armature. The angle of throw of the coil is β and the complete armature span is taken as $2\,\pi$. The values of the different harmonics are found from (5). The component of lowest harmonic order will have a length equal to the complete armature; that is, it will be the fundamental wave and the other component waves will have harmonic orders which are multiples of its order.

The problem then resolves itself into locating all the other coils in their correct positions and adding

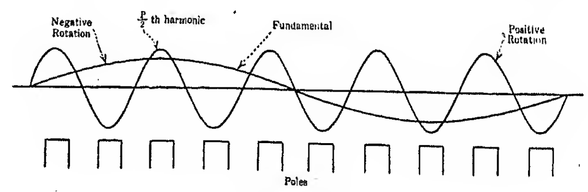

Fig. 4

together the waves of the same harmonic order. Appendix B shows the method of carrying out this calculation for the case of fractional slot, three-phase windings. Fig. 4 shows the fundamental wave and the $\frac{P}{2}$th or synchronous harmonic for a 10-pole machine. The magnitude of the fundamental is exaggerated in the sketch.

If the same method of analysis were applied to a winding which is not of the irregular type, the harmonics of lower orders appearing in the m. m. f. of a single coil would cancel out when combined with those of the other coils. This is simply stating that when the armature winding for one pair of poles is the same as for every other pair of poles, the m. m. f. wave repeats itself for each pair of poles.

Fractional Slot Windings

Modern a-c. machines make extensive use of windings in which the number of slots per pole is not an integer. These fractional slot windings give perfectly balanced terminal voltages and usually produce voltage wave shapes which are noticeably free from harmonics. There are many design and manufacturing advantages in the use of these windings since the possible numbers of slots for a given machine are not limited to multiples of the number of poles.

The method of determining the possible numbers of slots for any combination of poles and phases and of distributing the coils so as to obtain balanced voltages, has been published[4] previously. For three-phase windings the rule is that the number of slots must contain the factor $3^{(r+1)}$ where r is the number of times the factor 3 appears in the number of poles. The distribution of coils into pole groups is illustrated by the chart in Fig. 5. The procedure to be followed in laying out such a chart can be explained more easily by the use of an example.

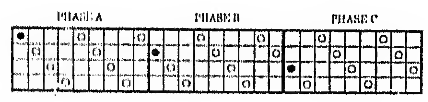

Fig. 5 Winding Chart for Machine with 6¾ Slots per Pole ($y = 4$)

Chart covers one repeatable group for each phase. It is applicable to any machine having the same number of slots per pole and having a number of poles which is a mutiple of 4. The beginning of each phase is shown by the symbol •

Let us take a 20-pole, three-phase machine having 135 slots. The number of slots per phase per pole expressed as a fraction is 9/4. Select a scale such that four divisions equal a slot pitch. Then nine divisions will represent a phase belt and 27 divisions a complete pole pitch. Locate the conductors a slot pitch apart on the chart, regardless of their relation to the phase belts, placing the succeeding poles under the first pole. Continue this until it is seen that the positions of the conductors along the horizontal scale are the same as those at the beginning of the chart. It will be found that four pole pitches must be covered before the winding begins to repeat. In any winding of this type the number of poles passed through before the winding repeats is the same as the denominator of the fraction expressing the slots per pole per phase. In the discussion that follows, y will be used to represent this number of poles.

The winding chart, Fig. 5, now shows the number of slots to be used in each phase group under each pole. The first pole will have 3 coils in phase A, 2 in phase B and 2 in phase C; the second pole will have 2 coils in phase A, 3 in phase B and 2 in phase C; and so on. Each group of 4 poles will be a repetition of the first 4 poles. Since there are 20 poles in the machine there will be 5 equal groups. These groups may be in series or parallel connection. The term "repeatable group" is used here to designate the coils of one phase in the 4, or in general, y adjacent poles.

In the determination of the m. m. f. waves as shown in Appendix B, the angular position of each coil in a repeatable group with reference to the initial coil must be found from the winding chart. In Fig. 5 the angular positions of the coils in phase A with respect to the first coil are as shown below. All angles are multiples of the slot pitch except that the angle π has been added to the actual physical position of coils in alternate poles to take into account the reversal of the direction of current in those coils. Letting S represent a slot pitch in angular measure the angles with respect to the nth harmonic wavelength are:

	Angles
Coil No. 1.................	o
Coil No. 2.................	$n\,s$
Coil No. 3.................	$2\,n\,s$
Coil No. 4.................	$7\,n\,s + \pi$
Coil No. 5.................	$8\,n\,s + \pi$
Coil No. 6.................	$14\,n\,s$
Coil No. 7.................	$15\,n\,s$
Coil No. 8.................	$21\,n\,s + \pi$
Coil No. 9.................	$22\,n\,s + \pi$

These are the angles to be used in adding the m. m. f. waves of the individual coils to obtain the quantity M used in Appendix B.

While the determination of the magnitude of any harmonic component in the final m. m. f. wave is rather tedious, the test for the existence of any harmonic is quite simple. It is shown in Appendix B that if

$$\frac{n + \dfrac{P}{2}}{\dfrac{P}{y}} = K_1 \qquad \textbf{(21)}$$

and if

$$\frac{y\,(P \pm 2\,n)}{6\,P} = K_2 \qquad \textbf{(22)}$$

where K_1 and K_2 are integers, including zero, the nth harmonic exists. Otherwise, although it is present in the coil m. m. f., it is cancelled when the summation is made.

4. See "Two- and Three-Phase Lap Windings in Unequal Groups," by E. M. Tingley, *Electric Review and Western Electrician*, Vol. 66, No. 4.

Table I shows the magnitude of the sub-synchronous harmonics in the m. m. f. waves of a number of typical fractional slot machines. All of these windings fulfill the conditions necessary to obtain balanced terminal voltages. The value of each harmonic is expressed in per cent of the synchronous component.

TABLE I

No. poles	No. slots per pole per phase	Per cent harmonics total	Per cent harmonics		
10	4- 2/5	3.6	3.6_1		
10	4- 4/5	5.2	5.2_1		
22	1- 7/11	15.9	4.2_1	4.4_5	7.3_7
24	3- 3/8	6.6	3.4_3	3.2_6	
26	2-10/13	14.4	2.1_1	7.7_5	2.2_7
			2.4_{11}		
44	2- 1/22	28.8	3.3_2	4.1_4	2.6_8
			5.8_{10}	2.0_{14}	9.5_{16}
			1.5_{20}		
48	2- 1/4	11.0	11.0_{12}		
72	1- 3/4	14.3	14.3_{18}		

This table shows the value of the sub-synchronous harmonics in per cent of the synchronous m. m. f. The subscripts indicate the order of the harmonic. All machines listed are three-phase. Harmonics of orders higher than that of the synchronous component but not multiples of it are not shown, although they may exist and may be, in some cases, as important as those that are sub-synchronous.

Effect of Sub-Synchronous Harmonics on Performance

When the existence of m. m. f. waves of low harmonic order has been established, there arises the question of their possible effects on performance. The equations in Appendix B show that these waves, like the usual higher harmonics, have speeds proportional to $\frac{1}{n}$. They set up corresponding flux waves, assuming constant permeance of the gap, which induce voltages of line frequency in the armature conductors. Thus they add to the reactance of the machine. Their speed relative to the rotor (of a synchronous machine) is such as to develop in the rotor windings voltages of frequency f_n where

$$f_n = f\left(\frac{2\,n}{P} \pm 1\right)$$

In a machine having a damper winding there will be secondary currents of this frequency which will react on the stator and reduce the value of the corresponding flux wave. The possible sources of loss, then, are $I^2 r$ loss in the damper winding, if the machine has one, and iron loss in both the stator and the rotor.

Losses. It seems probable that the presence of sub-synchronous harmonics in the m. m. f. wave may cause appreciable rotor loss, particularly in machines having damper windings. It is important to note that the frequency of the induced rotor currents, for any sub-synchronous harmonic, is between zero and 200 per cent of the line frequency, as shown by the expression

$$f_n = f\left(\frac{2\,n}{P} \pm 1\right)$$

The damper winding loss of single-phase machines is caused by rotor currents of 200 per cent frequency and there are plenty of data to show that this loss may be an important factor in the efficiency. It is true that the magnitude of the non-synchronous component of m. m. f. in a single-phase machine is equal to the synchronous component and therefore is greater than in any of the polyphase machines under consideration. But with a total of, say, 20 per cent harmonic m. m. f., which may easily exist, causing rotor currents of various frequencies between zero and 200 per cent, it is reasonable to believe the losses may be appreciable. It is interesting to note in passing that the space harmonics of integral slot three-phase windings, those of 5th, 7th, 11th, 13th, etc., harmonic order compared to the synchronous component, cause rotor currents of six times normal frequency or multiples thereof and thus operate on relatively high impedance circuits and produce negligible loss.

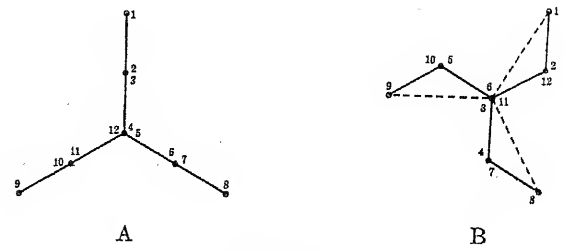

FIG. 6
A—STAR-CONNECTED WINDING
B—INTERCONNECTED STAR WINDING

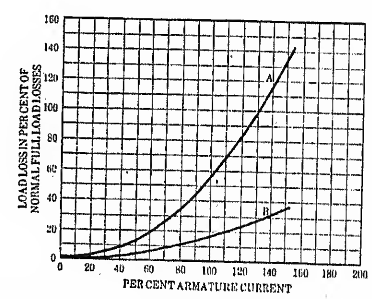

FIG. 7—MACHINE EQUIPPED WITH DAMPER WINDING

Curve A, loss with winding connected to produce sub-synchronous harmonics.

Curve B, loss with normal windings.

In order to obtain test data bearing on the question of losses, a normal three-phase machine with an integral number of slots was reconnected according to the diagram in Fig. 6. This type of connection, which has had some practical use, is usually called an interconnected star. It gives a simple means of changing a star-connected machine so as to have 86.6 per cent of the effective turns. In making this connection, however, the armature m. m. f. is unbalanced in such a way that sub-synchronous harmonics are set up. Table II gives the values of the various components. It will be seen that both the fundamental and the

third harmonic have positive and negative waves. These arise because the space positions of the phases are no longer symmetrical, whereas the phase groups of fractional slot windings are always equally spaced. For our purpose, however, it is not necessary that a given harmonic have only one direction of travel.

Curve A in Fig. 7 gives the total load loss[5] of this machine with the interconnected star winding. Curve B gives the load loss with the winding arranged in star connection but with 120-deg. grouping so as to obtain the same synchronous m. m. f. per ampere as with the interconnected winding. The 120-deg. grouping gives an m. m. f. wave, free from sub-synchronous components, just as in the usual 60-deg. winding. The curves give a direct measure of the increased loss due to the presence of harmonics of lower order. At rated current the load loss increased to 3.6 times its normal value.[6] The sum of the four components given in Table II is 65.9 per cent which is more than double that of any of the machines listed in Table I. It is, of course, an exceptionally flagrant case of unbalanced m. m. f. but it indicates that machines with lower values of harmonics may be worthy of study.

TABLE II

No. Poles	No. slots per pole per phase	Per cent harmonics total	Per cent harmonics
8	4	65.9	$7.7+_1$ $5.6-_1$ $41.6+_3$ $11.0-_3$

Harmonics present with interconnected star winding. Values are given in per cent of the synchronous m. m. f. Positive and negative waves of the same harmonic order are present.

An attempt was made to simulate the conditions in the rotor due to these harmonics by applying various frequencies to the stator winding, with the normal star connection, and with the rotor locked. In this way currents of any desired frequency may be set up in the rotor bars and the loss in the rotor may be determined. It is realized that the distribution of current in the rotor is affected by the wavelength of the flux wave which induces the current, so that even though the frequency is the same, the loss may be slightly different. The test results, which were not particularly accurate, showed that about 70 per cent of the increased load loss could be accounted for as loss in the rotor.

A similar test was made on another machine giving the results shown in Fig. 8. In this case the load loss at rated current increased many times due to the fact that the normal load loss was almost negligible. While this was a much smaller machine than was used in the preceding test, the number of poles and number of slots were the same and the per cent of harmonic m. m. fs. given in Table II holds for this case also.

5. The load loss is the difference between the measured short-circuit loss and the armature $I^2 R$ loss.

6. In an unpublished report written by Mr. M. W. Smith during 1921, the existence of high load loss in machines with interconnected star windings was noted and was explained by means of a graphical plot of the m. m. f. wave.

Load loss tests made on machines such as those listed in Table I have not given convincing data concerning the additional losses due to harmonics in the m. m. f. This has been due partly to the fact that most of the machines with high percentages of harmonics have been in the low speed class where the total load loss is small and difficult to measure with accuracy. A comparison of losses of similar machines, one with and one without harmonics, is not sufficient since a change in number of slots is always involved. With the present knowledge of load losses it is usually impossible to take into account these changes in magnetic proportions and thereby segregate particular losses. The data given in this paper are offered simply as evidence that there is a possibility of additional losses due to m. m. f. harmonics when irregular windings are used. Further study is needed to determine how important these losses are.

Reactance Voltage. The method of finding the reactance voltage due to any particular harmonic is shown in Appendix B for the case in which there is no opposing rotor current. The equations show that the voltages due to the various harmonics are not in phase with one another. The total reactance voltage due to m. m. f. harmonics may be found by adding together, in the proper phase relation, the various component voltages.

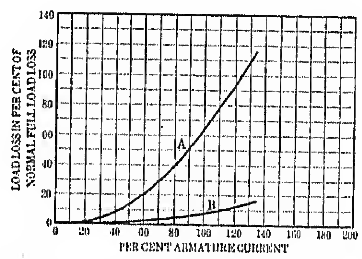

Fig. 8—Machine Equipped With Damper Winding

Curve A, loss with winding connected to produce subsynchronous harmonics.
Curve B, loss with normal windings.

What may be said of the magnitude of the reactance voltage calculated in this manner? At first glance it would appear that fairly large values are to be expected considering the amplitude of the non-synchronous flux waves. However, when the actual interlinkages are worked out the result is found to be quite low. In the machines that have been examined up to the present time, all of them salient-pole synchronous machines, the total reactance voltage due to m. m. f. harmonics has been less than one per cent of rated voltage. It appears, therefore, that this part of the reactance is of no great importance. The whole subject of reactance, particularly that of fractional slot machines, is being investigated by other engineers and it is possible that, eventually, the factors treated here will assume more importance than appears likely at present.

Vibration. Severe vibration of the stator of a small machine having a fractional slot winding was largely responsible for the present investigation of m. m. f. forms. This particular machine had a fundamental wave of about four per cent of the synchronous component. This wave might be replaced by an equivalent two-pole rotor revolving at 3600 rev. per min. (for 60-cycle supply). Thus there were variations in magnetic attraction, tending to distort the stator at its weakest section, which occurred 120 times a second. Measurement by means of a torsiograph showed vibrations of exactly this frequency. Further tests showed that the natural frequency of vibration of the stator was almost identical with the forced vibration. A minor change in construction was sufficient to remove the natural frequency from the danger zone and stop the vibration. Such a coincidence of natural and forced frequency is probably rare but the experience indicates another of the possible effects of lower order harmonics.

ACKNOWLEDGMENTS

I am indebted to Mr. H. Brookins for assistance in working out the data in Table I and to Mr. H. V. Putman and Mr. C. M. Laffoon for much valuable criticism.

Appendix A

M. M. F. of a Single Coil

Let the coil shown in Fig. 3 be excited with unit current. Assume that the air-gap is uniform and that the iron is unsaturated. The flux set up by this coil must pass across the gap in one direction over the space between zero and β and return between β and 2π. We can then draw a rectangular wave, representing the density, in which the areas under the two half-waves are equal. With a uniform gap this curve may be used to represent m. m. f. also. Let the total m. m. f. of the coil be unity. Then if the positive ordinate of the wave is h, the negative ordinate will be $(h - 1)$. The wave may be expressed as

$$f(\alpha) = \Big[h \Big]_{\alpha=0}^{\alpha=\beta} + \Big[h - 1 \Big]_{\alpha=\beta}^{\alpha=2\pi} \qquad (1)$$

The value of the sine component of any harmonic of a periodic function is known to be

$$a_s = \frac{1}{\pi} \int_0^{2\pi} f(\alpha) \sin(n\alpha)\, d\alpha$$

or, in this case,

$$a_s = \frac{1}{\pi} \int_0^{\beta} h \sin(n\alpha)\, d\alpha + \frac{1}{\pi} \int_{\beta}^{2\pi} (h-1) \sin(n\alpha)\, d\alpha \qquad (2)$$

Integrating,

$$a_s = \frac{1}{n\pi}(1 - \cos n\beta) \qquad (3)$$

Similarly, the cosine component is found to be

$$a_c = \frac{1}{n\pi} \sin n\beta \qquad (4)$$

The resultant value of the nth harmonic is

$$a_r = \sqrt{a_s^2 + a_c^2}$$

or,

$$a_r = \frac{1}{n\pi} \sqrt{(1 - \cos n\beta)^2 + (\sin n\beta)^2}$$

Solving,

$$a_r = \frac{0.45}{n} \sqrt{1 - \cos n\beta} \qquad (5)$$

The zero point of the resultant wave is displaced from the origin by the angle,

$$\theta_n = \tan^{-1} \frac{a_c}{a_s}$$

$$\theta_n = \tan^{-1} \frac{\sin n\beta}{1 - \cos n\beta} \qquad (6)$$

Appendix B

M. M. F. and Reactance Voltage of Fractional-Slot, Three-Phase Windings

Let the coil shown in Fig. 3 be excited with a current equal to $\sqrt{2} \sin \omega t$. The maximum ordinate of the nth harmonic wave will be, from Equation (5),

$$\frac{0.45\sqrt{2}}{n} \sqrt{1 - \cos n\beta}\, \sin \omega t$$

At any point in space the ordinate of the wave will be

$$a_1 = \frac{0.636}{n} \sqrt{1 - \cos n\beta}\, \sin \omega t \sin n(\alpha - \theta_n) \qquad (7)$$

since the zero point of the wave is displaced from the origin by the angle θ_n.

For any other coil in the same phase the nth harmonic wave is expressed by

$$a_2 = \frac{0.636}{n} \sqrt{1 - \cos n\beta}\, \sin \omega t \sin n(\alpha - \theta_n - \phi_2) \qquad (8)$$

where ϕ_2 is the angle between that coil and the origin.

To find the combined nth harmonic wave due to the entire phase it is necessary to add the single coil waves in proper angular relationship. These individual coil waves are all equal in magnitude but are spaced in irregular fashion. To find the resultant wave it is convenient to consider the waves as vectors of equal length separated from the zero vector by various angles corresponding to the positions of the coils with respect to the reference coil. It is necessary to consider only the coils in one repeatable group instead of the whole phase, as will be shown later. The actual angles must

be obtained from the winding chart. These vectors are then added and the resultant is determined both in magnitude and position. If M is taken as the ratio of the length of this resultant vector to the length of a single vector and $n\,\psi$ is the angle that the resultant makes with the zero vector, the equation for the m. m. f. of a repeatable group is

$$a_0 = \frac{0.636\,M}{n}\sqrt{1-\cos n\beta}\,\sin\omega t\,\sin n(\alpha-\theta_n-\psi) \quad (9)$$

The quantities M and $n\,\psi$ must be determined in each case by performing the vector addition. This is the laborious part of working out the m. m. f. wave for any particular harmonic. Each phase contains $\frac{P}{y}$ repeatable groups. The angle between the beginnings of these groups is $\frac{y\,2\,\pi}{P}$. If y, which is equal to the number of poles per group, is an even number, the angle between the nth harmonic waves of adjacent groups is also $\frac{y\,2\,\pi}{P}$.

However, since y may be odd, the waves of adjacent repeatable groups may be reversed due to the fact that alternate pole groups are wound in opposite directions. This may be taken into account by writing the angular space between the nth harmonic waves of adjacent repeatable groups as

$$\frac{y\,2\,\pi}{P} + \frac{y\,\pi}{n}$$

or $\left(\dfrac{n+\dfrac{P}{2}}{\dfrac{P}{y}}\right)$ nth harmonic wavelengths.

Since both numerator and denominator of this fraction are known to be integers, we may write

$$\frac{n+\dfrac{P}{2}}{P/y} = K_1 + \frac{K_2}{P/y} \quad (10)$$

where K_1 is any integer and K_2 is any integer less than P/y including zero.

If $K_2 = 0$, the angle between the waves of the various repeatable groups is an integral number of wavelengths and the waves add arithmetically. If, on the other hand, K_2 is not zero, the $\frac{P}{y}$ waves are spaced by equal multiples of $\frac{y\,2\,\pi}{n\,P}$ and must add up to zero.

Thus when $\dfrac{n+\dfrac{P}{2}}{P/y}$ is an integer, the resultant wave for the whole phase becomes

$$a_{p1} = \frac{0.636\,M\,P}{n\,y}\sqrt{1-\cos n\,\beta}\,\sin\,\omega\,t\,\sin\,n(\alpha-\theta_n-\psi) \quad (11)$$

And, when $\dfrac{n+\dfrac{P}{2}}{P/y}$ is not an integer, the nth harmonic is not present in the m. m. f. wave.

The next step is to combine the wave set up by the first phase with the corresponding waves of the other phases. In a fractional-slot, three-phase winding the beginning of the second phase is at an angle $\frac{y\,2\,\pi}{3\,P}$ from the beginning of the first phase, as can be seen from the winding chart. The beginning of phase 2 is understood to be the point from which the subsequent pole groupings for that phase follow the same sequence as in the first phase when starting from the original reference coil.

The time phase of the current in phase 2 may be expressed by $\left(\omega\,t-\frac{y\,2\,\pi}{6}\right)$ since, as the winding chart shows, there are y pole phase groups between the starting points.

The equation for the nth harmonic wave of phase 2 is, then,

$$a_{p2} = \frac{0.636\,M\,P}{n\,y}\sqrt{1-\cos n\,\beta}\,\sin\left(\omega\,t-\frac{2\,\pi\,y}{6}\right)$$
$$\sin n\left(\alpha-\theta_n-\psi-\frac{2\,\pi\,y}{3\,P}\right) \quad (12)$$

and similarly, for phase 3,

$$a_{p3} = \frac{0.636\,M\,P}{n\,y}\sqrt{1-\cos n\,\beta}\,\sin\left(\omega\,t-\frac{4\,\pi\,y}{6}\right)$$
$$\sin n\left(\alpha-\theta_n-\psi-\frac{4\,\pi\,y}{3\,P}\right) \quad (13)$$

For convenience, let

$$C = \frac{0.636\,M\,P}{n\,y}\sqrt{1-\cos n\,\beta}$$

and

$$D = (\alpha-\theta_n-\psi)$$

Then, substituting C and D in Equations (11), (12) and (13) and expanding,

$$a_{p1} = \frac{C}{2} [\cos(\omega t - n D) - \cos(\omega t + n D)] \quad (14)$$

$$a_{p2} = \frac{C}{2} \left[\cos\left(\omega t - \frac{2 \pi y}{6} - n D + \frac{2 \pi y n}{3 P}\right) - \cos\left(\omega t - \frac{2 \pi y}{6} + n D - \frac{2 \pi y n}{3 P}\right)\right] \quad (15)$$

$$a_{p3} = \frac{C}{2} \left[\cos\left(\omega t - \frac{4 \pi y}{6} - n D + \frac{4 \pi y n}{3 P}\right) - \cos\left(\omega t - \frac{4 \pi y}{6} + n D - \frac{4 \pi y n}{3 P}\right)\right] \quad (16)$$

The sum of the waves of the three phases will give the final resultant wave for the whole armature. Adding a_{p1}, a_{p2} and a_{p3},

$$a_n = \frac{C}{2} \left[\cos(\omega t - n D) + \cos\left(\omega t - \frac{2 \pi y}{6} - n D + \frac{2 \pi y n}{3 P}\right) + \cos\left(\omega t - \frac{4 \pi y}{6} - n D + \frac{4 \pi y n}{3 P}\right)\right]$$
$$- \frac{C}{2} \left[\cos(\omega t + n D + \cos\left(\omega t - \frac{2 \pi y}{6} + n D - \frac{2 \pi y n}{3 P}\right) + \cos\left(\omega t - \frac{4 \pi y}{6} + n D - \frac{4 \pi y n}{3 P}\right)\right] \quad (17)$$

It will be observed that if

$$- \frac{y}{6} + \frac{y n}{3 P} = K_1$$

where K_1 is any integer, including zero, Equation (17) becomes

$$a_n = \frac{C}{2} [3 \cos(\omega t - n D)]$$
$$- \frac{C}{2} \left[\cos(\omega t + n D) + \cos\left(\omega t + n D - \frac{2 \pi y}{3}\right) + \cos\left(\omega t + n D - \frac{4 \pi y}{3}\right)\right] \quad (18)$$

Since y is always an integer but is never a multiple of 3, the last term equals zero and the expression becomes

$$a_n = \frac{3 C}{2} \cos(\omega t - n D) \quad (19)$$

Similarly, when

$$- \frac{y}{6} - \frac{y n}{3 P} = K_1$$

it follows that

$$a_n = \frac{3 C}{2} \cos(\omega t + n D) \quad (20)$$

Suppose that neither of the foregoing assumptions is true. That is, $\left(- \frac{y}{6} \pm \frac{y n}{3 P}\right)$ is not equal to an integer. It has been shown that in order for the nth harmonic to exist in the m. m. f. wave of a single phase,

$$\frac{n + \frac{P}{2}}{P/y} \text{ must equal } K_1$$

That is,

$$n = \frac{K_1 P}{y} - \frac{P}{2}$$

Substituting this value of n in the expression

$$- \frac{y}{6} \pm \frac{y n}{3 P}$$

we obtain $\frac{K_1 - y}{3}$ when the plus sign is used and $\frac{K_1}{3}$ when the minus sign is used. When these values, neither of which is an integer, are substituted in Equation (17), both terms become zero.

The criteria for the existence of the nth harmonic in the final wave are, then,
first,

$$\left(\frac{n + \frac{P}{2}}{P/y}\right) \text{ must equal } K_1, \quad (21)$$

and second,

$$\left(- \frac{y}{6} \pm \frac{y n}{3 P}\right) \text{ must equal } K_2,$$

which may be written

$$\frac{y (P \pm 2 n)}{6 P} \text{ must equal } K_2 \quad (22)$$

where K_1 and K_2 are integers, including zero.

When the negative sign is used, the equation for the m. m. f. is

$$a_n = \frac{3\,C}{2} \cos(\omega\,t + n\,D) \tag{20}$$

When the positive sign is used,

$$a_n = \frac{3\,C}{2} \cos(\omega\,t - n\,D) \tag{19}$$

Substituting the values of C and D, the equations become

$$a_n = \frac{0.95\,M\,P}{n\,y} \sqrt{1 - \cos n\,\beta}\,\cos(\omega\,t + n\,\alpha - n\,\theta_n - n\,\psi) \tag{23}$$

and

$$a_n = \frac{0.95\,M\,P}{n\,y} \sqrt{1 - \cos n\,\beta}\,\cos(\omega\,t - n\,\alpha + n\,\theta_n + n\,\psi) \tag{24}$$

These expressions represent waves of constant magnitude which glide around the armature at speeds equal to one wavelength per cycle of current. Equation (23) is a wave traveling in one direction while (24) is a wave with opposite rotation. If n is made equal to $\frac{P}{2}$, the expression $\frac{y\,(P + 2\,n)}{6\,P}$ becomes an integer (zero in this case) when the minus sign is used. That is, Equation (20) represents the m. m. f. wave. Since a value of n equal to $\frac{P}{2}$ corresponds to the synchronous component of the m. m. f., it follows that for those cases in which the minus sign is used to satisfy the equation

$$\frac{y\,(P \pm 2\,n)}{6\,P} = K_2$$

the wave travels with rotation. When the positive sign is used the wave moves opposite to the direction of the rotor.

Reactive Voltages. Let a_n' equal the maximum ordinate of the nth harmonic m. m. f. wave. Then,

$$a_n' = \frac{0.95\,M\,P}{n\,y} \sqrt{1 - \cos n\,\beta}$$

The flux density at any point, assuming a constant permeance, p, is

$$B_n = a_n'\,p \cos[\omega\,t + n\,\alpha - n\,\theta_n - n\,\psi] \tag{25}$$

for a positively rotating wave.

The flux enclosed by the reference coil is

$$\Phi_n = a_n'\,p\,N \int_0^\beta \cos[\,\omega\,t + n\,\alpha - n\,\theta_n - n\,\psi]\,d\,\alpha \tag{26}$$

where N is a constant equal to the surface of the armature divided by $2\,\pi$.

Integrating,

$$\Phi_n = \frac{a_n'}{n}\,p\,N\,[\sin(\omega\,t + n\,\beta - n\,\theta_n - n\,\psi) - \sin(\omega\,t - n\,\theta_n - n\,\psi)\,] \tag{27}$$

The voltage induced in the coil is

$$e_n = -\,10^{-8}\,\frac{d\,\Phi_n}{d\,t} \tag{28}$$

Differentiating,

$$e_n = \frac{a_n'\,p\,N\,\omega}{n\,10^8}\,[\cos(\omega\,t + n\,\beta - n\,\theta_n - n\,\psi) - \cos(\omega\,t - n\,\theta_n - n\,\psi)\,] \tag{29}$$

which reduces to

$$e_n = \frac{2\,a_n'\,p\,N\,\omega}{n\,10^8} \sin\frac{n\,\beta}{2} \sin\left(\frac{n\,\beta}{2} + \omega\,t - n\,\theta_n - n\,\psi - \pi\right) \tag{30}$$

The voltage per phase is found by adding vectorially the voltages of the individual coils. But the time angle between the voltages of any two coils is the same as the space angle between their m. m. f. waves. We can make use of the previous vector addition, therefore, and write the expression for the voltage per phase:

$$E_n = \frac{e_n\,M\,P}{y} \tag{31}$$

which is a voltage wave displaced from the voltage of the reference coil by the angle $n\,\psi$. Thus the complete expression for the phase voltage is

$$E_n = \frac{2\,a_n'\,p\,N\,\omega\,M\,P}{n\,y\,10^8} \sin\frac{n\,\beta}{2} \sin\left(\frac{n\,\beta}{2} + \omega\,t - n\,\theta_n - 2\,n\,\psi - \pi\right) \tag{32}$$

Substituting the value of a_n',

$$E_n = \frac{2.68\,p\,N\,\omega\,M^2\,P^2}{n^2\,y^2\,10^8} \sin^2\frac{n\,\beta}{2} \sin\left(\frac{n\,\beta}{2} + \omega\,t - n\,\theta_n - 2\,n\,\psi - \pi\right) \tag{33}$$

It will be convenient, usually, to express the reactance voltage in per cent of normal voltage. If $a_n'\,p$ is expressed as a percentage of normal flux we may write,

from Equation (32), the expression for reactance voltage due to the nth harmonic as

$$\% E_n = \frac{(a_n'\,p)\,N_s\,M_n \sin \frac{n\,\beta}{2}}{N\,M_s \sin \frac{n_s\,\beta}{2}}$$

$$\sin\left(\frac{n\,\beta}{2} + \omega\,t - n\,\theta_n - 2\,n\,\psi - \pi\right) \qquad (34)$$

where N_s and M_s correspond to the synchronous harmonic.

Equation (34) gives the reactance voltage per phase due to the flux set up by any one harmonic in the armature m. m. f. It will be seen that the phase position of this voltage varies with the order of the harmonic. To find the total reactance voltage due to m. m. f. harmonics it is necessary to solve for each component voltage and then add all components in proper angular relation.

List of Symbols

α = distance along the armature in radian measure
a = ordinate of m. m. f. wave
a' = maximum ordinate of resultant m. m. f. wave
β = coil throw in radians
B = flux density

$$C = \frac{0.636\,M\,P}{n\,y}\sqrt{1 - \cos n\,\beta}$$

$D = (\alpha - \theta_n - \psi)$
e = reactance voltage of single coil
E = reactance voltage of one phase
f = frequency
K = an integer
M = ratio of resultant vector to single vector
n = order of harmonic
N = constant depending on machine dimensions
p = permeance
P = number of poles
S = slot pitch in angular measure
t = time in seconds
$\omega = 2\,\pi\,f$
y = denominator of fraction equal to slots per pole
θ = displacement of wave from the origin
ϕ = angular position of any coil
ψ = angle between resultant vector and zero vector

Discussion

P. L. Alger: This paper raises questions whose discussion might be carried to great lengths, since the ramifications of the effects of harmonics on various characteristics of the motor are very extensive. I will confine myself, however, to making two comments on this paper and then giving a few things from my own experience.

In the first place, Mr. Graham develops a formula for the magnitude of any particular harmonic, which contains the coefficient $\sqrt{1 - \cos n\,B}$. That, to my mind, is very hard to visualize, and it is much better to replace it by the exactly equivalent expression $\sqrt{2} \sin \frac{n\,B}{2}$. When this is done, the magnitude of each harmonic is seen to be proportional to the pitch factor for that particular harmonic. As the pitch factor is a very familiar thing to all designers, this expression tells the relative magnitudes of different harmonics almost by inspection.

In the second place, it appears obvious to me from physical considerations that with a perfectly balanced winding, every phase being like every other phase, the other phases can only introduce purely reactive voltages in the first phase, similar to the voltages induced by that phase in itself. That is, if you have a perfectly balanced arrangement, the currents in each phase being displaced in time by the same angle as they are in space position, there cannot be produced any two harmonic waves of the same order but opposite directions of rotation. So the nth pulsating harmonic made by phase 1 alone will either be converted into a revolving field of amplitude 3/2, due to the three phases, or else will be cancelled out altogether. For that reason, it is clear that Graham's equations showing a phase difference between the various harmonic voltages in a single phase must be wrong. There is no phase difference because all of them are purely reactive voltages.

Once we have admitted the existence of these harmonics and shown they are present and undesirable, the really interesting thing is how to avoid them. That Mr. Graham did not touch upon at all.

By rearranging the windings in various groupings, a great many effects can be produced. There are a number of arrangements possible for any particular winding, all of which give balanced phase voltages, but which have different characteristics. Systems of distribution can be worked out to give minimum vibration, minimum reactance or minimum load losses, or to meet other conditions, and some of those other arrangements have distribution factors so little different from the one that we ordinarily use, that they are more desirable than the ordinary arrangement.

An interesting case illustrating these possibilities is that of a 1000-h. p. induction motor, with 14 poles and 4 2/7 slots per pole per phase, which I had the opportunity of observing in 1923. When the motor was tested the first time, it developed a very severe load vibration, similar to that Mr. Graham observed on his motor. We determined the vibration to be of twice line frequency, and due to the 10-pole field produced by the irregular winding arrangement. By reconnecting the winding to the arrangement giving a minimum 10-pole field, the trouble was remedied without any mechanical change. In general, unbalanced magnetic pull occurs whenever two fields of nearly the same numbers of poles exist together, and so the way to avoid vibration is to arrange the winding to minimize that particular harmonic whose number of poles is nearest the fundamental.

The study of the best winding arrangement, taking into account all the factors, is very fascinating, but it is quite difficult to make a complete analysis of the problem. I have been working on this matter for some time, and I hope ultimately to be able to say for any given number of fractional slots per pole per phase what arrangement gives the best combined characteristics, taking into account noise, fundamental distribution factor, reactance and losses.

C. A. Nickle: I agree with Mr. Alger that in a rotor with uniform permeance, reactive voltages other than 90 deg. out of phase with the currents cannot be obtained. When such voltages exist, we must have reluctance torques in the machine, we must have consumption of power, and we cannot have reluctance torques in a uniform-permeance machine.

The author has made calculations of the leakage reactance introduced by sub-harmonics and he gets a value of approxi-

mately 1 per cent. Of course, if we add reactance voltages vectorially, we shall get a much smaller voltage than if we add them arithmetically. If all these reactance voltages were added in time phase, the total reactance voltage might be considerably greater, and I think might be worth investigating.

W. V. Lyon: Mr. Graham has applied the principles of harmonic analysis to an interesting and not uncommon problem, the most important aspects of which I believe are the extra losses and vibration which may occur when these irregular windings are employed. He has clearly shown how the problem may be attacked.

In the spring of 1926, apparently at about the time when Mr. Graham was preparing this paper, I analyzed the same problem with a class of graduate engineers at the General Electric Works at Lynn. Curiously enough, the illustrative problem that we worked through was the same that Mr. Graham has chosen, *viz.*, one in which there are 6¾ slots per pole. Also the winding arrangement was the same in both cases. The only difference was that ours was a stator having 54 slots and wound for 8 poles. We found no particular difficulty in obtaining a resultant nth harmonic reduction factor for this winding which was a combination of the ordinary pitch and breadth factors. We did not, however, determine the criteria for the existance of the nth harmonic nor for its direction of rotation.

One point that Mr. Graham has made is well worth emphasizing. When a uniform air-gap is acted upon by a magnetizing winding there will in general be produced component sinusoidal flux distributions which have two poles, four poles, six poles, eight poles, etc. By properly arranging the winding, certain of these distributions can be completely or partially eliminated. If, for example, a symmetrical three-phase winding having an integral number of slots per pole per phase and wound for 4 poles is used, there will be no components except the 4-polar, 20-polar, 28-polar, 44-polar, 52-polar, etc. Again in the 20-pole winding that Mr. Graham cites there will be 10-polar, 20-polar, 30-polar, 40-polar, 50-polar, 70-polar, etc., distributions.

I should like to add a little to what Mr. Graham has said about vibration. If the stator and rotor were perfectly rigid, the internal stresses between them due to the magnetic field could cause no vibration. Actually, however, both the stator and rotor have a certain amount of flexibility and thus these internal stresses may produce serious vibration. There are two distinct types of internal stress. One is due to the action of a single sinusoidal flux distribution and the other is due to the joint of two sinusoidal distributions of different wavelengths. If there is a single sinusoidal component of flux in the gap, the rotor will be acted upon by balanced radial forces which can cause no vibration in the rotor if its laminations are rigidly connected to the shaft. On the other hand the rotation of the flux distribution will produce a harmonic variation in the magnetic force between the stator and rotor in any fixed radial direction of such a frequency that it will go through one cycle while the magnetic field is moving one pole pitch. If the stator frame is flexible in a radial direction, this harmonically varying force may set up serious vibration. This is apparently the case that Mr. Graham cites.

The other cause of vibration may, I believe, be equally important. If there are in the gap two component distributions of different wavelengths the radial forces acting on the rotor may be unbalanced. Two polar distributions that differ by a single pair of poles will produce this effect. This unbalanced force on the rotor may be either constant or variable. If the distributions are moving properly with respect to each other the unbalanced force acting on the rotor will vary harmonically, and serious vibrations may result.

Quentin Graham: Mr. Alger has suggested the substitution of $\sqrt{2}\ \sin\ \dfrac{n\,\beta}{2}$ for the expression $\sqrt{1 - \cos n\,\beta}$ which I have used. I agree that this change would aid in visualizing the magnitude of the harmonics.

Mr. Alger and Mr. Nickle have both pointed out the error contained in the last paragraph of Appendix B and also in the body of the paper where it is stated that the reactance voltages of the various harmonics are not in phase. I am giving below a number of corrections in the mathematics, changing the final equation on which this false conclusion was based. I am indebted to Mr. Nickle for having pointed out the particular points which were in error. The corrections are as follows:

Equation (6) should read

$$n\,\theta_n = -\tan^{-1}\frac{\sin n\,\beta}{1 - \cos n\,\beta}$$

which can be simplified to

$$n\,\theta_n - \frac{n\,\beta}{2} - \frac{\pi}{2}$$

Using this value for $n\,\theta_n$ Equation (30) may be simplified so that the quantity in the parenthesis becomes $\left(\omega\,t - n\psi - \dfrac{\pi}{2}\right)$

The statement following Equation (31) should give the displacement angle as $-n\,\psi$ instead of $n\,\psi$.

With this correction the quantity in the parenthesis in equations (32), (33) and (34) will be $\left(\omega\,t - \dfrac{\pi}{2}\right)$. It is clear then that the final paragraph, following Equation (34), is in error and that the reactance voltage components of the various harmonics must be in phase.

I have experimented to some extent with the rearrangement of windings, as Mr. Alger suggests, for the purpose of reducing some particular harmonic. This is usually accomplished at the expense of increasing some other harmonic but, as he says, the total result may be beneficial.

Mr. Lyon's discussion of the vibration problem is very interesting and his conclusions appear to agree with Mr. Alger's experience.

Transverse Reaction in Synchronous Machines

BY J. F. H. DOUGLAS[1]

Associate, A. I. E. E.

Synopsis—The confusion existing at present in the theory of synchronous machines is shown to be due to insufficient experimental evidence of the behavior of this type of machine under transverse magnetizing (cross magnetizing) conditions. A method of testing which yields the needed data is described. The results of these tests on a particular machine are given and analyzed. It is proved, for the machine tested, that the effect of transverse reaction can be most accurately estimated by the use of a magnetomotive force diagram. Experimental constants useful in design are found. A theory of the operation of synchronous machines is proposed, and a diagram for finding the performance of a synchronous machine from experimental tests is given; which, it is hoped, will be more accurate than present methods.

* * * * *

INTRODUCTION

THE subject of the performance of synchronous machines seems to be of perennial interest. Many theories have been proposed with their appropriate methods of computation. Nearly every text-book is a monument to the confusion of this subject, a confusion resulting from an insufficiency of facts. It is interesting to note how theory has become more sound as experimental facts have become more extensive.

When the open and the short-circuit tests were the usual compromise tests, we had the e. m. f. and the m. m. f. methods which were based upon them, with the Torda-Heyman method as a compromise. When the shape of the full-load zero power-factor saturation curve became known, the improved Kapp diagram and the Potier diagram were developed. A number of discrepancies between observed and computed results, together with theoretical studies of the variation of air-gap permeance, have led to various proposals for the perfection of the theory of this machine. In the judgement of the writer, the best method derived to date is that of Andre Blondel[2], and the best exposition of this method that of Professor V. Karapetoff[3]. As expounded, it is chiefly a design method. Although it is possible to apply it to experimental data, the directions are not clear enough to enable it to be easily applied for this purpose. Some recent refinements in this method have been made by Karapetoff, and Doherty and Nickle[4].

The elimination of guarantees of regulation at other than zero power factor, has led to the attitude that present methods are good enough for practical purposes. There has been a gradually increasing number of facts, however, that indicates that further improvements are necessary. Hunting frequencies and pull-out torques some thirty per cent in excess of predicted values, for example, indicate considerable error in customary theory. The Blondel theory does give better results in these cases. The phenomena of pull-in torque in motors and instability of generators (pole slipping) are entirely unpredictable except with some form of two-reaction theory such as that proposed by Blondel.

Experimental data for machines operating under demagnetizing conditions are easily obtainable; the methods for securing them and the general character of the results secured are well known, and a theory able to account for the results has been developed which is adequate also as a basis of computation. A very different situation holds for the effects in a synchronous machine under transverse (cross magnetizing) conditions. Enough facts are available, indeed, to show that magnetic conditions are then radically different. A plausible theory has been developed which is applicable to design with some measure of success. However, the writer is unaware of any systematic experimental data which will show what the effect of transverse armature reaction in a synchronous machine is in reality.

The conditions for such an experimental study may be stated very simply. In the first place, the load placed upon the machine should be wholly transverse in effect; that is, the armature currents must attain their maximum value when opposite a pole center. This condition must exist in order that the effects observed shall be due to one cause only, and not complicated by direct magnetization. This carries as a corollary, that the experimental method must have a flexible power factor control; that is, a quick and accurate adjustment of the phase angle of current is needed. In the second place, for an experimental study of transverse reaction, we must be able to measure the terminal voltage of the machine not only in magnitude, but in phase position with reference to the pole axis. In other words, the components of the terminal voltage with reference to the pole axis must be known. Lacking this information, unwarranted assumptions as to the phase angle of the reactance drop would have to be made.

AN EXPERIMENTAL METHOD FOR STUDYING TRANSVERSE REACTION

The basic idea on which the following experimental method rests is to measure not the voltages and currents of the machine tested but their components with

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., Feb. 7-11, 1927.

reference to the pole axis—that is, with reference to the no-load voltage of the machine. The second important idea in these experiments is the use of a wattmeter as a device for the measurement of components of voltage and of current.

The machine tested was a 15-kv-a., 6-pole, 60-cycle, synchronous machine rated at 190 volts with its two-phase connection, one of a set of two machines made by the Westinghouse company, for educational institutions. A description of the design details of this machine is in the A. I. E. E. JOURNAL[5]. The diagram

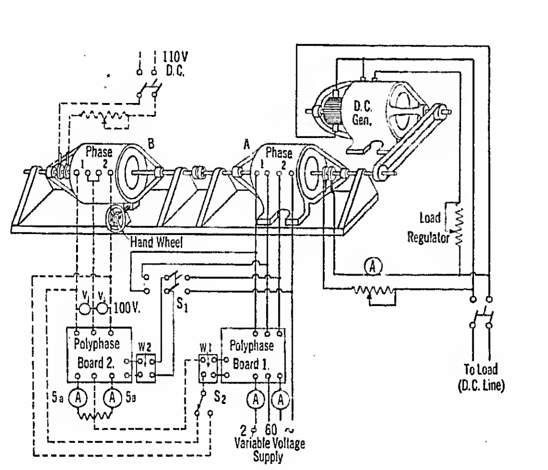

FIG. 1

of connections used is shown in Fig. 1. Machine A was the one tested for its performance, and it was loaded as a motor, by the d-c. generator belted to it. The load on the motor was regulated by the generator field rheostat. The d-c. generator returned its surplus power to the laboratory d-c. line, so that on occasion the set could be run from the d-c. machine as a motor. The current for the synchronous motor A was supplied from the mains of the Milwaukee Electric Co. with 60-cycle current. This current was supplied through a Scott connection and an induction regulator. The voltage supplied could be regulated for any value from 100 to 300 volts. By varying the impressed voltage, the motor could be made to take current at any phase angle desired.

The voltage of machine A was measured by wattmeter (2) excited with five amperes from machine B. Thus the reading of the wattmeter divided by five gave the component of voltage in phase with the excitation. The current in machine A was measured by wattmeter (1) excited with 100 volts from machine B. Thus the reading of this wattmeter divided by 100 gave the component of current in phase with the excitation. Since machine B was loaded on a Cutler-Hammer load rheostat, made of Advance wire wound on flat spools, it was assumed that the excitation of both wattmeters were in the same phase.

Machine B was connected as a two-phase machine, and a double throw switch $S2$ and a polyphase board $P2$ were provided. In this way the excitation of the wattmeters could be transferred to either phase of machine B. The components of current and voltage in machine A were measured, therefore, in two perpendicular phase positions. The double throw switch $S1$ and the polyphase board $P1$ enabled measurements to be taken on both phases of machine A. By adjusting the hand-wheel of machine B, the axes on which the components of current and voltage were read could be brought into any position. The hand-wheel was actually adjusted so that these axes were the same as the voltages of machine A at no load. Thus the wattmeters gave directly the direct and the transverse component of both current and voltage supplied to machine A.

A number of runs was made, each for a definite field current in machine A. In all the runs the induction regulator was adjusted so that the current supplied machine A was wholly transverse in character; that is, wattmeter (1) excited with phase (1) of A and phase (2) of B or *vice versa* read zero. In each run the load was varied from zero to full load. At each load the excitations were checked and all the wattmeter readings taken. The range of field currents used was from 3.25 to 23 amperes, giving saturations of from 100-300 no-load volts.

The data for the two phases were averaged to eliminate small unbalances. The polarities of all the wattmeter combinations were established definitely. The data were corrected for systematic error, including $I\,R$ drop. The data were corrected for other constant errors such as residual demagnetizing currents. The readings of transverse and direct voltage were plotted against transverse current and smooth curves drawn,

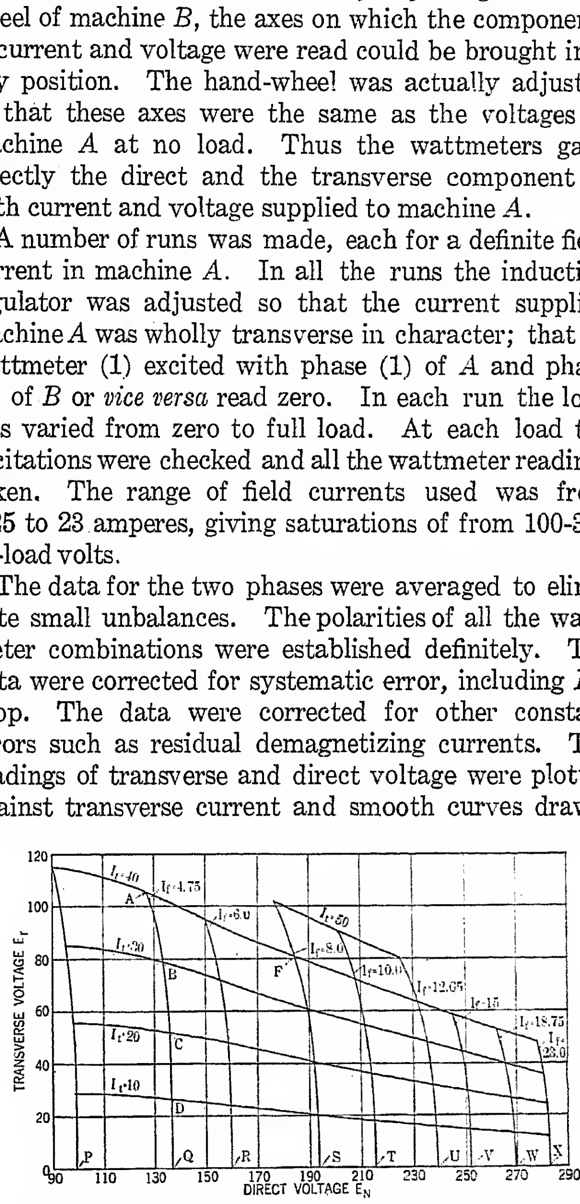

FIG. 2—TRANSVERSE AND DIRECT VOLTAGE WITH TRANSVERSE ARMATURE REACTION

eliminating small observational errors. The data are recorded in graphical form in Fig. 2, and represent the results after correction for the above mentioned errors. The errors were small, and the uncorrected data gave approximately the same set of curves.

DISCUSSION OF THE EXPERIMENTAL DATA

Fig. 2 shows the transverse voltage induced in the machine, under various amounts of transverse mganetizing current, plotted against the direct voltage

5. A. I. E. E. JOURNAL, May 1925, page 543.

induced. The lines sloping downward and to the right are loci for constant values of the transverse current (I_t) of 50, 40, 30, 20 and 10 amperes. The nearly vertical lines are for constant field currents. The direct voltage is designated by the symbol E_n meaning the voltage induced by the net magnetomotive force along the polar axis.

The corresponding loci were calculated from the Blondel theory, using the following data. A demagnetizing reaction equivalent to 7.0 amperes of field current for 40 amperes of demagnetizing armature current, an armature reactance of 0.5 ohm, and a slope of the saturation curve of 31 volts per ampere of field current agree with experimental data in Fig. 5. It was assumed that the transverse reaction was 40 per cent of the direct, and that the armature reactance was a constant. The loci of E_t, for constant transverse magnetizing armature current of 40, 30, 20 and 10 amperes, were lines parallel to the E_n axis and passing through the points A, B, C, and D in Fig. 2. The loci of E_t for constant field current were straight lines perpendicular to the axis E_n and passing through the points P, Q, R, S, T, U, V, W, and X. Even with other assumptions as to the constants, the loci would be a system of lines parallel and perpendicular to the axis E_n. The discrepancy in Fig. 2 between the observed and computed loci is disappointing and does not give promise of any practical method of predicting the effects of transverse reaction from an e. m. f. diagram.

If we analyze Fig. 2 we see several important results. In the first place the transverse voltage for a constant field current is proportional to the transverse armature current. Their constant ratio may be denoted by the symbol X_{st} and may be appropriately called the "transverse synchronous reactance," since it includes the effects of both transverse reactance and transverse reaction.

In the second place, for a constant armature current the tranverse voltage E_t decreases as the saturation

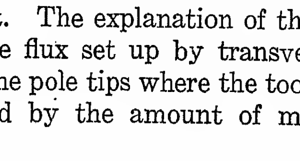

FIG. 3—DERIVATION OF M. M. F. FROM E. M. F. DIAGRAM

increases. The transverse synchronous reactance is not a constant for different saturations, therefore, but decreases from a value of 3.0 ohms with 3.25 amperes of field current to a value of 1.2 ohms with 23 amperes of field current. The explanation of this phenomenon is simple. The flux set up by transverse reaction is chiefly under the pole tips where the tooth and pole tip iron is affected by the amount of main flux as to saturation.

In the third place, the direct voltage E_n is decreased as the amount of transverse current is increased, even though the field current is constant. This points definitely to a demagnetizing action of the transverse reaction. The voltage E_n, therefore, is not a function of the field current alone. This is shown clearly at all loads and at all field currents, in spite of the fact that there was no demagnetizing current present in the armature. The explanation of this effect is also simple. The cross magnetizing or transverse effect operates to strengthen one pole tip of a pole and to weaken the other; but, owing to saturation, the weakening effect is larger than the strengthening effect. Consequently the

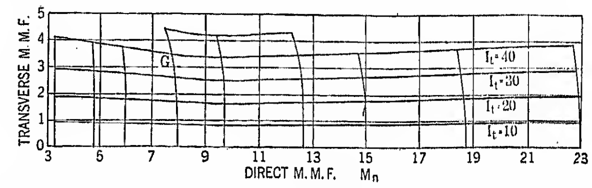

FIG. 4—M. M. F. DIAGRAM OF MOTOR UNDER TRANSVERSE LOAD

total flux per pole is reduced. The decrease in E_n varies approximately as the square of the current.

The variation in X_{st} with the saturation most seriously affects predictions as to the internal phase angles, but it also affects calculations of needed field current. The variation in E_n affects regulation and field current calculations alone.

It is a mistake to build up a theory of transverse reaction on the basis of an unsaturated magnetic circuit for the transverse flux, since such a theory leads to a constant value of the transverse synchronous reactance. The predicted values of transverse reactance may be correct for some one particular voltage, but at other voltages the performance will be off. For example, in Fig. 2, pull-out torques will be actually larger than computed values for voltages in excess of 130 volts.

The Blondel theory of transverse reaction is in reality a reactance method, since the vectors appearing in the Blondel diagram are $I\,X$ drops. Since the reactances used replace the effects of reaction, the $I\,X$ drops appearing in the diagram are properly termed synchronous reactance drops. It is but natural to turn to an m. m. f. diagram, to see if it gives superior, that is, more constant, results. To convert any point such as F in Fig. 2 into a corresponding point G in a m. m. f. diagram, we use the construction in Fig. 3 and the saturation curve in Fig. 5. We take the voltage E', the resultant of E_n and E_t, to the saturation curve and read there the corresponding resultant magnetomotive force expressed in equivalent field amperes, which we denote by I_{fr}. Since the flux inducing E' is set up by the resultant magnetomotive force, we draw I_{fr} in phase with E'. This magnetomotive force is made up of two components. One produced along the pole axis by the net action of field and direct reaction, we denote by I_{fn}, since it is expressed in equivalent field amperes. The other component of I_{fr} is the trans-

verse m. m. f., which we denote by I_{ft} since it is expressed in equivalent field amperes. Each point in Fig. 2 was converted by this means into a point in the m. m. f. diagram shown in Fig. 4.

Fig. 4 consists of a system of approximately horizontal lines for constant armature current, intersected by a system of approximately vertical lines for constant field current. We may say, therefore, with substantial accuracy, that transverse reaction may be represented on a magnetomotive force diagram, by a vector proportional to the armature current, independent of the field current, and perpendicular to the armature current. Secondary demagnetizing effects do not

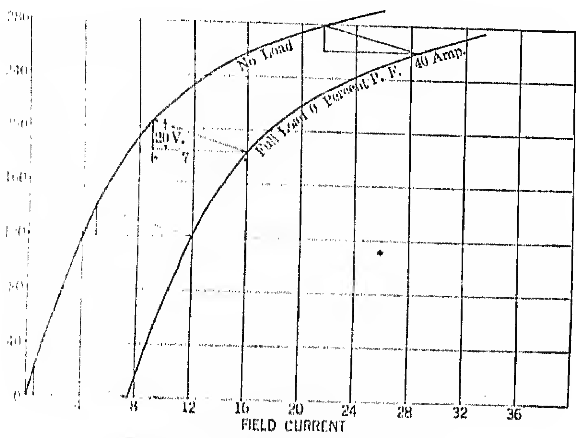

Fig. 5—Saturation Curves

appear on the m. m. f. diagram to any appreciable extent. This diagram proves that we may regard the magnetic flux set up in a machine as produced by a resulting magnetomotive force acting on a single magnetic circuit of substantially uniform saturation. There is no evidence in either Figs. 2 or 3 of any transverse flux component directly proportional to the armature current and independent of saturation. Stated in other words, the transverse leakage reactance X_t appears to be zero; that is, the leakage reactance appears to be less for conductors under the poles than for conductors between the poles. If a transverse leakage reactance existed, the lines in Fig. 4 would all slope upward and to the right. In any machine showing such characteristics, the two effects reactance and reaction could be separated, by trial.

Fig. 5 shows the saturation curves of the machine tested. From it the constants previously used were obtained. We define the experimental coefficients of armature reaction as the ratios of equivalent magnetomotive force expressed in field amperes to armature current. The direct coefficient $C_d = 0.175$, the transverse $C_t = 0.09$, for average conditions in the machines tested. It is worthy of note that the transverse coefficient is approximately one-half the direct coefficient. In solving for the performance of a synchronous machine, for which only the data like that in Fig. 5 were available, the writer would be inclined to use a value of $X_t = 0$ and a value of $C_t = (C_d/2)$. However, it is not permissible to generalize too much from the data on one machine.

Taking the dimensions of the machine and the winding data given by Mr. Quentin Graham[6], the writer has checked the various constants found. The resistance when increased by the A. I. E. E. allowance agrees with the measured value 0.25 ohm per phase. The armature reactance at zero power factor, of 0.5 ohm, checks 25 per cent higher than that computed using Hobart's values of slot and end-connection permeance (10 perms per in. and 2 perms per in.) and somewhat higher than the value computed from data on page 230 of the "Magnetic Circuit."[7] In the equations for direct and transverse reaction given in Karapetoff's "Magnetic Circuit," Art. 49 and 50, we shall for the present take M_d as $N_f\, I_{fd}$ and M_t as $N_f\, I_{ft}$, since the constants there derived are for equivalent field ampere-turns. Thus

$$N_f\, I_{fd} = K_d\, K_b\, K_w\, m\, n\, I_d; \quad N_f\, I_{ft} = K_t\, K_b\, K_w\, m\, n\, I_t \tag{1}$$

We will take $N_f = 185$ turns per pole, $I_{fd} = 7.0$ from Fig. 5, $K_b = 0.907$ for two phases and six slots per pole per phase, $K_w = 0.925$ for 75 per cent winding pitch, $m = 2$ phases, $n = 22$ equivalent turns per pole per phase for winding undivided in group, $I_d = 40$. The equivalent transverse magnetomotive force corresponding to $I_t = 40$ was taken as 3.6 amperes of field current. Using the above data, the constants are

$$K_d = 0.875; \quad K_t = 0.451 \tag{2}$$

The writer made a careful estimate of the wave of air-gap permeance, the waves of direct, transverse and field flux, analyzing them for their sine wave components, and arrived theoretically at the values

$$K_d = 0.755; \quad K_t = 0.405 \tag{3}$$

It is plain, therefore, that the design constants need experimental correction.

A Theory of Synchronous Machines

It may be presumptuous from the test of one machine to announce a theory of the synchronous machine and give yet another diagram for its performance. However, the results of our tests point very definitely to such a theory and such a diagram, and they are offered for experimental confirmation or rejection. The writer does not have ready access to recent literature, and therefore does not know whether the theory proposed is new or not.

In Fig. 6 the magnetic effect of armature currents in position A is entirely different from that produced by currents in position B. With reference to the pole, the first is transverse; the second is direct. From considerations of symmetry, the armature currents should be resolved into components in these two positions. The magnetic effect of the transverse current in posi-

6. Loc. Cit.

7. Doherty and Nickle's work accounts for some of the discrepancy observed. See paper cited.

tion A is obviously much smaller than that of an equal current acting in position B because it acts on a magnetic path of much higher reluctance.

The magnetic effect of the two components of the armature current may be considered as two-fold; namely, that effect produced individually by each,—that is, as if the other magnetomotive forces were not there,—and that effect produced jointly through the cooperation of the field,—the direct and the transverse currents. Each of the components of armature current may be considered as producing a component of flux, mainly local in character, proportional to the current and independent of saturation, which we may call armature leakage fluxes. They cause a drop in voltage which we may call the leakage reactance drops, each leading its component of current 90 electrical degrees. The direct reactance drop caused by the direct component of current in position B is appreciable, because this drop is due to flux set up in the interpolar regions where there is little interference with the main flux. The transverse reactance drop is small and may be sometimes neglected for the reason that this flux

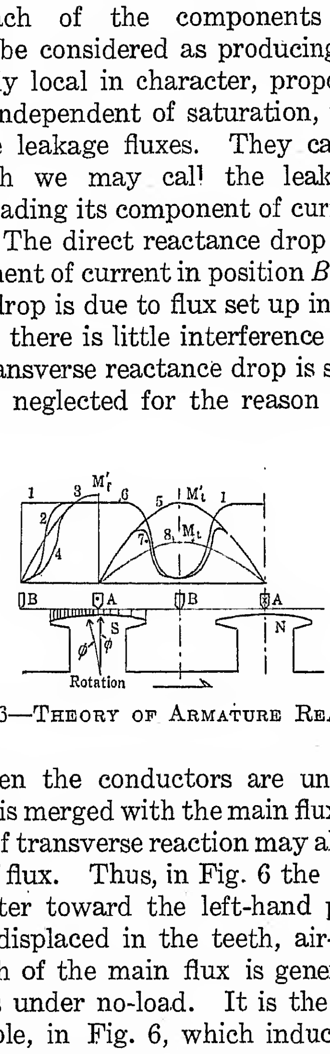

FIG. 6—THEORY OF ARMATURE REACTION

is set up when the conductors are under the poles and therefore is merged with the main flux[8].

The effect of transverse reaction may also be stated as a distortion of flux. Thus, in Fig. 6 the flux is crowded from the center toward the left-hand pole tips. Although thus displaced in the teeth, air-gap, and pole shoe, the path of the main flux is generally the same under load as under no-load. It is the resultant flux ϕ', for example, in Fig. 6, which induces the voltage at the terminals plus the $I\,R$ and the two $I\,X$ drops. It is the resultant m. m. f. of the machine which produces this resultant flux, and consequently the no-load saturation curve should serve to correlate the induced voltage and the resultant magnetomotive force.

The resultant magnetomotive force may be taken as the vector sum of the three component magnetomotive forces, namely the field, the direct and the transverse magnetomotive forces. Since only sine waves combine to give a sine wave and only sine waves can be represented by vectors, it is obvious that the actual m. m. fs. must be reduced to equivalent sine waves acting upon a uniform active layer. The maximum value of the field, the direct and the transverse magnetomotive forces must therefore each be multiplied by some coefficient to reduce it to the equivalent sine wave m. m. f. applied to a uniform active layer. For the present it is sufficient to notice that the coefficient for the transversely reacting armature current is about one-half of that for the directly reacting armature current. Thus the armature reaction is not 90 degrees from the edge of the coil carrying maximum current, but each component of current must be computed separately. The direct reaction ($I_{fd} = C_d\,I_d$) can be combined algebraically with the field current I_f, to get the net m. m. f. along the polar axis I_{fn} in equivalent field amperes; the transverse reaction ($I_{ft} = C_t\,I_t$) must be combined with I_{fn} at right angles to give the magnetomotive force I_{fr}.

Let the maximum values of the actual waves of field, direct and transverse reaction magnetomotive force be M_f', M_d' and M_t'. Let the maximum values of the equivalent sinusoidal m. m. fs. as applied to an active layer of uniform reluctance be M_f, M_d, and M_t. Then we may define three coefficients J_f, J_d, and J_t by the equations

$$M_f = J_f\,M_f'; \; M_d = J_d\,M_d'; \; M_t = J_t\,M_t' \qquad (4)$$

The wave of magnetomotive force of the field is a flat topped wave of maximum value of $M_f' = N_f\,I_f$. The maximum values of the waves of armature reaction are[9]

$$M_d' = 0.9\,K_b\,K_w\,m\,n\,I_d; \; M_t' = 0.9\,K_b\,K_w\,m\,n\,I_t \qquad (5)$$

In Fig. 6, curve 1 is the rectangular wave of field magnetomotive force. Curve 2 is the wave of air-gap permeance for direct flux denoted by $P_d\,(X)$. Curve 2 is also the wave of equivalent field m. m. f. applied to a uniform active layer. Curve 3 is the fundamental sine wave of curve 2, and is the equivalent sinusoidal wave of field m. m. f. as applied to a uniform gap. It is higher than curve 2 because of a prominent fifth harmonic. The constant J_f is the ratio of the maximum value of curve 3 to that of curve 2 and is 1.13 for the machine tested.

If we assume the sine wave curve 3 to be the wave of direct m. m. f. M_f' applied to the machine with curve 2 of direct permeance, the equivalent wave of m. m. f. as applied to a uniform active layer will be curve 4 obtained as a product of curves 2 and 3. If curve 4 be analyzed for its fundamental sine wave, that would be the equivalent sine wave of direct reaction m. m. f. as applied to a uniform gap. This wave is not shown but is some 5 per cent lower than curve 3; that is, $J_d = 0.95$.

Let curve 5 be the wave of actual transverse m. m. f., and curve 6 be the wave of transverse permeance $P_t\,(X)$. The product of curves 5 and 6 will yield curve 7, the wave of equivalent m. m. f. applied to a uniform active layer. Curve 8 is the equivalent sine wave for curve 7 and is much lower

8. Apparently all the fluxes except that due to (X_{td}) are affected by saturation. This appears to be in contradiction to the assumptions of Doherty and Nickle, in Fig. 27 of paper cited.

9. See Karapetoff's "Magnetic Circuit" Arts.

than curve 5 because of a large third harmonic. The ratio of curve 8 to curve 5 is the coefficient $J_t = 0.51$.

The coefficients J_f, J_d, and J_t are defined by the equations for a Fourier analysis, namely

$$J_f = (2/\pi) \int_0^\pi P_d (x) \sin (x) \, d x \tag{6}$$

$$J_d = (2/\pi) \int_0^\pi P_d (x) \sin^2 (x) \, d x \tag{7}$$

$$J_t = (2/\pi) \int_0^\pi P_t (x) \cos^2 (x) \, d x \tag{8}$$

$P_t (x)$ is a trifle higher than $P_d (x)$ in the interpolar regions.

The design coefficients used by Professor Karapetoff are defined in terms of the coefficients above as

	Theory	Experiment[10]	
$K_d = 0.9\, J_d/J_f$			
$= 0.9 \times 0.95/1.13 =$	0.755	0.875	(9)
$K_t = 0.9\, J_t/J_f$			
$= 0.9 \times 0.51/1.13 =$	0.405	0.46	(10)

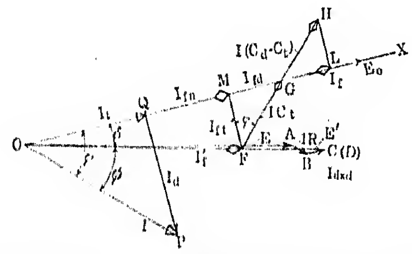

Fig. 7—Proposed Vector Diagram of a Synchronous Machine

A better correspondence could be obtained with experiment if an empirical coefficient were substituted for the rational coefficient 0.9. For our test the value of the coefficient is indicated as approximately unity.

The experimental constants C_d and C_t are most useful even in design calculations; the formulas for these coefficients are

$$C_d = K\, J_b\, K_b\, K_w\, m\, n/J_f\, N_f;$$

$$C_t = K\, J_t\, K_b\, K_w\, m\, n/J_f\, N_f \tag{11}$$

Here K is an empirical factor approximately unity, K_b and K_w are the breadth and winding pitch factors of the winding, m is the number of phases, n is the number of turns per pole per phase, N_f is the number of field turns per pole, and J_f, J_d and J_t are defined by the equations above. If it is not practical to estimate the waves of air-gap permeance in a particular case the values of the J coefficients found here might be used.

Performance Diagram

The problem of finding the performance of a synchronous machine may be formulated thus: Given the terminal voltage, output (input) current and power factor, the no-load saturation curve of the machine, and the constants of the machine, namely R, X_d, X_t, C_d and C_t; it is required to predict the location of the pole axis and find the needed excitation. For definiteness let us find the performance of the machine tested as a generator with normal voltage, normal current, and 86.6 per cent lagging power factor. Let us assume the constants $R = 0.25$, $X_d = 0.50$, $X_t = 0$, $C_d = 0.175$, $C_t = 0.090$.

In Fig. 7 we draw the terminal voltage E from the origin O to the point A, and the current $I = 40$ from O to P lagging E by 30 deg. We draw $A\,B$ equal to the $I\,R$ drop of 10 volts parallel to I. We assume the polar axis $O\,X$ and project P on $O\,X$ giving the direct reacting current $P\,Q$ of 28 amperes. We draw $B\,C$, the direct $I\,X$ drop of $28 \times 0.5 = 14$ volts parallel to $O\,X$. If there were a transverse $I\,X$ drop we would draw it perpendicular to the pole axis arriving at point D. In this case D and C are one point. The line $O\,D$ is the induced voltage E' scaling as 212 volts. We take E' to the saturation curve obtaining the resultant magnetomotive force $I_{fr} = 10.5$ equivalent field amperes, which we lay off along E' from the origin to point F.

We draw $F\,G$ perpendicular to I and equal to $C_t\,I = 0.09 \times 40 = 3.6$ equivalent field amperes, and $F\,H$ in the same direction equal to $C_d\,I = 0.175 \times 40 = 7.0$ equivalent field amperes. We draw the line $O\,G$, which is the pole axis. If serious error was made in assuming $O\,X$, we repeat the work to this point. We project the point H on $O\,G$ giving the point L. The line $O\,L$ is the field current $I_f = 14.2$ amperes. The angle between pole center and the voltage is 14 deg. and the pole center and current is 44 deg.

If we want the regulation we find from I_f that $E_o = 245$ volts and the regulation is 29 per cent. If we want the direct, transverse and net magnetomotive forces, we project F on the pole axis giving point M. The transverse reaction is $F\,M$, the direct reaction is $M\,L$, and the net magnetomotive force is $M\,O$. The formal proof of the above construction is implied in the theory given above; we need only note the following relations:

$$F\,M = F\,G \cos \psi = C_t\, I \cos \psi = C_t\, I_t = I_{ft} \tag{12}$$

$$M\,L = F\,H \sin \psi = C_d\, I \sin \psi = C_d\, I_d = I_{fd} \tag{13}$$

Conclusions

In addition to the conclusions enumerated above, it is hoped that it is now clear that the way is open for a systematic experimental study of the constants of synchronous machines. Studies are needed to determine:

1. Whether the performance of a synchronous machine can be predicted with a saturation curve and the five constants R, X_d, X_t, C_d, and C_t.

10. The theoretical coefficient may have to be modified in view of Doherty and Nickle's paper. Priority must be accorded them for certain features of our Fig. 7.

2. Whether there is any definite ratio between X_t and X_d, and if there is any definite ratio between C_t and C_d.

3. What the correlation is between the coefficients C_d and C_t and the design constants.

4. What values of slot and end connection permeance will best check the values of X_d and X_t.

5. What improvements can be made in the experimental method here proposed.

Thanks are due the following Marquette engineering students for assistance in carrying out the tests, making valuable suggestions as to procedure, and pointing out some of the conclusions: Messrs. R. M. Smith, C. McClurg, L. V. Sparks, M. Kempf, F. Stodola.

Discussion

H. V. Putman: I have been intensely interested in Professor Douglas's paper because in my own work I use Blondel's two-reaction theory exclusively for calculating the performance of salient-pole machines.

His method of measuring the phase angles between the terminal voltage, current and the pole axis by the use of two wattmeters is extremely interesting, but I do not see clearly how this same method could be applied to 3-phase machines (the machines he used were 2-phase machines), because in the 3-phase machine there would be no way to check the current by getting the zero reading on the wattmeter, to get it in phase with the pole axis. Maybe there is some way, and I should like to ask Professor Douglas if he has some similar way worked out for the 3-phase machine.

Professor Douglas has called attention to the fact that the transverse synchronous reactance decreases with increasing saturation. He also states that it is a mistake to build a two-reaction theory on the basis of an unsaturated magnetic circuit. We must not forget in this connection that not only the transverse synchronous reactance but also the direct synchronous reactance decreases with the saturation. Actually, I believe the direct synchronous reactance decreases more rapidly with increased saturation than does the transverse. Dr. Berg defines the direct synchronous reactance as the sum of the real armature reactance plus the reactance equivalent of the armature reaction, and he expresses it in this form:

$X + \frac{m}{c}$ where X is the reactance, m is the coefficient of armature reaction and c is the factor that depends on the saturation.

If one expresses m in percentage based on the no-load excitation of the machine, as is usually done, then c is unity for a condition of saturation that corresponds to no-load excitation. Under short circuit, where there is no saturation in the machine, c is less than unity, and at higher saturations it is much greater than unity, so that the synchronous reactance for high saturation is considerably less than one would measure from the short-circuit test. One should certainly not use the same value of synchronous reactance measured at full load under a condition of normal saturation. Nor would one use the same value for a condition of load at a leading power factor where there is a high degree of saturation present. Consequently, Professor Douglas should not calculate orthogonal lines for those shown in his Fig. 2.

It is always necessary to determine first, the point on the saturation curve corresponding to the condition under investigation. c is then known and consequently one can calculate the correct values of synchronous reactance to be used in Blondel's theory.

It is all right to have a theoretical structure based on the assumption of no saturation, provided it can be made to give the right answer, and I think this is true of Blondel's theory. It may not give the pull-out torque absolutely correct, but I feel sure that it will give it closer than 30 per cent when handled correctly. In his discussion he referred to the work of Mr. Doherty and now I wonder if he meant the sudden pull-out, which of course would be higher than calculated for the steady-state condition.

Professor Douglas says that in order to make an experimental study of the transverse reaction it is necessary that the load be placed so that the effect shall be wholly transverse; that is, the armature currents shall attain their maximum values when opposite a pole axis. I think this is at least interesting, but Blondel pointed out that this is not necessary. In his book on "Synchronous Motors and Converters" he gives the equation for the angular displacement of a synchronous motor as follows:

$$\operatorname{Tan} \delta - \frac{I\, X s' - E_0 \sin \theta}{E_0 \cos \theta - I\, r}$$

δ is the angle between the current and the pole axis. The angle of displacement is this same angle plus the power-factor angle of the machine. I is the current and θ is the power-factor angle of the machine between the terminal voltage and the current. Xs' is the transverse synchronous reactance.

Notice that nowhere in this equation is the direct synchronous reactance involved at all, and Blondel called particular attention to this point: The angular displacement of a machine, under any condition of load and power factor, depends not at all on the direct synchronous reactance but only on the transverse synchronous reactance, so that it is only necessary to measure the angular displacement at any load and power factor whatever, and then substitute in this formula and calculate backwards to get the transverse synchronous reactance. Of course, this does not assume the validity of the general theory that Blondel bases his diagram on and that superposition is possible. If, however, one denies the validity of the Blondel diagram, he would say that this is also invalid.

However, the common use of Blondel's theory is in the calculation of characteristics which depend on the displacement. If, by intelligent comparison of calculations with test results, it is possible to determine the constants in such manner that they give the correct displacement characteristics, the theory fulfills its purpose.

There is one point in connection with Professor Douglas's experimental set-up which is not clear to me. I understood from his description that the terminal voltage of machine B is supposed to correspond in phase position to the pole axis of machine A. This would be true if the rotors and stators of the two machines were lined up; that is, if the rotors were in line on the shaft, and the stators were in line on the floor, and if there were no load on machine B. But machine B was loaded with 5 amperes. If B is also rated 15 kv-a. (which, incidentally, he did not state), this 5 amperes would produce a displacement of three or four electrical degrees. Was this corrected for by adjusting the hand-wheel, and if so, how could it be done without an oscillograph to show when the terminal voltage of machine B, when loaded on the rheostat, was in line with the no-load voltage of machine A?

Professor Douglas refers to the great confusion of statements on the subject of transverse reaction.

In 1918 we were discussing the subject of armature reactance and reaction at zero power factor. The problem then was simply to divide the reactance flux from the armature reaction flux. The total flux or interlinkages were known directly from the short-circuit test.

Now we are discussing the armature reactance and reaction at unity power factor referred to the pole axis. The problem is twofold. It is first necessary to find out the total interlinkages

corresponding to the transverse synchronous reactance and then to divide this total into reactance and armature reaction. The first part of the problem can be handled experimentally by measuring the angular displacement. As I pointed out, that will give the value of the transverse synchronous reactance. It will give the total flux in the transverse field. So the accuracy with which the transverse synchronous reactance can be known will depend on how accurately the angular displacement can be measured. The second part of the problem, that is, the division of this flux, I think is not of great importance. It is usually only necessary to know the total transverse reaction for most problems, not the component parts of it. It will, however, be desirable to make the separation in order to understand more clearly the nature of the tranverse synchronous reactance and also to settle the question about the magnitude of the transverse reactance. This question is perhaps the one on which there is more difference of opinion than on any other relating to Blondel's theory.

Blondel himself considered the transverse reactance equal to the direct reactance. At least, he used only a single value of reactance in his diagram.

Dr. Steinmetz and Dr. Berg both used a transverse reactance much larger than the direct reactance. Dr. Berg states definitely in his "First Course in Electrical Engineering" that the direct reactance is only about 60 per cent of the transverse. That means that if an ordinary synchronous machine had 30 per cent reactance, for instance, the transverse reactance would be in the neighborhood of 50 per cent—not reaction but reactance.

Professor Karapetoff is also of the same opinion, if one may judge from his paper on "Variable Leakage Reactance." While he does not state definitely how much larger the transverse reactance is than the direct reactance, if one may scale his diagrams, he would agree substantially with Dr. Berg.

Professor Arnold, on the other hand, holds that the transverse reactance is considerably smaller than the direct. He says that when a phase belt is above a pole face, only that flux which links the phase belt without entering the pole iron is reactance flux. This means that there is practically no tooth-tip leakage in this position.

Personally, I never could see why, because a line of flux in trying to get around a phase belt found it convenient to enter a friendly pole face for a part of its journey, it had to have its name changed from "reactance" to "reaction." So I agree with Dr. Berg and not with Professor Arnold.

Messrs. Doherty and Nickle, after a thorough and elaborate investigation, conclude that the transverse and direct reactances are practically equal, differing by not more than 1 or 2 per cent.

And now Professor Douglas concludes that the transverse reactance is zero, or at least negligible.

C. A. Nickle: I am inclined to agree with Mr. Putman that the effect of saturation upon quadrature reactance is not quite as great as concluded in this paper.

I think that one question might be raised. The author points out that "the voltage E_n," that is, the voltage in the direct axis, "is not a function of the field current alone." This is true. This merely means that due to pole-tip saturation, instead of the quadrature and direct axes being in their geometric position, they have been slightly shifted, so that the quadrature current now has a mutual component with the field winding and reduces the flux in that circle. I think on that basis that it is reasonable to say that the curve in the main field winding, under these conditions, will have a mutual effect on the quadrature axis. If the quadrature axis has a mutual effect on the direct, it should work the other way. If such is the case, we would expect the values as measured to be much lower than the true values. If the transverse-current magnetomotive force produces a certain transverse flux and in addition to that flux we have another component which is 180 deg. out of phase, this flux being actually produced by the main field winding, the total flux that we measure in the quadrature axis is not the flux produced by the quadrature curve but is a composite flux. I think that quadrature reactance should at least be defined by the flux produced by the quadrature curve. Before we can say what transverse reactance is, we must separate the two components of flux so as to get that component of flux which is due to the main field winding.

It is found when the pole-tip saturates, we have the effect of having removed a small amount of iron from the tip of this pole. The two direct axes are no longer the geometric direct axes but have been shifted slightly to the left. Therefore, since the fluxes in the main field winding, especially at the right-hand end of this curve, are very high compared to the fluxes in the quadrature axis, it requires but a 1- or 2-deg. shift of the two axes so that the main field winding will give a component of flux in the quadrature path which is probably 50 per cent as large as the flux that exists there due to the current alone. I think when this is taken into account, we shall find that quadrature reactance is not affected so vitally by saturation as we would be led to believe from these tests. Large numbers of tests have been made in the past and the angles, pull-out torques, and so forth have checked very well.

R. E. Doherty: Prof. Douglas has offered something for us to think about though there are some things in the paper that are not altogether clear and the results are not what most of us who study these matters might have anticipated.

I would like to mention one point which Prof. Douglas has made, namely, the necessity of distinguishing between a rational method of analysis and one which is largely empirical. The theory of superposition applies only when no saturation is present. If saturation is present, it may be negligible to such an extent that one may apply a theory based on no saturation and get approximate results, or he may, as Mr. Putman has mentioned, shade the constants to take care of it and assume that it can be used; and then interpret the results accordingly.

So this is the point: If those pictures of saturation curves and methods referred to by Professor Douglas are intended to represent a philosophy underlying a method of making such calculations, it must be considered as a relic of the past, because I am pretty sure that nowadays not very many informed engineers so regard them. However, very many calculations on important machines are made according to a theory which, strictly, does not apply—let us say Potier's diagram applied to salient-pole synchronous machines. Why? Because it gives results that are as close, practically, as you can test them. It gives practically correct results in magnitudes of excitation, but not in phase angle. But it is an engineer's privilege to use such tools as he sees fit, so long as he gets results that he can depend upon. Thus, if you can compute the magnitude of excitation under load on a salient-pole machine, when some saturation exists, by using Potier's diagram, that is a perfectly justifiable procedure so long as you recognize its limitations and understand why it gives practically the same magnitude as Blondel's method, which of course is theoretically more sound.

I might say that the reasons why Potier's diagram will give practically the same magnitude of excitation as Blondel's treatment are explained fully in the literature.[2]

Mr. Putman mentioned the different opinions regarding reactance. It is not a question of difference of opinion regarding reactance, but difference of definition; that is, Dr. Berg and Dr. Steinmetz are right; and Blondel is right. Also Doherty and Nickle, Professor Karapetoff and Professor Douglas may be right. The only person who is wrong is one who, not clearly understanding the definition and physical significance of some particular value of reactance, uses it where it is not applicable. In the case of a synchronous motor, for instance, there is a number of different reactances which must be known separately in order to calculate the various operating characteristics. It is therefore meaningless merely to refer to the "reactance" of a synchronous machine.

Going a step further, there may be a legitimate difference in view regarding the segregation of armature leakage reactance into its components. According to the usual view, armature leakage reactance comprises three components: (a) *slot reactance,* about which there is little or no question; (b) *end-winding reactance,* that is, the reactance due to leakage flux around the ends of the coils, about the nature of which there is very little question; and (c) *zigzag* or *tooth-tip reactance,* about which there has been considerable question and discussion. Now if one can build up a consistent theory, using only (a) and (b) as comprising armature reactance, it would be a logical thing to do, provided everybody who used the theory understood that. On the other hand, since it is more in keeping with the established view of things to include all three of these terms in *armature reactance,* and include the remainder reactance effects of the armature current as the effective reactance of armature reaction, this point of view was taken in our paper on *Synchronous Machines—I.*[1] And we believe it is a comprehensive and logical treatment of the problem. It is a question of definition, as I stated at the outset, and if we wish to discuss the particular term which Professor Karapetoff treated, then let us discuss it as such, and not be confused by comparing its value with the whole, of which it is only a part.

Vladimir Karapetoff: To me, the principal value of Professor Douglas's paper lies in a novel experimental method which permits the obtainments of partial data in addition to the usual load data. It seems to me that further progress should lie not in juggling any more with vector diagrams and introducing more factors, but primarily in devising new experimental ways whereby we could get not only "bulk data," that is, the terminal voltage, current and power factor, but partial data as well. A synchronous machine is a comparatively complex aggregate of physical phenomena and if one provides a sufficient number of arbitrary factors, one can usually duplicate the performance of the machine with a sufficient degree of accuracy. However, the progress of the art requires checking those individual factors and not the final performance alone.

I judge from Professor Douglas's paper that he is familiar only with Blondel's early work. Since 1918 Blondel has done a considerable amount of work on synchronous machines. I refer in particular to the investigation, of which the purpose was checking the individual fluxes and voltage drops in the machine, rather than the final performance. Special, rather complicated experimental means were devised for that purpose.[3] Besides, Blondel presented several papers before the French Academy of Sciences, discussing several advanced phases of the theory of synchronous machines. In the third edition of Vol. II of my *Experimental Electrical Engineering* (1927) there is a fairly complete bibliography on the subject, and I hope that Prof. Douglas's paper will create a new stimulus for attacking the problem with modern experimental means and coordinating the results with a more rational theory.

J. F. H. Douglas: Mr. Putman mentioned the test of the 3-phase machine. We did not make such a test although we saw some simple modifications by which it could be done. We submit that the line voltage, perpendicular to the Y voltage, would give us the two reference axes necessary. For convenience, we chose the 2-phase connection which was available on the machine.

Mr. Putman mentioned that the direct synchronous reactance was also a variable. With this we agree. For this reason I advocated following Prof. Karapetoff's idea in this respect, treating it in a magnetomotive force diagram, where it will be a constant. My paper has no reference to sudden pull-out or suddenly applied torques. When I alluded to Mr. Doherty's paper, it was to a formula included which applied to steady-state conditions. This formula has a term which includes $\sin 2\,\delta$ and consequently makes use of a transverse coefficient different from the direct coefficient.

1. JOURNAL A. I. E. E., October, 1926, p. 974.

With reference to the formula advocated by Prof. Blondel quoted by Mr. Putman, I did not mean to imply that the transverse coefficient could not be computed unless the action were wholly transverse, but rather that under those conditions, having one system of causation present, the effect would be less subject to constant or systematic error. As a matter of fact, Mr. Nickle called our attention particularly to the fact that direct demagnetizing current might have an effect on transverse conditions. We foresaw that possibility and for that reason the tests were made as nearly as possible with the current fully transverse in its action.

And again, if we refer to Fig. 2 in the paper, we were looking for a demagnetizing effect of transverse reaction, and consequently if we had a large demagnetizing current present, we would not have been able to separate it with accuracy from that produced by the cross-magnetizing current.

With reference to the question raised as to how we lined up the two machines without knowledge of how the coupling between them was adjusted, I would say that, when we said that we brought the two machines so that the pole axes were in the same line, it was simply a short way of saying that we lined up the reference voltage with the no-load voltage of the machine tested. The machine B was loaded to the 5-ampere load, which was used, before the hand-wheel was turned, and so it was the terminal voltage under load that was adjusted to the same phase as the no-load voltage of machine A.

I will not respond further to Mr. Putman's and Mr. Doherty's remarks on reactance than to say that my attitude is entirely empirical. It is a question of how you define reactance. If you define reactance as including non-synchronous revolving fluxes, then undoubtedly the reactance will be larger under transverse than under demagnetizing condition. I think that for the purposes of calculation, the most useful division of the effect between the e. m. f. and the m. m. f. diagrams is that one giving factors which remain fairly constant. If we define reactance as due to those flux components unaffected by saturation, and if all flux components are affected by saturation in a given condition, as we found in the case of transverse reactance condition, we can say that the transverse reactance is zero. This same attitude is taken when we use the zero per cent power-factor characteristic to find the direct reactance and reaction components, although it is well known that the reactance thus determined is considerably larger than what can be computed with rational formulas.

Mr. Nickle's remarks deserve a better discussion than I can give. Pole-tip saturation should be important. I am not at all sure that his analysis is not correct. The case seems to me to be an exact analog of the corresponding case in d-c. machines. The treatment given in Prof. Karapetoff's "Magnetic Circuit" for d-c. machines could be applied almost bodily to the synchronous machines. In this theory there is a demagnetizing effect produced by transverse reaction but no cross-magnetizing effect produced by demagnetizing reaction. The loci of our e. m. f. vectors were parabolas proving the existance of a demagnetizing component of cross-reaction. However, on the m. m. f. diagram the loci were approximately straight lines. In other machines this result may not prove to be true. Since writing the paper, the writer and his students have used three other different methods, and have tested one other machine, the results being the same; the transverse effect is a constant only when placed wholly in the m. m. f. diagram. The question whether the transverse reactance is unaffected by saturation or whether it is constant in the m. m. f. diagram should be easily verified, since at, say, 50 per cent overvoltage the pull-out torques predicted by the two theories are quite different.

I am heartily in accord with what Prof. Karapetoff has said, and it means that there is still a lot of work to be done on the subject.

In particular the writer has assumed a reasonable active layer characteristic for the machine tested, and has by calculation been able to check the curves shown quite closely.

Starting Performance of Synchronous Motors

BY H. V. PUTMAN[1]

Associate, A. I. E. E.

Synopsis.—This paper deals with the theory underlying the starting performance of the salient-pole synchronous motor equipped with damper windings. The theory, while involving some approximations, is accurate enough for practical engineering calculations. Formulas are developed for the starting torque, pull-in torque and inrush. A method is also given for calculating the speed torque curve from standstill to synchronous speed.

Due to the fact that the damper winding is not continuous around the periphery and due to the presence of the single-phase field winding, the rotor circuit is not a perfect polyphase secondary but is unbalanced to some extent. In order to take care of this unbalance, it is necessary, in addition to the usual system of positively rotating vectors, to employ a second system of negatively rotating vectors as is done in unbalanced three-phase problems.

The stator resistance has been disregarded in working out the general case of the unbalanced or partial polyphase secondary in order to obtain a torque formula which will be simple and at the same time accurate enough for practical calculations. Mr. Q. Graham is working on this problem and expects to present in an Institute paper, in the near future, the general solution including the stator resistance.

The use of the double squirrel-cage type of damper winding in salient-pole machines has been examined both theoretically and experimentally. Other methods of obtaining unusual starting performance are suggested and the results of some actual calculations presented.

Introduction

PROBABLY the earliest published work on the starting performance of synchronous motors was done by Carl J. Fechheimer in 1912[2]. This was a paper of great merit and a valuable contribution to the art. Not only did it give much valuable experimental data concerning the synchronous motor but it added much to our knowledge of the calculation of reactance. The discussion which followed the presentation of this paper showed clearly that the synchronous motor was well understood experimentally in 1912. Engineers knew *what* the motor would do under various conditions but the "why" was often in doubt. The theory developed in the present paper explains some of the "whys." Mr. Fechheimer limited his theoretical work to the conditions at standstill. In this paper the starting conditions are examined not only at standstill but through the whole starting period up to the pull-in point.

Notation

The following notation will be used throughout the paper. The subscript p used with a vector quantity denotes that the vector belongs to the positive system of vectors, while the subscript n denotes that the vector belongs to the negative system. For instance:

$\dot{E}_{ip}$ = Induced voltage, positively rotating,

$\dot{E}_{in}$ = Induced voltage, negatively rotating.

In a similar manner the subscripts p and n may appear with any of the vectors.

$\dot{E}_0$ = Impressed voltage,

$\dot{I}_1$ = Stator current,

$\dot{I}_{00}$ = Magnetizing current,

$\dot{I}_2$ = Rotor current,

$\dot{I}_b$ = Rotor bar current,

$\dot{I}_f$ = Rotor current in the field winding,

$\dot{I}_{2nn}$ = Negatively rotating rotor current due to E_{in}. (The subscript 2 indicates rotor current. The first subscript n indicates that the vector is a negatively rotating vector. The last subscript n indicates that the current is produced by the negatively rotating induced voltage E_{in}.)

Similarly,

$\dot{I}_{2np}$ = Negatively rotating rotor current due to E_{ip},

$\dot{I}_{2pp}$ = Positively rotating rotor current due to $\dot{E}_{ip}$,

$\dot{I}_{2pn}$ = Positively rotating rotor current due to $\dot{E}_{in}$,

$\dot{V}$ = $x_2 + j\, r_{2s}$,

$\dot{V}$ = Z_{bs}/Z_{fs},

a = Half the depth of double squirrel-cage damper bar (App. II),

b = Width of double squirrel-cage damper bar (App. II),

B = $1/x_1 + b_{00}$,

b_{00} = Magnetizing admittance,

f = Frequency in cycles per second,

j = $\sqrt{-1}$, indicates the imaginary term in vector expressions,

K = Ratio $\dfrac{\text{N. R. V.}}{\text{P. R. V.}} = \dfrac{\sin\theta}{\theta}$ (see Equation (**14**)),

K_c = Value of K corrected for effect of closed field circuit,

$$K^2 = \frac{4\,\pi\,p}{\sigma} \text{ (App. } II\text{)}$$

p = Operator $\dfrac{d}{d\,t}$ and denotes differentiation with respect to time (App. II),

r_1 = Stator resistance,

r_2 = Rotor resistance,

r_b = Rotor bar resistance,

r_{2s} = r_2/S,

r_f = Field circuit resistance,

r_{fs} = r_f/S,

r_0 = $r_1 + r_2$,

S = Slip,

i = Time in seconds,
T_p = Motor torque due to positively rotating flux and positively rotating rotor current,
v = Ratio Z_{bs}/Z_{fs},
x_1 = Stator reactance,
x_2 = Rotor reactance,
x_b = Rotor bar reactance,
x_f = Field winding reactance,
x_0 = $x_1 + x_2$,
z = $\sqrt{1 + 2\,B\,x_2 + B^2\,Z_{2s}^2}$
Z_2 = Rotor impedance = $\sqrt{r_2^2 + S^2\,x_2^2}$
Z_{2s} = $\sqrt{r_{2s}^2 + x_2^2}$
Z_{bs} = $\sqrt{r_{bs}^2 + x_b^2}$
Z_{fs} = $\sqrt{r_{fs}^2 + x_f^2}$
Z_0 = $\sqrt{r_0^2 + x_0^2}$,
Z_1 = Stator impedance = $\sqrt{r_1^2 + x_1^2}$,
θ = Bar span in electrical radians (Part I),
θ = $\tan^{-1}\dfrac{x_b}{r_{bs}} + \alpha$ = phase angle of rotor circuit with field closed (Part IV),
α = $\tan^{-1}\dfrac{v\cos\varphi}{1 + v\sin\varphi}$,
φ = $\tan^{-1}\dfrac{x_b}{r_{bs}} + \tan^{-1}\dfrac{r_{fs}}{x_f}$,
Φ = M. m. f. (Part I),
Φ = Self-inductive flux (App. II),
ω = Angular velocity in radians per sec.,
σ = Specific resistance of material used in double squirrel-cage damper bar (Abohms per cu. cm.).

Part I. Theory of the Partial Polyphase Rotor Circuit

The expression,

$$\cos\omega t + j\sin\omega t \qquad (1)$$

represents a vector of unit length rotating forward in the positive direction with angular velocity ω and starting at the zero position at the instant of counting time.

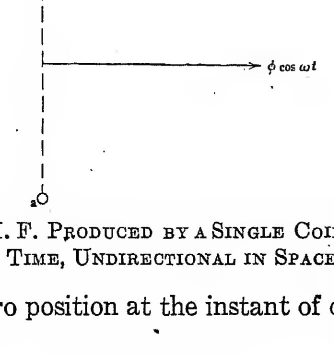

FIG. 1—M. M. F. PRODUCED BY A SINGLE COIL, PULSATING IN TIME, UNDIRECTIONAL IN SPACE

Similarly,

$$\cos\omega t - j\sin\omega t \qquad (2)$$

represents a vector rotating backwards or in the negative direction with angular velocity ω.

The sum of these two rotating vectors is

$$2\cos\omega t \qquad (3)$$

which is simply a pulsating quantity in one direction in space.

If, now, Equation (3) represents the m. m. f. due to a single-phase winding, it follows from the above that this m. m. f., which is unidirectional in space and pulsating in time, can be represented by, or split up into, two vectors constant in time but rotating in space, one rotating in the positive direction and the other in the negative direction.

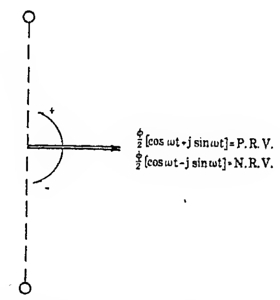

FIG. 2—M. M. F. PRODUCED BY A SINGLE COIL, RESOLVED INTO TWO ROTATING VECTORS

As an example of the above, let the field produced by a coil $a - a$, Fig. 1, be $\Phi\cos\omega t$.

In Fig. 2 the equivalent rotating vectors are shown.

$$\frac{\Phi}{2}\,[\cos\omega t + j\sin\omega t] = \text{positively rotating vector.}$$

$$\frac{\Phi}{2}\,[\cos\omega t - j\sin\omega t] = \text{negatively rotating vector.}$$

It should be noted that the length of each rotating vector is only half the maximum value of the stationary vector. In Fig. 1, when $t = 0$, $\Phi\cos\omega t$ is maximum and the current in the coil is, therefore, a maximum. In Fig. 2, then, time is counted from the instant the current in the coil is maximum, and at this instant it should be particularly noted that the positively rotating vector and negatively rotating vector are together in space.

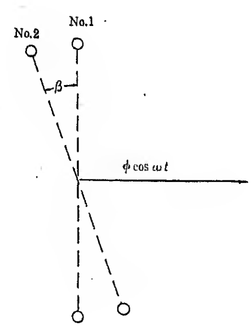

FIG. 3—M. M. F. PRODUCED BY TWO COILS SEPARATED BY ANGLE β, RESOLVED INTO TWO ROTATING VECTORS

The Partial Polyphase Secondary Produced by Damper Bars in the Pole Face

Consider now the m. m. f. produced by two coils or pairs of bars shown in Fig. 3, as No. 1 and No. 2. Let time be counted from the instant the current in coil No. 1 is a maximum. Let the current in coil No. 2 lag behind that of No. 1 by an angle β equal to the space angle between the coils, as this would be the case with damper bars.

The m. m. f. due to coil No. 1 is

$$\left.\begin{aligned} &\frac{1}{2}\Phi\,[\cos\omega t + j\sin\omega t] = \text{positively rotating vector} \\ &\frac{1}{2}\Phi\,[\cos\omega t - j\sin\omega t] = \text{negatively rotating vector} \end{aligned}\right\} \quad (4)$$

To find the m. m. f. due to No. 2 coil, proceed as follows: Assume temporarily that the current in No. 2 is in time phase with that in No. 1. On this assumption the rotating vectors would be

$$\left.\begin{aligned} &\frac{1}{2}\Phi\,\{\cos(\omega t + \beta) + j\sin(\omega t + \beta)\} \\ &\qquad = \text{positively rotating vector} \\ &\frac{1}{2}\Phi\,\{\cos(\omega t - \beta) - j\sin(\omega t - \beta)\} \\ &\qquad = \text{negatively rotating vector} \end{aligned}\right\} \quad (5)$$

But the current in No. 2 lags behind that in No. 1 by an angle β. Hence it is necessary to substitute $(\omega t - \beta)$ for ωt in (5). This gives for the rotating vectors for coil No. 2 under the conditions specified above:

$$\left.\begin{aligned} &\frac{1}{2}\Phi\,\{\cos\omega t + j\sin\omega t\} \\ &\qquad = \text{positively rotating vector} \\ &\frac{1}{2}\Phi\,\{\cos(\omega t - 2\beta) - j\sin(\omega t - 2\beta)\} \\ &\qquad = \text{negatively rotating vector.} \end{aligned}\right\} \quad (6)$$

It should be noted that the positively rotating vectors for both coils No. 1 and No. 2 are in phase with each other. The negatively rotating vectors are, however, out of phase by an angle 2β.

To get the combined m. m. f. due to both coils No. 1 and No. 2 it is only necessary to add Equations (4) and (6) together.

This gives:

$$\left.\begin{aligned} &\text{Positively rotating vector} = \Phi\,(\cos\omega t + j\sin\omega t) \\ &\text{Negatively rotating vector} = \Phi\cos\beta\,\{\cos(\omega t - \beta) \\ &\qquad\qquad - j\sin(\omega t - \beta)\} \end{aligned}\right\} \quad (7)$$

It is seen that the negatively rotating vector has been shortened by $\cos\beta$ factor. This is due to the fact that the two coils constitute a partial or imperfect polyphase field. For a perfect polyphase field the negatively rotating vector would disappear entirely. The positively rotating vector and negatively rotating vector are not together in space when $t = 0$. This is because time was counted from the instant the current in coil No. 1 was maximum. If, now, time had been counted from the instant the current in coil No. 2 was maximum, the rotating vectors would have been:

$$\left.\begin{aligned} &\text{Positively rotating vector} = \Phi\,(\cos\omega t + j\sin\omega t) \\ &\text{Negatively rotating vector} = \Phi\cos\beta\,\{\cos(\omega t + \beta) \\ &\qquad\qquad - j\sin(\omega t + \beta)\} \end{aligned}\right\} \quad (8)$$

The phase angle of the negatively rotating vector thus depends upon the instant from which time is counted.

Consider, now, the m. m. f. produced by a number of coils uniformly distributed over an arc or angle θ, Fig. 4. Thus:

Let

$\Delta\beta$ = angle between coils

Φ = m. m. f. per radian periphery. The m. m. f. of each coil is then $\Phi\,\Delta\beta$ and there are

$$\frac{\theta}{\Delta\beta} = n \text{ coils.}$$

Count time from the instant the current in coil No. 1

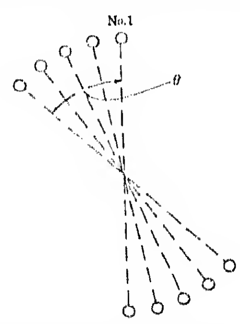

Fig. 4—M. M. F. Produced by a Number of Coils Distributed Over Angle θ to the Left of Coil No. 1

is maximum. Since the positively rotating vectors are all in phase and each has a magnitude of $\frac{\Phi\,\Delta\beta}{2}$, and there are $\frac{\theta}{\Delta\beta}$ coils, the

$$\text{positively rotating vector} = \frac{\Phi\,\theta}{2}\,(\cos\omega t + j\sin\omega t) \quad (9)$$

The negatively rotating vectors are all out of phase and the sum of them is:

Negatively rotating vector

$$= \frac{\Phi\,\Delta\beta}{2}\left\{\begin{aligned} &\sum^{n\text{ terms}} \cos\omega t + \cos(\omega t - 2\Delta\beta) \\ &+ \cos(\omega t - 4\Delta\beta) + \ldots - j\sum^{n\text{ terms}}\sin\omega t \\ &+ \sin(\omega t - 2\Delta\beta) + \sin(\omega t - 4\Delta\beta) + \ldots \end{aligned}\right\} \quad (10)$$

$$= \frac{\Phi \Delta \beta}{2} \left\{ \sum_{r=1}^{r=n} \cos \{ \omega t - 2(r-1) \Delta \beta \} \right.$$

$$\left. - j \sum_{r=1}^{r=n} \sin \{ \omega t - 2(r-1) \Delta \beta \} \right\} \quad (11)$$

Now let $\Delta \beta \to 0$ and $n \to \infty$

The Σ's then become integrals as follows:

Negatively rotating vector

$$= \frac{\Phi}{2} \left\{ \int_{x=0}^{x=\theta} \cos(\omega t - 2x)\, dx - j \int_{x=0}^{x=\theta} \sin(\omega t - 2x)\, dx \right\} \quad (12)$$

$$= \frac{\Phi}{2} \sin \theta \left[\cos(\omega t - \theta) - j \sin(\omega t - \theta) \right] \quad (13)$$

which is the negatively rotating field.

The ratio of the magnitude of the negative field to that of the positive field is from (9) and (13),

$$\text{Ratio} \frac{\text{Negatively rotating vector}}{\text{Positively rotating vector}} = K = \frac{\sin \theta}{\theta} \quad (14)$$

K is really a measure of the single-phase action in the rotor. It shows how nearly the rotor circuit

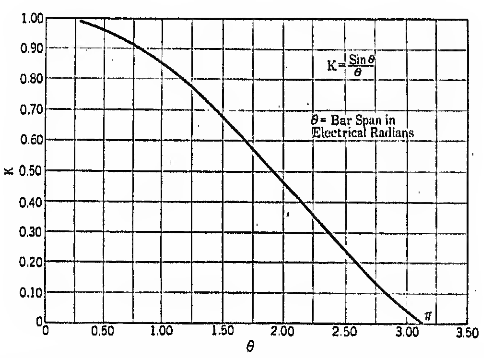

FIG. 5—CURVE SHOWING VALUES OF K AS FUNCTION OF THE DAMPER BAR SPAN. K IS A MEASURE OF THE SINGLE-PHASE ACTION PRODUCED BY THE DAMPER WINDING

approaches the perfect polyphase condition. If, in Equation (14), θ is put equal to zero for the case of the single-phase rotor, $K = 1$, since $\lim_{\theta \to 0} \frac{\sin \theta}{\theta} = 1$, so that the negatively rotating field is equal to the positively rotating field which is correct for the single-phase rotor. But if in (14) θ is made equal to π corresponding to a damper winding which is continuous around the periphery as in a squirrel-cage induction motor, then $K = 0$, and there is no negatively rotating field. Fig. 5 shows a curve which gives values of K corresponding to different values of the bar span θ.

It should be noted that the magnitude of the positive field is always equal to one-half the m. m. f. in the whole winding, assuming all currents in phase.

It can be shown in a similar manner that for a group of coils as shown in Fig. 6 covering an angle to the right of coil No. 1 (instead of to the left as in the previous case) that the vectors are:

Positively rotating vector

$$= \frac{\Phi \theta}{2} [\cos \omega t + j \sin \omega t] \quad (15)$$

Negatively rotating vector

$$= \frac{\Phi \sin \theta}{2} [\cos(\omega t + \theta) - j \sin(\omega t + \theta)] \quad (16)$$

Here again time was counted from the instant the current in coil No. 1, Fig. 6, was maximum.

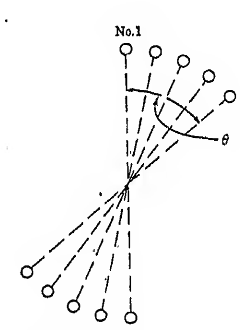

FIG. 6—M. M. F. PRODUCED BY A NUMBER OF COILS DISTRIBUTED OVER ANGLE θ TO THE RIGHT OF COIL NO. 1

Combining the results of Figs. 4 and 6 gives the m. m. f. for the arrangement of coils shown in Fig. 7, time being counted from the instant the current is maximum in coil No. 1, which is the middle coil of the group.

The angle or arc covered by the winding is in this

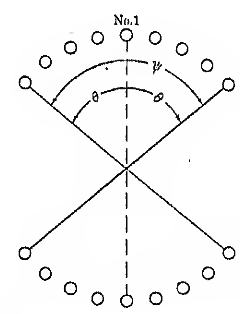

FIG. 7—M. M. F. OF A SYMMETRICAL ARRANGEMENT OF COILS

case $\psi = 2\theta$. To get the positively rotating vector it is only necessary to add (9) and (15).

$$\text{Positively rotating vector} = \Phi \theta [\cos \omega t + j \sin \omega t] \quad (17)$$

To get the negatively rotating vector add Equations (13) and (16) which gives:

Negatively rotating vector

$$= \frac{\Phi}{2} \sin \theta \{ \cos(\omega t - \theta) + \cos(\omega t + \theta)$$

$$- j [\sin (\omega t - \theta) + \sin (\omega t + \theta)]\}$$
$$= \Phi \sin \theta \cos \theta [\cos \omega t - j \sin \omega t] \quad (18)$$

Substituting $2 \theta = \psi$ in (17) and (18) gives

Positively rotating vector

$$\left.\begin{aligned} &= \frac{\Phi \psi}{2} [\cos \omega t + j \sin \omega t] \\ &\text{Negatively rotating vector} \\ &= \frac{\Phi}{2} \sin \psi [\cos \omega t - j \sin \omega t] \end{aligned}\right\} \quad (19)$$

Hence it is seen that if time is counted from the instant that the current is maximum in the middle of the belt of conductors, the positively rotating vector and negatively rotating vector are in phase with each other; that is, they are together in space. Or, more generally, it may be stated that regardless of the instant from which time is counted, the positively rotating vector and negatively rotating vector are together in space at the instant the current is maximum in the middle bar in the pole face.

Part II. Construction of the Vector Diagram of a Synchronous Motor With Partial Polyphase Rotor Circuit

It is well known, of course, that the ordinary vector diagram of a polyphase induction motor represents not only the time relation of the various quantities but the actual space relation in the machine as well. The same will be true of the vector diagram of a motor with a partial polyphase rotor circuit. It will be found convenient to represent by the vector for the rotor bar current the current in the bar in the middle of the pole.

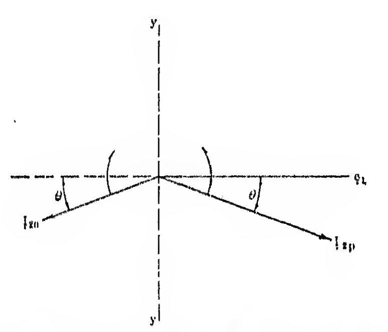

Fig. 8—Diagram Showing Simple Positive and Negative Rotating Systems

Relation Between Negatively Rotating System and Positively Rotating System

It has been shown above that if, due to a positively rotating sine wave of flux in the gap, there is induced a voltage in each of the rotor bars which causes a sine wave of current to flow in each of the bars, the resultant m. m. f. may be represented by two rotating vectors, one rotating positively and the other negatively. In Fig. 8, let e_i be the voltage induced in each of the bars.

Two current vectors are produced, the positively rotating vector which is I_{2p} and lags behind the induced voltage by angle θ, the phase angle of the damper bar circuit, and the negatively rotating vector which is I_{2n} and which lies along the reflection of I_{2p} about the y axis. Now, how does one know for sure the position of I_{2n}? It has been shown very clearly that I_{2n} must be so located that I_{2n} and I_{2p} will come together in space at the instant the current in the middle bar of the pole is maximum. Since the projection of any of

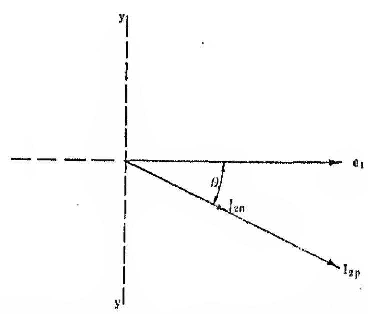

Fig. 9—Diagram Illustrating the Principle of Reflection

the vectors on the y axis as they rotate gives their instantaneous values in time, this will occur when I_{2p} comes in line with the y axis. Since I_{2n} is rotating negatively, it will come in line with the y axis at the same time as does I_{2p}. Hence, it is seen that by making I_{2n} lie along the reflection of I_{2p} about the y axis, the condition that the positively rotating vector and negatively rotating vector shall be together in space at the instant the current is maximum, is fulfilled.

Principle of Reflection of the Negative System

It is evident that the conventional system of vector notation cannot be applied directly to the condition existing in Fig. 8. In fact, it cannot be applied to a vector diagram in which there are vectors rotating in opposite directions, so that, for the purpose of mathematical analysis it is necessary to construct the diagram in such a manner that the actual vectors in the diagram rotate in the positive direction. Such a diagram is shown in Fig. 9.

This diagram is obtained from that in Fig. 8, by applying the principle of reflection which may be stated as follows: If the negative system of vectors (in this case only the single vector I_{2n}, Fig. 8) be reflected about the y axis and made to rotate positively, the instantaneous values of the quantities represented by the vectors of the negative system remain unchanged. In other words, if in Fig. 9 I_{2n} rotates positively, it produces the same projections on the y axis (which projections are the instantaneous values) as does I_{2n} in Fig. 8 when rotating negatively. Now, the diagram in Fig. 9 has the advantage that it lends itself to analysis by regular vector equations. It has the disadvantage that it is a time diagram only and does not represent the space relations in the machine as does the diagram in Fig. 8. Either diagram can, of

course, be obtained from the other by simply reflecting the negative system.

Vector Diagram of Synchronous Motor with Partial Polyphase Rotor Circuit in Fig. 10

Fig. 10 gives the complete vector diagram of a motor. It is of the same type as Fig. 8, giving space as well as time relations. It is similar to the ordinary diagram of an induction motor except more complicated because of the negative system. All dotted vectors are actually rotating negatively in this diagram.

In the machine there are two fluxes in the gap, one rotating positively, the other negatively. The positive flux generates a positive induced voltage E_{ip} in the damper bars.[3] This, as has been described, produces two current vectors: I_{2pp}[4] which is the positively rotating vector and I_{2np} which is the negatively rotating vector and which lies along the reflection of I_{2pp} about the y axis.

In a similar manner the negatively rotating flux

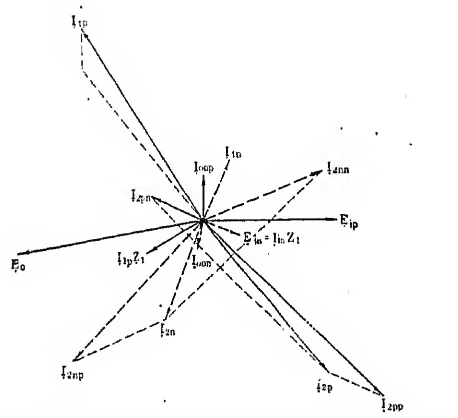

Fig. 10—Motor Vector Diagram at Standstill with Partial Polyphase Rotor Circuit

Dotted lines represent negatively rotating vectors.

generates a negative induced voltage E_{in} in the damper bars which again sets up two current vectors. The larger of these in this case is the negatively rotating vector which is I_{2nn} and lags behind E_{in} by the phase angle of the damper bars. The other is I_{2pn} which is the positively rotating vector and lies along the reflection of I_{2nn} about the y axis.

The total positive m. m. f. in the rotor is represented by I_{2p} and is the sum of I_{2pp} and I_{2pn}. Similarly, the total negative m. m. f. in the rotor is I_{2n} and is the sum of I_{2nn} and I_{2np}.

The positive m. m. f. in the stator is the sum of $-I_{2p}$ and the magnetizing current I_{00p},[5] which produces the positive flux in the gap. Similarly, the negative m. m. f. in the stator is the sum of $-I_{2n}$ and the negative magnetizing current I_{00n} which produces the negative flux in the gap.

The impressed voltage on the motor is the sum of $-E_{ip}$ and the $I_{1p} Z_1$ drop. Since there is no negatively rotating impressed voltage (if the phases are balanced as assumed) the negative induced voltage E_{in} is equal to the $I_{1n} Z_1$ drop, as shown in the diagram.

Part III. Vector Equations—Derivation of the Torque Formula

In writing these equations the stator resistance will be disregarded. This leads to many simplifications which are impossible if it is included.

The positive secondary current is

$$I_{2p} = I_{2pp} + I_{2pn} \tag{20}$$

or

$$I_{2p} = \frac{E_{ip}}{Z_2} + \frac{K\, E_{in}}{Z_2} \tag{21}$$

where K is the ratio of the $\dfrac{\text{negatively rotating vector}}{\text{positively rotating vector}}$

given by Equation (14).

$$\text{Actually } K = \frac{\text{Magnitude of } I_{2pn}}{\text{Magnitude of } I_{2nn}} = \frac{\text{Magnitude of } I_{2np}}{\text{Magnitude of } I_{2pp}}$$

or

$$I_{2p} = \frac{E_{ip} + K\, E_{in}}{S\, Z_{2s}^2}\,(r_{2s} - j\, x_2) \tag{22}$$

where $r_{2s} = \dfrac{r_2}{S}$ and $Z_{2s}^2 = x_2^2 + r_{2s}^2$

The positive magnetizing current is

$$I_{00p} = j\, b_{00}\, \frac{E_{ip}}{S}$$

The S enters in the denominator because E_{ip} was taken as the voltage induced in the rotor bars, not in the stator.

$$I_{1p} = -\, I_{2p} + I_{00p}$$

or

$$I_{1p} = \frac{-\,E_{ip}}{S\, Z_{2s}^2}\,[r_{2s} - j\,(x_2 + b_{00}\, Z_{2s}^2)\,] - \frac{K\, E_{in}}{S\, Z_{2s}^2}\,(r_{2s} - j\, x_2) \tag{23}$$

3. It is easier, in describing the diagram, to forget about the field winding. Its effect is discussed later. The diagram is perfectly general, applying to any machine with a partial polyphase rotor of any type.

4. I_{2pp} is read as follows: Secondary current positively rotating produced by the positively rotating induced voltage. The 2 means secondary. The first p means positively rotating and the last p means due to the positive induced voltage.

5. It is, of course, not entirely correct to represent the magnetizing current by a simple vector on account of the non-uniformity of the air-gap in a synchronous motor. To take care of this correctly would probably involve the introduction of harmonics of higher order than fundamental. The error is probably not large, although it is a fact that the magnetizing admittance in a synchronous machine is large, the exciting current usually being greater than the normal full load current of the machine. Possibly this point is worthy of further study and investigation.

$$\dot{I}_{1p}\dot{Z}_1 = j\,\dot{I}_{1p}\,x_1 = \frac{-\dot{E}_{ip}\,x_1}{S\,Z_{2s}^{\,2}}\left[x_2 + b_{00}\,Z_{2s}^{\,2} + j\,r_{2s}\right] - \frac{K\,\dot{E}_{in}\,x_1}{S\,Z_{2s}^{\,2}}\,(x_2 + j\,r_{2s}) \qquad (24)$$

but

$$\dot{E}_0 = \frac{-\dot{E}_{ip}}{S} + \dot{I}_{1p}\dot{Z}_1$$

or

$$\dot{E}_0 = \frac{-\dot{E}_{ip}\,x_1}{S\,Z_{2s}^{\,2}}\left[x_2 + B\,Z_{2s}^{\,2} + j\,r_{2s}\right] - \frac{K\,\dot{E}_{in}\,x_1}{S\,Z_{2s}^{\,2}}\,(x_2 + j\,r_{2s}) \qquad (25)$$

where

$$B = \left(\frac{1}{x_1} + b_{00}\right)$$

Similarly for the negative current,

$$\dot{I}_{2n} = \frac{\dot{E}_{in} + K\,\dot{E}_{ip}}{S\,Z_{2s}^{\,2}}\,(r_{2s} - j\,x_2) \qquad (26)$$

The negative magnetizing current is

$$\dot{I}_{00n} = j\,b_{00}\left(\frac{2\,S - 1}{S}\right)\dot{E}_{in}\,\frac{1}{(2\,S - 1)} = j\,b_{00}\,\frac{\dot{E}_{in}}{S} \qquad (27)$$

To understand this equation clearly it must be

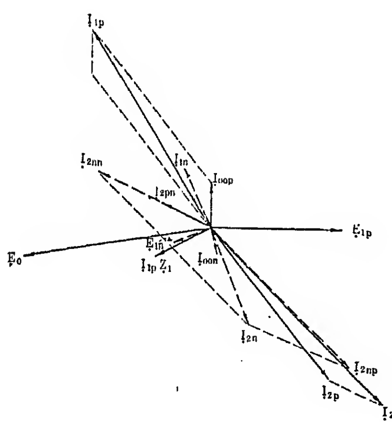

FIG. 11—MOTOR VECTOR DIAGRAM AT STANDSTILL, ALL VECTORS ROTATING POSITIVELY IN THE DIAGRAM

Vector equations are based on this diagram.

remembered that this magnetizing current is assumed to flow in the stator[6]; that the magnetizing admittance is inversely proportional to the frequency; and that b_{00} is given per unit volt in the stator while $\dot{E}_{in}$ is the voltage generated in the rotor bars. Since the negative flux actually moves backward on the rotor at a speed S, while the rotor moves forward at a speed $(1 - S)$, the negative flux really cuts the stator at a frequency of $(2\,S - 1)$, while it cuts the rotor bars at a frequency S. The exciting admittance in the stator for this negative flux is then

$$b_{00}\left(\frac{1}{2\,S - 1}\right)$$

since it is inversely proportional to the frequency and the voltage induced in the stator is $\left(\frac{2\,S - 1}{S}\right)\dot{E}_{in}$.

The stator negative current is

$$\dot{I}_{1n} = -\,\dot{I}_{2n} + \dot{I}_{00n}$$

or

$$\dot{I}_{1n} = \frac{-\dot{E}_{in}}{S\,Z_{2s}^{\,2}}\left[r_{2s} - j\,(x_2 + b_{00}\,Z_{2s}^{\,2})\right] - \frac{K\,\dot{E}_{ip}}{S\,Z_{2s}^{\,2}}\,(r_{2s} - j\,x_2) \qquad (28)$$

$$\dot{I}_{1n}\dot{Z}_1 = j\,\dot{I}_{1n}\,x_1\,(2\,S - 1) = \frac{-\dot{E}_{in}\,x_1\,(2\,S - 1)}{S\,Z_{2s}^{\,2}}\,(x_2 + b_{00}\,Z_{2s}^{\,2} + j\,r_{2s}) - \frac{K\,\dot{E}_{ip}\,x_1\,(2\,S - 1)}{S\,Z_{2s}^{\,2}}\,(x_2 + j\,r_{2s}) \qquad (29)$$

But

$$\dot{I}_{1n}\dot{Z}_1 = \dot{E}_{1n}\,\frac{(2\,S - 1)}{S} \qquad (30)$$

Equating (29) and (30), reducing and solving for $\dot{E}_{in}$ gives:

$$\dot{E}_{in} = -\,K\,\dot{E}_{ip}\,\frac{\dot{V}}{\dot{V} + B\,Z_{2s}^{\,2}} \qquad (31)$$

where

$$\dot{V} = x_2 + j\,r_{2s}$$

Substituting (31) in (25) and putting $x_2 + j\,r_{2s} = \dot{V}$ gives:

$$\dot{E}_0 = \frac{-\dot{E}_{ip}\,x_1}{S\,Z_{2s}^{\,2}}\left[\frac{(\dot{V} + B\,Z_{2s}^{\,2})^2 - K^2\,\dot{V}^2}{\dot{V} + B\,Z_{2s}^{\,2}}\right] \qquad (32)$$

In Appendix I, it is shown that the numerical value of the bracket is:

$$\frac{Z_{2s}}{z}\,\sqrt{(z^2 - K^2)^2 - (2\,K\,B\,r_{2s})^2} \qquad (33)$$

where

$$z = \sqrt{1 + 2\,B\,x_2 + B^2\,Z_{2s}^{\,2}}$$

Substituting (33) for the bracket in (32) and making $\dot{E}_{ip}$ zero vector, (32) may be solved for the positive induced voltage.

6. This assumption is not necessary. The point of view could be taken that the negative magnetizing current flows in the rotor and precisely the same result reached. Actually, the negative magnetizing current does flow in the rotor bars as can be seen from either diagram, Fig. 10 or Fig. 11. It will be noted that $\dot{I}_{2n}$ is larger than $\dot{I}_{1n}$, which simply means that since the negative m. m. f. in the rotor is greater than that in the stator, it must supply the magnetization. Of course, just the opposite is true of the positive m. m. fs. $\dot{I}_{1p}$ is always greater than $\dot{I}_{2p}$ so that the positive magnetizing current is carried in the stator.

$$\frac{E_{ip}}{S} = \frac{E_0 Z_{2s} z}{x_1 \sqrt{(z^2 - K^2)^2 - (2 K B r_{2s})^2}} \qquad (34)$$

The positive torque which is due to the positive flux in the gap reacting on the positive current in the rotor bars is

$$T_p = \frac{E_{ip}}{S} \times \text{real part of } I_{2p} \qquad (35)$$

From (31)

$$E_{ip} + K E_{in} = E_{ip} \left[\frac{V (1 - K^2) + B Z_{2s}^2}{V \quad B + Z_{2s}^2} \right] \qquad (36)$$

Substituting (36) in (22) gives:

$$I_{2p} = \frac{E_{ip}}{S Z_{2s}^2} \left[\frac{V (1 - K^2) + B Z_{2s}^2}{V + B Z_{2s}^2} \right] (r_{2s} - j x_2) \qquad (37)$$

Now, the rationalizing factor in the denominator is $x_2 + B Z_{2s}^2 - j r_{2s}$, so that the problem of finding the real part of I_{2p} resolves itself into that of finding the real part of

$$(x_2 + B Z_{2s}^2 - j r_{2s}) [x_2 + B Z_{2s}^2 + j r_{2s} - K^2 (x_2 + j r_{2s})] (r_{2s} - j x_2) \qquad (38)$$

Multiplying this out and reducing the real part is found to be

$$Z_{2s}^2 r_{2s} [z^2 - K^2 (1 + 2 B x_2)] \qquad (39)$$

The real part of I_{2p} is, therefore,

$$I_{2p} \text{ (real part only) } \doteq \frac{E_{ip} r_{2s}}{S Z_{2s}^2 z^2} [z^2 - K^2 (1 + 2 B x_2)]$$

Substituting in (35) gives the positive torque,

$$T'_p = \left(\frac{E_{ip}}{S}\right)^2 \frac{r_{2s}}{Z_{2s}^2 z^2} [z^2 - K^2 (1 + 2 B x_2)] \qquad (41)$$

Substituting (34) in (41) and reducing gives,

$$T_p = \frac{E_0^2}{x_1^2} r_{2s} \frac{[(z^2 - K^2) - 2 K^2 B x_2]}{[(z^2 - K^2)^2 + (2 B K r_{2s})^2]} \qquad (42)$$

In this formula,

$$z^2 = 1 + 2 B x_2 + B^2 Z_{2s}^2$$

and

$$B = \frac{1}{x_1} + b_{00}$$

This is the torque of the motor produced by the positively rotating flux in the gap and by the positive current in the rotor bars. On the assumption of no stator resistance this is the total motor torque, since if there is no stator resistance there is no component of I_{2n} in phase with E_{in}. (See vector diagram Fig. 10). In other words, there is no current in time phase with the negatively rotating flux in the gap, so there can be no torque due to this flux.

If in (42) K is put equal to 1 for the case of a single-phase rotor circuit, the torque is

$$T = \frac{r_{2s}}{x_1^2 \{ B^2 r_{2s}^2 + (2 + B x_2)^2 \}} \qquad (43)$$

By differentiating this expression with respect to slip, it is easily seen that maximum torque occurs at

$$S = \frac{B r_2}{2 + B x_2} \qquad (44)$$

and the maximum torque is

$$T_{max.} = \frac{.5}{B x_1^2 (2 + B x_2)} \qquad (45)$$

Formulas (44) and (45) are useful in studying the conditions at pull-in as will be seen later.

By substituting the numerical values of the several constants of the machine in Equation (42) for different values of slip, a speed torque curve could be made for the case of open field circuit. This is of little practical value as machines are almost never started with the field open and even if they are started with the field open, it is usually closed before the motor reaches the pull-in point. This is necessary because a motor has very little pull-in torque with open field. Hence, it is necessary, before one can make a speed torque curve with closed field circuit, to study the effect of closing the field circuit on the other constants of the machine.

Part IV. Effect of Field Winding on the Characteristics of the Rotor Circuit

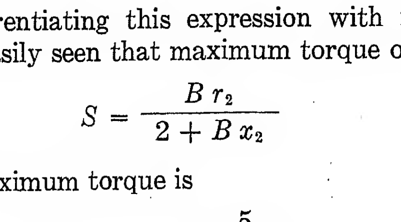

FIG. 12—TIME DIAGRAM OF ROTOR BAR AND FIELD CIRCUITS

Let:

x_b = reactance of the rotor bars,
r_b = resistance of the rotor bars,
x_f = reactance of the field circuit,
r_f = resistance of the field circuit including any external resistance in series with it,
I_b = rotor bar current,
I_f = field current.

All constants are, of course, referred to the stator.

Let E_i be the voltage induced in the rotor bars by a sine wave of flux. Then

$$I_b = \frac{E_i}{r_b + j S x_b} = \frac{E_i/S}{Z_{bs}^2} (r_{bs} - j x_b) \qquad (46)$$

With the direction of flux rotation assumed in Fig. 13, the induced voltage in the field is 90 deg. ahead of that in the bars, so that

$$I_f = \frac{j E_i}{r_f + j S x_f} = \frac{E_i/S}{Z_{fs}^2} (x_f + j r_{fs}) \qquad (47)$$

The time relations expressed in Equations (46) and (47) are clearly shown in Fig. 12. In other words, the current in the field circuit in time, is ahead of the current in the bar circuit by an angle

$$\left.\begin{aligned} \varphi &= \tan^{-1}\frac{x_b}{r_{bs}} + \tan^{-1}\frac{r_{fs}}{x_f} \\ &\text{or} \\ \varphi &= \tan^{-1}\frac{x_b\, x_f + r_{bs}\, r_{fs}}{r_{bs}\, x_f - x_b\, r_{fs}} \end{aligned}\right\} \quad (48)$$

It will now be convenient to draw a space diagram, Fig. 14, representing the combined reaction of both the

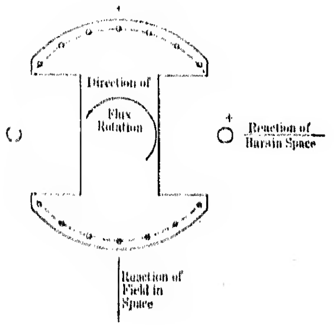

FIG. 13—SPACE DIAGRAM OF ROTOR BAR AND FIELD CIRCUITS

bars and the field on the stator. Both positively and negatively rotating fields will be required. It will also be convenient to draw this diagram as it would appear at the instant in time when the positively rotating vector and negatively rotating vector, due to the bar current, are in line, which, it will be remembered, occurs at the instant the current in the middle bar is maximum.

Referring to Fig. 14, if the current in the field circuit had been in time phase with the bar current, its two vectors I_{fp} and I_{fn} would have been in line with the y axis pointing downward. (See Fig. 13.) They have, however, moved in their respective directions through an angle φ, since the field current is φ degrees ahead in time of the bar current. This is shown in Fig. 14. The total positively rotating m. m. f. in the rotor is represented by I_{2p} and is the vector sum of I_{bp} and I_{fp}. Similarly, the total negatively rotating m. m. f. is represented by I_{2n} and is the vector sum of I_{fn} and I_{bn}. Expressed mathematically, the first relation is

$$I_{2p} = I_{bp} + I_{fp}\,(\sin\varphi - j\cos\varphi) \quad (49)$$

or numerically

$$I_{2p} = \sqrt{I_{bp}^2 + I_{fp}^2 + 2\, I_{bp}\, I_{fp} \sin\varphi} \quad (50)$$

Now let

$Z_{2s} = \sqrt{x_2^2 + r_{2s}^2}$ = impedance of the rotor circuit-bars and field combined

and

$Z_{bs} = \sqrt{x_b^2 + r_{bs}^2}$ = impedance of the bar circuit alone.

Then obviously

$$\frac{Z_{2s}}{Z_{bs}} = \frac{I_{bp}}{I_{2p}}$$

or

$$Z_{2s} = Z_{bs}\frac{I_{bp}}{I_{2p}} \quad (51)$$

But from (50)

$$\frac{I_{2p}}{I_{bp}} = \sqrt{1 + \left(\frac{I_{fp}}{I_{bp}}\right)^2 + 2\left(\frac{I_{fp}}{I_{bp}}\right)\sin\varphi} \quad (52)$$

Now let

$$V = \frac{I_{fp}}{I_{bp}} = \frac{Z_{bs}}{Z_{fs}} \quad (53)$$

where

$$Z_{fs} = \sqrt{x_f^2 + r_{fs}^2}$$

Substituting (53) in (52) and then (52) in (51) gives

$$Z_{2s} = \frac{Z_{bs}}{\sqrt{1 + V^2 + 2\, V\sin\varphi}} \quad (54)$$

which is the impedance of the rotor circuit with the field closed.

It can be seen from Fig. 14 that the phase angle of the rotor circuit has been increased by angle α, where

$$\alpha = \tan^{-1}\frac{V\cos\varphi}{1 + V\sin\varphi} \quad (55)$$

so that, if θ is the phase angle of the rotor circuit with field closed,

$$\theta = \tan^{-1}\frac{x_b}{r_{bs}} + \tan^{-1}\frac{V\cos\varphi}{1 + V\sin\varphi} \quad (56)$$

and hence

$$\left.\begin{aligned} r_{2s} &= Z_{2s}\cos\theta \\ x_2 &= Z_{2s}\sin\theta \end{aligned}\right\} \quad (57)$$

Equation (57) gives the values of the rotor resistance

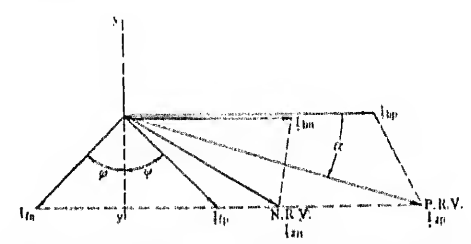

FIG. 14—SPACE DIAGRAM SHOWING CONTINUED REACTION OF FIELD AND FOUR CIRCUITS ON THE STATOR

and reactance with the field circuit closed. It can be seen from (54) that there is in general a decrease in the impedance of the rotor circuit when the field is closed. It is usually found that at starting, the rotor resistance is considerably decreased and the rotor reactance slightly increased. In some cases however, where the rotor bar impedance is very high—approaching that of the field—there is a very considerable increase in the reactance of the rotor circuit.

There is another effect of closing the field which is apparent from a study of Fig. 14. The value of K, which is a measure of the single-phase action in the rotor, is changed. Let the new value of K be K_c. It will be remembered that for the damper bars alone K is determined by the bar span and is equal to the ratio of $\frac{I_{bn}}{I_{bp}}$. Similarly, K_c is equal to the ratio of $\frac{I_{2n}}{I_{2p}}$ in Fig. 14.

From the geometrical relations in Fig. 14 it is easily determined that

$$K_c = \sqrt{\frac{K^2 + V^2 - 2\,K\,V \sin \varphi}{1 + V^2 + 2\,V \sin \varphi}} \qquad (58)$$

Now, the effect of closing the field circuit has been determined both upon the rotor resistance and reactance, and upon the single-phase action of the rotor. But it should be noted particularly that all of these equations contain the slip S, so that the effect of the field is different at every different value of slip. With the field open and only the damper bar circuit under consideration, it is possible to say the rotor resistance is this and the rotor reactance is that, but not so with the field closed. It is necessary to calculate the rotor resistance and reactance for every assigned value of slip from the combined effect of field circuit and bar circuit.

Part V. The Speed-Torque Curve—Pull-in Torque and In-rush.

The actual work involved in calculating a speed-torque curve is not so complicated or so great as might be assumed from the more or less elaborate theoretical investigation in the foregoing paragraphs. Especially is this true if the work is arranged in orderly fashion in a blank made for the purpose.

It is necessary to know all the constants of the machine, except the stator resistance which has been neglected. These are x_1, b_{00}, x_b, r_b, x_f, r_f.[7] They are, of course, to be given in percentage and referred to the stator. Then by assigning certain values of slip, for which it is desired to calculate the torque, and substituting in Equations (**53**) to (**58**), the rotor constants x_2, r_2, and K can be obtained. These values can then be substituted in Equation (**42**) and the torque obtained for each value of the slip.

The details of these calculations are made clear in Table I, where an actual example is worked out complete. The motor was rated 220 h. p., unity power factor, 2200 volts, three-phase, 60-cycles, 277 rev. per min. It had 1 $^{11}/_{13}$ slots per pole per phase in the stator and five ¼- by ¼-in. brass damper bars per pole

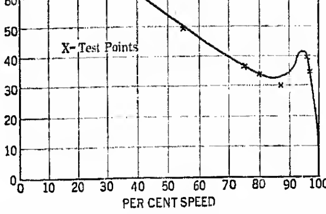

FIG. 15—COMPARISON OF TEST AND CALCULATED RESULTS ON 220-H. P., 277-REV. PER MIN., SYNCHRONOUS MOTOR

in the rotor. It was designed with a short-circuit ratio of 1.00.

The actual values of the constants calculated for this machine were as follows:

$x_1 = 0.153$, $r_b = 0.384$, $r_f = 0.0097$ (not including any external resistance),

$b_{00} = 1.23$, $x_b = 0.184$, $x_f = 0.675$.

Fig. 15 shows the speed torque curve calculated in Table I. The test values are also indicated in Fig.15 by crosses. Both test and calculation were made with a starting resistance in the field circuit equal to twice

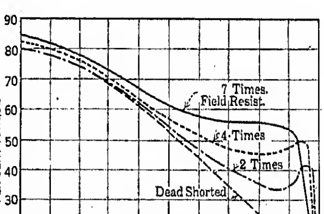

FIG. 16—SPEED TORQUE CURVES ON 220-H. P., 277-REV. PER MIN. MOTOR

Showing effect of different values of starting resistances in the field circuit, on the pull-in torque.

that of the field resistance. The agreement between test and calculated values is unusually good, although the usual discrepancy does not exceed about 10 per cent.

THE PULL-IN TORQUE

In Fig. 16 are shown several speed torques for the above motor calculated with different values of resistance in the field circuit. The one with two times the resistance of the field is the same as the curve in Fig. 15. It will be noted that all of the curves with values of starting resistance from 0 to 2 times show a distinct

7. It is not within the scope of this paper to present methods of calculating the several constants of the machine. The writer has found from experience that methods which give excellent results for one type of construction are not at all satisfactory for the other types. So much depends on the type of damper winding construction used, the method of making and connecting the damper end rings, and the type of damper slot, that no methods could be presented which would be universally applicable. These features vary so widely with the different manufacturers that it was thought better to present only the general theory and leave the calculation of the constants to the individual reader.

TABLE I

EXAMPLE CALCULATION OF SPEED-TORQUE CURVE

The last term in the denominator in equation (47) has been omitted in this calculation. This term will be found to be negligible.

	Slip $= S$	0.06	0.08	0.10	0.12	0.15	0.20	0.25	0.60	1.00*

*Calculated with field dead short-circuited Test which was used in finding starting torque was with field dead short-circuited.

cusp in the curve. But by increasing the starting resistance up to seven times the cusp disappears entirely and the speed torque curve assumes quite a different character. So it is possible to distinguish at least two distinct types of speed torque curves, those with a cusp and those without a cusp, and this presents a real difficulty in attempting to define the pull-in torque.

In the case of a curve with a cusp it is quite obvious that if the motor has sufficient torque to accelerate the load up through the low point of the cusp, it will pull into step because beyond the cusp the motor torque increases rapidly to a point very close to synchronism, usually within 2 or 3 per cent. Hence, the motor torque at the low point of the cusp becomes the pull-in torque of the motor, and there is no difficulty in defining pull-in torque for this type of curve. However, if there is no cusp, as in the case of the curve with six times field resistance, the problem becomes one of determining at what slip the motor will pull in; knowing the slip, the torque is given by the speed-torque curve. But to calculate the slip at which it will pull in is a difficult problem and one which has been the subject of much theoretical investigation and discussion[8]. Experience shows, however, that an ordinary machine may be expected to pull in at a slip of 6 or 7 per cent, while there are rare cases on record where it has been necessary to bring the machine up to within 3 per cent before it would pull in. In such cases, however, there has usually been a large flywheel on the driven machine which cannot properly be considered as part of the motor, and it has been this flywheel which has been responsible for the low value of slip required for pull-in. So far as the definition of pull-in torque is concerned, the best one can do is to give the motor torque at some slip, say from 5 to 7 per cent, and state the slip at which it is given.

Formula for Pull-In Torque

It is evident from what has been said that it is not possible to give an exact formula for the pull-in torque of a motor and the only correct way to obtain it is to calculate the speed torque curve. It is possible, however, to derive an approximate formula which will be found convenient for the designer. That portion of the speed torque in the neighborhood of synchronous speed may be considered as made up of two parts more or less independent, one due to the damper bars and one to the field winding. These two parts are shown in Fig. 17, part a due to the field winding and part b due to the damper bars. The dotted curve shows the combined effect of both.

Now the curve a in the neighborhood of synchronous

8. See references listed under item 6, in Bibliography.

speed is given approximately by formula (**43**), if $x_2 = x_f$ and $r_2 = r_{fs}$. The maximum point P can, therefore, be obtained from Equation (**45**) as follows:

$$T_{max}. \text{ at point } P = \frac{0.5}{B\, x_1^2\, (2 + B\, x_f)} \qquad \textbf{(59)}$$

and from this formula one is able to estimate the pull-in torque from the proportion of the various constants and a knowledge of the starting resistance to be used in the field circuit. The approximate formula for pull-in torque may be written

$$T_{pull\text{-}in} = \frac{0.4 \text{ to } 0.8}{B\, x_1^2\, (2 + B\, x_f)} \qquad \textbf{(60)}$$

Experience shows that if the rotor bar resistance is about equal to the total reactance (rotor and stator) of the machine and a starting resistance equal to twice the field resistance is used a value as low as 0.4 may be expected in the numerator, while, if the rotor bar resistance is equal to about half the total reactance of the machine and a starting resistance equal to 4 or 5 times the resistance of the field (which will usually

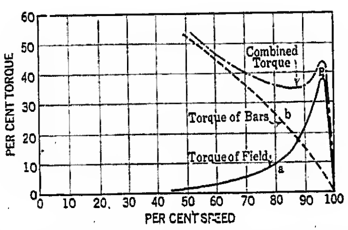

FIG. 17—CURVES SHOWING HOW THE TORQUE OF THE BARS AND THE TORQUE OF THE FIELD COMBINE TO GIVE THE PULL-IN TORQUE

eliminate the cusp in the torque curve completely) is used, then a value of 0.8 can often be obtained.

THE IN-RUSH CURRENT

It is comparatively easy to derive from Equations (**20**) to (**34**) a formula for the in-rush—in fact, two formulas, one for the positive current I_{1p} and one for the negative current I_{1n}. From these two values the unbalanced three-phase currents in each of the three lines can be determined. This unbalance is usually small and both the formulas for I_{1p} and I_{1n} are rather involved and cumbersome. No attempt is made to guarantee anything but an average value of the in-rush in each of the three lines. The writer has found that this average in-rush can be calculated with sufficient accuracy from the induction motor formula,

$$I_s = \frac{\sqrt{1 + 2\, b_{00}\, x_2}}{\sqrt{r_0^2 + x_0^2}} \qquad \textbf{(61)}$$

where

$r_0 = r_1 + r_2$

r_1 = stator resistance

r_2 = rotor resistance (combined effect of bars and field winding)

$x_0 = x_1 + x_2$

x_1 = stator reactance

x_2 = rotor reactance (combined effect of bars field winding).

If the machine is started with the field open one should use r_b the resistance of the bars in place of r_2, and x_b the bar reactance in place of x_2.

When the calculation is made with field closed, formula (**61**) usually gives values slightly higher than test so that they are conservative, while if the field is open it is apt to give values too low.

For the 220-h. p. motor calculated above, the in-rush obtained from formula (**61**) is

$$I_s = \frac{\sqrt{1.579}}{\sqrt{0.228^2 + 0.388^2}} = 2.8^9 = 120.5 \text{ amperes}$$

Test = 118 amperes

With field open

$$I_s = \frac{\sqrt{1.452}}{\sqrt{0.422^2 + 0.337^2}} = 2.07 = 89.2 \text{ amperes}$$

Test = 96 amperes

Part VI. Characteristics of Double Squirrel-Cage Windings in Salient-Pole Synchonous Motors

Any definite pole synchronous machine contains the necessary elements of the double squirrel-cage winding. The ordinary damper bars form a rotor circuit of high resistance and low reactance, while the field winding forms a circuit of low resistance and high reactance. At starting, the high damper bar circuit provides high starting torque and low in-rush because the resistance of the damper bars enters potentially into the impedance which limits the in-rush. This results in a high power factor at starting and consequently high torque for the kv-a. required. As the machine approaches full speed the field winding comes into play, and maintains a comparatively high value of torque up to within a few per cent of synchronism.

A machine designed with a low reactance, high resistance damper winding and provided with a large enough starting resistance in series with the field winding to remove the cusp from the speed torque curve, may be said to possess a double squirrel-cage rotor of a most effective type. It gives the usual double squirrel-cage characteristics as they are known in induction motor practise; low in-rush, high starting torque and comparatively high torque at low values of slip. These characteristics are well illustrated in Fig. 16 by the speed torque curve for the case of seven times resistance in the field circuit.

But when an actual double squirrel-cage winding is

9. This value is given in percentage based on the output current which is 43.1 amperes. The in-rush in amperes is 2.8 × 43.1 = 120.5 amperes.

put in the pole faces it is rather difficult to produce characteristics of this type. One difficulty the designer encounters is the limited depth of slot he may use in the head of a synchronous motor pole. The depth of the pole head cannot be increased appreciably without an excessive increase in the field leakage, and it is well known that in order to obtain any appreciable double squirrel-cage effect, that is, any appreciable change in the bar resistance with the frequency, a reasonable amount of slot depth is absolutely essential.

It is also well known that the double squirrel-cage effect obtained depends on the resistance of the material

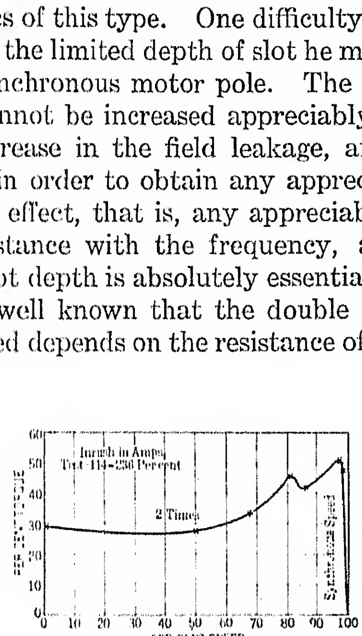

FIG. 18—TEST RESULTS ON 225-H. P., 257-REV. PER MIN. SYNCHRONOUS MOTOR EQUIPPED WITH DOUBLE SQUIRREL-CAGE DAMPER WINDING, SHOWING TYPICAL DOUBLE SQUIRREL-CAGE CHARACTERISTICS.

used in the bar, the lower the resistance the greater being the effect. In other words, in order to obtain any appreciable decrease in the resistance of the bar as the frequency decreases (this is the object of the double squirrel-cage construction) it is necessary to employ a material with as low a specific resistance as possible, and hence copper. Especially is this true if the depth of the slot is limited. These facts are illustrated very clearly in Equation (**34**) of Appendix II, where a simple method is worked out for the calculation of the inverted *T*- or *L*-shaped bar. Equation (**34**) shows that the modulus of the vector upon which the double squirrel-cage effect or skin effect depends, involves the factor

$$a \sqrt{\frac{f}{\sigma}}$$

where a is the depth of the bar, (actually half of the depth).

f is the frequency

and

σ is the specific resistance of the material of the bar. Thus, it is seen that if the depth of the bar could be doubled the same skin effect would be obtained as with the original bar at four times the frequency. This shows clearly the handicap of limited depth. Also, it is evident that increasing the bar resistance has exactly the same effect as decreasing the frequency so that if the material of the bar were changed from copper to brass the same skin effect would be obtained as with the copper bar at a frequency of $\frac{60}{3.3} = 18.2$ cycles.[10] This simply means that with the limited depth available in the head of a synchronous motor pole a brass winding gives practically no skin effect.

There is also another point to be borne in mind. Any double squirrel-cage winding, because of the depth of the slot is bound to have a considerably higher reactance than a single cage winding of the same resistance.

The conclusion, therefore, which has been reached without making any figures at all, is that a synchronous motor equipped with a double squirrel-cage damper winding will inherently have a rotor bar circuit of low resistance and high reactance and hence poor power factor. The power factor will be further decreased by closing the field circuit. The in-rush will be limited almost entirely by the reactance of the machine, and may be expected to be low due to the excessive bar reactance. The starting torque will be comparatively low due to the low damper bar resistance and the poor power factor. The pull-in torque will be comparatively high and there will probably be very little cusp in the speed-torque curve even with a low value of starting resistance in the field circuit. It would be difficult, perhaps impossible, to design a double squirrel-cage winding in a synchronous motor so that the starting torque was equal to, or at least appreciably greater than, the pull-in torque.

Of course, there are some special applications such as pumps and fans, where low starting torques and high pull-in torques are desirable and for these the double squirrel-cage synchronous motor is especially suited. For most applications, however, it is better to have a motor with higher starting torque than pull-in torque

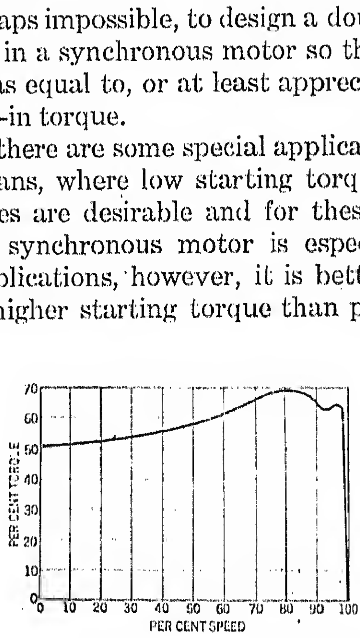

FIG. 19—CALCULATED RESULTS OF 220-H. P., 277-REV. PER MIN. SYNCHRONOUS MOTOR EQUIPPED WITH DOUBLE SQUIRREL-CAGE COPPER DAMPER BAR OF THE INVERTED T TYPE

and this, as has been pointed out, is a condition which would be very difficult to obtain with a double squirrel-cage winding.

Experimental confirmation of these conclusions is presented in Fig. 18 which gives a speed torque curve plotted from test results on a commercial synchronous motor equipped with a double squirrel-cage damper winding. This machine was rated 225 h. p., 257 rev. per min., 2200 volts, three-phase, 60 cycles, unity power factor. The characteristics of low in-rush, low

10. Brass has a resistance of approximately 3.3 times that of copper at 100 deg. cent.

starting torque and high pull-in torque are clearly shown.

Theoretical confirmation of these conclusions is found in Appendix II where the resistance and reactance of a double squirrel-cage bar are calculated. This bar is so designed that it could be used in the 220-h. p., 277-rev. per min. motor calculated in Table I. The bar is $^9/_{16}$ in. deep overall, $^1/_{16}$ in. wide at the top, and $^3/_{16}$ in. wide at the bottom. It is made narrow in order to keep the resistance as high as possible and still use copper. Likewise, the bar extends clear to the top of the pole face to keep the reactance low. Both of these features combine to make the power factor of the bar as high as possible and yet it is only 0.46 as compared with 0.84, the power factor of the plain square brass bar. These values are shown in Table III, Appendix II.

A complete calculation of the performance of the above synchronous motor (220 h. p., 227 rev. per min.) when equipped with this double squirrel-cage bar has been made. The speed-torque curve and other data are given in Fig. 19. It will be noted that the performance is excellent, but the general characteristics of the double squirrel-cage motor, as discussed, are apparent.

Table II shows a comparison of the performance of the 220-h. p., 277-rev. per min. motor equipped with both the brass damper winding and with the double squirrel cage, and also the 225-h. p., 257-rev. per min. motor tested with the double squirrel-cage winding.

TABLE II

TABLE SHOWING COMPARATIVE PERFORMANCE OF SINGLE SQUIRREL-CAGE AND DOUBLE SQUIRREL-CAGE MOTORS

Motor	Starting torque per cent	Pull-in torque per cent	In-rush per cent	Starting torque per kv-a.	Pull-in torque[11] per kv-a.	Avg. torque per kv-a.
225 h. p., 257 rev. per min., with double squirrel-cage—test results	28	52	236	0.118	0.220	0.169
220 h. p., 277 rev. per min., with plain brass dampers—test results	75	50[12]	246	0.304	0.203	0.253
220 h. p., 277 rev. per min., with double squirrel-cage T-shaped copper bars—calculated results	50	63	303	0.164	0.208	0.186

11. It is unusual to state the pull-in torque per in-rush kv-a. but it is convenient to do so in comparing the merits of damper windings, in different machines having different values of stator reactance. The 225-h. p. motor had considerably higher stator reactance than did the 220-h. p. machine. This accounts for its lower values of torque and in-rush in percentage.

12. Calculated value with starting resistance equal to seven times the field resistance.

Part VII. Possibilities of External Damper Bar Circuit.

To obtain synchronous motor starting performance nearly equivalent to slip ring induction motor characteristics has probably been a secret ambition cherished in the heart of every engineer who has wrestled with the starting problem in salient-pole motors in the last two decades. The fact that this problem has not been solved in a commercial way may indicate either one of two things; either the problem is extremely difficult, or else there has not, up to the present time, been a sufficient market for motors of such excellent starting characteristics. However, it has been felt that if a motor with these characteristics could be developed, the field of application of the synchronous motor could be greatly extended, and it is probably this feeling which continues to revive interest in this problem.

Perhaps this same feeling has been responsible for the development and use of the synchronous induction motor in Europe. The high cost, low efficiency, and low pull-out torque of this type of machine has been largely responsible for its very meagre use in this country. Still the problem of obtaining the excellent starting performance of the slip ring motor and maintaining the excellent running performance of the salient-pole synchronous motor has remained unsolved.

Comparatively recently, the synchronous motor has found some new applications in steel mill service for driving certain types of rolling mills. For some of these applications the starting duty is severe and manufacturers have attempted to improve the sturdiness of the damper windings supplied in their motors with a view to meeting these severe starting conditions and extending the field of application of the synchronous motor in steel mill service. One feature which is limiting the application of these motors in steel mills is the low torque per kv-a. obtained in ordinary low speed synchronous motors, and consequently the high in-rush required. Another difficult feature is the absolute reliability required. In some cases manufacturers have been asked to guarantee continued operation on the damper winding for an indefinite period, in case of d-c. failure. This is a difficult requirement because the rolling peaks are usually much higher than the rating of the motor and this means that the machine must have a pull-out torque as an induction motor practically equal to its pull-out torque under synchronous operation. In other cases, it has been necessary to guarantee several starts in succession and the problem of absorbing the heat generated in the damper winding has become difficult. Perhaps here in this new application of synchronous motors an opportunity will be afforded for some entirely new developments in the starting arrangements of synchronous motors.

In this connection an investigation was made to determine the possibilities of an external damper bar circuit used in conjunction with a very high starting resistance in the field circuit—a resistance equal to or

greater than the reactance of the field winding at full slip. Mr. Fechheimer[13] pointed out in 1912 the increased starting torque and the improved power factor at starting which results from the use of a high resistance of this type in the field circuit. These advantages would obviously be augmented by making the damper bar circuit with as high a power factor as possible also, that is, with high resistance and low reactance. The low reactance is also necessary for high pull-out torque as an induction motor, but the high resistance must be arranged external to the damper bar circuit so that it can be short-circuited for running as an induction motor. This is necessary because a very low value of damper bar resistance is necessary to maintain a low value of slip at full load and to prevent the machine from slowing down too much on the peak loads.

The simplest type of circuit which would provide an external resistance in series with the damper winding (this is probably a very old idea) is shown in Fig. 20.

An analysis of the possibilities of this circuit showed, as was expected, that the power factor of the damper winding could be increased by increasing the external resistance up to a certain point, but beyond that point the power factor began to decrease again. This was to be expected because in the limiting case of an infinite resistance it is evident that the power factor of the damper winding would be very poor with very low resistance bars. This simply means that the amount of power which could be drawn out of the rotor circuit into the external resistor is limited.

The analysis also showed that if the external circuit were split up into two or more circuits, as shown in Fig. 21, it would be possible to insert enough resistance to obtain a very good power factor in the damper winding before the limiting resistance is reached.

The mechanical construction of the end ring connections did not seem to present any serious difficulties. In attempting to apply this scheme to an actual design of a 2500-h. p., 62½-rev. per. min., 25-cycle synchronous motor it was found that heavy brass slip rings and metallic brushes, such as are used on rotary converters, were required. A difficulty was also encountered in connection with the resistor for the field circuit. It was found that a very high voltage would be developed across the resistor and consequently across the slip rings at start. This was sufficiently reduced by designing the field for 50-volt excitation instead of 125. The calculated performance of the machine showed that it would carry full load continuously as an induction motor with a power factor of approximately 50 per cent. Its pull-out torque was approximately 225 per cent as an induction motor and 250 per cent as a synchronous motor. The starting torque depended upon the external resistances used, but it was found possible to obtain 150 per cent starting torque with an in-rush of 300 per cent. The pull-in torque at five per cent slip was 175 per cent.

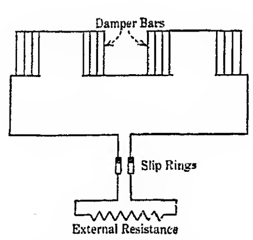

FIG. 20—SINGLE EXTERNAL DAMPER BAR CIRCUIT

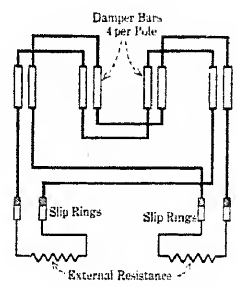

FIG. 21—DOUBLE EXTERNAL DAMPER BAR CIRCUIT

These figures seem to indicate great possibilities in the improvement of the starting performance of synchronous motors. No doubt developments to this end will take place rapidly if there becomes sufficient demand to warrant them.

ACKNOWLEDGMENTS

The writer wishes to acknowledge the assistance of Mr. E. S. Perrine and Mr. H. R. Goss in making calculations and preparing data for the manuscript. Credit is also due to Mr. Q. Graham for many helpful suggestions in connection with the vector diagrams in Figs. 10 and 11, and also to Mr. M. L. Annappa who has contributed some valuable suggestions in regard to the theoretical work in Appendix II. Item 6 of the bibliography is due to Mr. Graham.

Appendix I

To show that the numerical value of the vector expression

$$\frac{(V + B Z_{2s}^2)^2 - K^2 V^2}{V + B Z_{2s}^2} \qquad (1)$$

is

$$\frac{Z_2}{z} \sqrt{(z^2 - K^2)^2 - (2 K B r_{2s})^2} \qquad (2)$$

13. See Bibliography, 2.

let

$$\left.\begin{aligned} Z_{2s} &= \text{modulus of } \dot{V} \\ M &= \text{modulus of } \dot{V} + B\,Z_{2s}^2 \\ \theta_1 &= 2\tan^{-1}\frac{r_{2s}}{x_2} = \tan^{-1}\frac{2\,r_{2s}\,x_2}{x_2^2 - r_{2s}^2} \\ \theta_2 &= 2\tan^{-1}\frac{r_{2s}}{x_2 + B\,Z_{2s}^2} \\ &= \tan^{-1}\frac{2\,r_{2s}\,(x_2 + B\,Z_{2s}^2)}{(x_2 + B\,Z_{2s}^2)^2 - r_{2s}^2} \end{aligned}\right\} \qquad (3)$$

The numerator of (1) may be written

$$M^2 \underline{/\theta_2} - K^2\,Z_{2s}^2 \underline{/\theta_1} \qquad (4)$$

But

$$M^2 = Z_{2s}^2\,z^2 \qquad (5)$$

where

$$z^2 = (1 + 2\,B\,x_2 + B^2\,Z_{2s}^2)$$

Substituting (5) in (4) gives for the numerator

$$Z_{2s}^2\,[z^2 \underline{/\theta_2} - K^2 \underline{/\theta_1}] \qquad (6)$$

The magnitude of this is from the cosine law

$$Z_{2s}^2\,\sqrt{z^4 + K^4 - 2\,z^2\,K^2\,(\cos\theta_1\cos\theta_2 + \sin\theta_1\sin\theta_2)} \qquad (7)$$

But

$$\cos\theta_1\cos\theta_2 + \sin\theta_1\sin\theta_2$$

$$= \frac{(x_2^2 - r_{2s}^2)\,[(x_2 + B\,Z_{2s}^2)^2 - r_{2s}^2] + 4\,r_{2s}^2\,x_2(x_2 + B\,Z_{2s}^2)}{Z_{2s}^4\,z^2} \qquad (8)$$

which reduces to

$$\frac{1 + 2\,B\,x_2 + B^2\,(x_2^2 - r_{2s}^2)}{z^2} \qquad (9)$$

Substituting (9) in (7) gives:

$$Z_{2s}^2\,\sqrt{(z^2 - K^2)^2 - (2\,K\,B\,r_{2s})^2} \qquad (10)$$

as the numerical value of the numerator.

The numerical value of the denominator of (1) is $Z_{2s}\,z$ so that the numerical value of the whole vector expression (1) is

$$\frac{Z_{2s}}{z}\,\sqrt{(z^2 - K^2)^2 - (2\,K\,B\,r_{2s})^2} \qquad (11)$$

Q. E. D.

Appendix II[14]

Resistance and Reactance of an Inverted *T*- or *L*-Shaped Damper Bar

Consider a slot which is narrow at the top and wide at the bottom, shaped either like an inverted T or an L (Fig. 22).

Let

σ = specific resistance of the bar,

$f\,(x)$ = distribution of current in bottom part, x being measured from the bottom of the slot,

$F\,(x)$ = distribution of current in top part, x being measured from the division line $0 - 0$.

The distribution of current in the wide part of the bar will be calculated first[15]. Consider the flux through an element $d\,x$ due to the m. m. f. in an element $d\,u$. This m. m. f. is:

$$b_1\,f\,(u)\,d\,u \qquad (1)$$

Therefore

$$d\,[d\,\varphi] = \frac{4\,\pi\,b_1\,f\,(u)\,d\,u}{b_1/d\,x} = 4\,\pi\,f\,(u)\,d\,u\,d\,x \qquad (2)$$

Now, the total flux through the element $d\,x$ is due to all such elements as $d\,u$ from the bottom of the slot up to the element $d\,x$. Thus:

$$d\,\varphi = 4\,\pi\int_0^x f\,(u)\,d\,u\,d\,x \qquad (3)$$

which is the total flux passing through any element $d\,x$ at distance x from the bottom of the slot.

The flux which produces the e. m. f. of self-induction at any point x in the conductor is all the flux which threads through the conductor from the top of the conductor down to the point x, plus the flux in the wedge and air-gap. Let Φ be the self-inductive flux in the

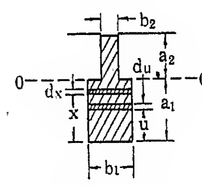

Fig. 22

wedge, air-gap and that which threads through the narrow part of the bar down to the division line $0 - 0$. Then the self-inductive flux at point x is

$$\varphi = 4\,\pi\int_x^a\int_0^x f\,(u)\,d\,u\,d\,x + \Phi$$

and the e. m. f. of self-induction is

$$p\,\varphi = 4\,\pi\,p\int_x^a\int_0^x f\,(u)\,d\,u\,d\,x + p\,\Phi^{16} \qquad (4)$$

14. Anyone interested in the calculation of double squirrel cages for synchronous motors will find App. II of especial interest. This problem can be handled by differential equations but the method of integral equations here presented will be found simpler and more straightforward and gives directly both the resistance and reactance of the bar. The problem of "setting up" the integral equation is much easier than the corresponding problem of "setting up" the differential equation. Especially is this true for those of us who have been taught the fundamentals of inductance from the point of view of interlinkages. The same integral equation can be applied to the calculation of a bar comprised of two different materials either T-shaped or of uniform width.

15. All this work is done in absolute electromagnetic units for simplicity.

16. p = the operator $\dfrac{d}{d\,t}$ and denotes differentiation with respect to time.

Since the induced voltage is the same at all points in the cross-section of the bar, and is equal to the e. m. f. consumed by resistance and self-induction, it follows that the sum of the e. m. fs. consumed by resistance and self-induction is the same in all parts of the bar. Hence,

$$\sigma f(x) + 4\pi p \int_x^a \int_0^x f(u)\, du\, dx + p\,\Phi$$

$$= \sigma f(0) + 4\pi p \int_0^a \int_0^x f(u)\, du\, dx + p\,\Phi \qquad (5)$$

$p\,\Phi$ cancels out and the equation becomes

$$\sigma f(x) = \sigma f(0) + 4\pi p \left\{ \int_x^a \int_0^x f(u)\, du\, dx \right.$$

$$\left. - \int_x^a \int_0^x f(u)\, du\, dx \right\} \qquad (6)$$

or

$$f(x) = f(0) + \frac{4\pi p}{\sigma} \int_0^x \int_0^x f(u)\, du^2 \qquad (7)$$

This is a simple integral equation and can be solved by the method of continued substitution. Substituting the right hand member of Equation (7) under the integral sign and putting $K^2 = \dfrac{4\pi p}{\sigma}$ Equation (7) becomes

$$f(x) = f(0) + K^2 \int_0^x \int_0^x [f(0) + K^2 \int_0^x \int_0^x f(u)\, du^2]\, du^2 \qquad (8)$$

$$= f(0) + K^2 f(0) \frac{x^2}{\underline{|2}} + K^4 \int_0^x \int_0^x \int_0^x \int_0^x f(u)\, du^4 \qquad (9)$$

Substituting again the right hand member of (7) under the integral sign in (9) and continuing the integration and repeating the process gives at once the infinite series:

$$f(x) = f(0) + K^2 f(0) \frac{x^2}{\underline{|2}} + K^4 f(0) \frac{x^4}{\underline{|4}} + \qquad (10)$$

or

$$f(x) = f(0) \cosh x K \qquad (11)$$

This is the current density in the wide portion of the bar, as function of the distance from the bottom of the bar.

Let

I_1 = current in the wide portion of the bar.

Then

$$I_1 = b_1 \int_0^{a_1} f(x)\, dx = \frac{b_1 f(0)}{K} \sinh a_1 K \qquad (12)$$

Now the flux which passes through an element $d\,x$ in the top of the slot is due to the total current in the lower part I_1, and also to the m. m. f. in the top part from the division line 0 — 0 up to the element $d\,x$.

This m. m. f. is

$$b_2 \int_0^x F(u)\, du \qquad (13)$$

The flux through $d\,x$ is, therefore:

$$d\varphi = \frac{4\pi \{I_1 + b_2 \int_0^x F(u)\, du\}\, dx}{b_2} \qquad (14)$$

The self-inductive flux at the point x is

$$\varphi = 4\pi \int_x^{a_2} \left\{ \frac{I_1}{b_2} + \int_0^x F(u)\, du \right\} dx \qquad (15)$$

and the e. m. f. of self-induction is

$$p\,\varphi = 4\pi p \int_x^{a_2} \left\{ \frac{I_1}{b_2} + \int_0^z F(u)\, du \right\} dx \qquad (16)$$

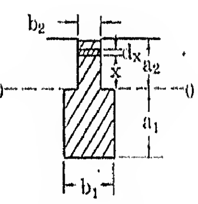

FIG. 23

Since the induced voltage is the same in all parts of the bar, it follows that

$$\sigma F(x) + 4\pi p \int_x^{a_2} \left\{ \frac{I_1}{b_2} + \int_0^x F(u)\, du \right\} dx$$

$$= \sigma F(0) + 4\pi p \int_0^{a_2} \left\{ \frac{I_1}{b_2} + \int_0^x F(u)\, du \right\} dx \qquad (17)$$

or

$$\sigma F(x) = \sigma F(0) + 4\pi p \int_0^x \left\{ \frac{I_1}{b} + \int_0^x F(u)\, du \right\} dx \qquad (18)$$

Therefore,

$$F(x) = F(0) + \frac{K^2 I_1 x}{b_2} + K^2 \int_0^x \int_0^x F(u)\, du^2 \qquad (19)$$

Using the same method of solution for this equation as was used for Equation (17), it easily reduces to

$$F(x) = F(0) \cosh x K + \frac{I_1}{b_2} K \sinh x K \qquad (20)$$

But

$$F(0) = f(a_1) = f(0) \cosh a_1 K \qquad (21)$$

Substituting (21) and (12) in Equation (20)

$$F(x) = f(0) \left[\cosh a_1 K \cosh x K + \frac{b_1}{b_2} \sinh a_1 K \sinh x K \right] \qquad (22)$$

This is the distribution of the current in the top of the slot as function of the distance x from the division line $0 - 0$. The total current flowing in the top is:

$$I_2 = b_2 \int_0^{a_2} F(x)\, d x$$

$$= b_2 \left[\frac{F(0)}{K} \sinh x K + \frac{I_2}{b_2} \cosh x K \right]_0^{a_2}$$

$$= \frac{F(0)\, b_2}{K} \sinh a_2 K + I_1 \cosh a_2 K - I_1 \qquad (23)$$

Substituting for $F(0)$ from (21) and for I_1 from (12) gives

$$I_2 = \frac{f(0)}{K} \{ b_2 \cosh a_1 K \sinh a_2 K + b_2 \sinh a_1 K \cosh a_2 K \} - I_1 \qquad (24)$$

The total current $I_0 = I_1 + I_2$ is, therefore,

$$I_0 = \frac{f(0)}{K} \{ b_2 \cosh a_1 K \sinh a_2 K + b_2 \sinh a_1 K \cosh a_2 K \} \qquad (25)$$

The voltage which produces this current is

$$E = \frac{4 \pi p I_0}{\rho} + \sigma F(a_2) \qquad (26)$$

where ρ is the reluctance of the leakage path above the conductor.

The effective impedance of the bar is, therefore,

$$Z = \frac{E}{I_0} = \frac{1}{I_0} \left[\frac{4 \pi p I_0}{\rho} + \sigma F(a_2) \right] \qquad (27)$$

$$Z = \frac{4 \pi p}{\rho} + \frac{\sigma K}{b_2} \left[\frac{\cosh a_1 K \cosh a_2 K + W \sinh a_1 K \sinh a_2 K}{\cosh a_1 K \sinh a_2 K + W \sinh a_1 K \cosh a_2 K} \right] \qquad (28)$$

where

$$W = \frac{b_1}{b_2}$$

This vector expression is the impedance of a T-shaped bar per unit length. The real part is the resistance, the j part, the reactance. Obviously the first term $\frac{4 \pi p}{\rho}$ is a pure reactance term and is the reactance of the bar due to the leakage flux in the slot above the bar and in the air-gap.

As a special case, let $a_1 = a_2$ which means that the narrow portion and wide portion are of the same depth. Neglect the first term. Then

$$Z = \frac{\sigma K}{b_2} \left[\frac{\cosh^2 a K + W \sinh^2 a K}{(1 + W) \sinh a K \cosh a K} \right] \qquad (29)$$

which reduces easily to

$$Z = \frac{\sigma a K}{a b_2} \left[\frac{Q + \cosh 2 a K}{\sinh 2 a K} \right] \qquad (30)$$

where

$$Q = \frac{1 - W}{1 + W} = \frac{b_2 - b_1}{b_2 + b_1} \qquad (31)$$

But

$$a K = a \sqrt{\frac{4 \pi p}{\sigma}} = a \sqrt{\frac{j 8 \pi^2 f}{\sigma}}$$

$$= 2 \pi a \sqrt{\frac{f}{\sigma}} (1 + j) \qquad (32)$$

Or

$$a K = A + j A \qquad (33)$$

where

$$A = 2 \pi a \sqrt{\frac{f}{\sigma}} \qquad (34)$$

Substituting (33) in (30) gives

$$Z = \frac{\sigma (A + j A)}{a b_2} \left[\frac{Q + \cosh 2 (A + j A)}{\sinh 2 (A + j A)} \right] \qquad (35)$$

This can be expanded to

$$Z = \frac{\sigma (A + j A)}{a b_2} \left[\frac{Q + \cosh 2 A \cos 2 A + j \sinh 2 A \sin 2 A}{\sinh 2 A \cos 2 A + j \cosh 2 A \sin 2 A} \right] \qquad (36)$$

This expression is simple enough to use for practical calculations.

As an example consider the calculation of the resistance and reactance of the copper bar shown in Fig. 23 which is about as large as one could use in a small size synchronous motor pole. The width of the bar has been made as small as is mechanically desirable, in order to keep the resistance as high as possible. The over-all depth of the bar is 9/16 in., width at top 1/16 in., at bottom 3/16 in. The dimensions on Fig. 23 are given in cms. as the calculation must be made in absolute units.

σ for cu. at 100 deg. cent. = 2240 abohms per cu. cm. at 60 cycles.

$$A = 2\pi \times 0.715 \sqrt{60 \div 2240} = 0.736,\ 2A = 1.472$$

$$Q = \frac{0.159 - 0.477}{0.159 + 0.477} = -0.50$$

$$\frac{\sigma(A + jA)}{a\,b_2} = \frac{2240\,(0.736 + j\,0.736)}{0.715 \times 0.159} = 20{,}500\underline{/45} \text{ deg.}$$

$$\begin{aligned}
\cosh 1.472 &= 2.294 \\
\sinh 1.472 &= 2.064 \\
\cos 1.472 &= 0.0986 \\
\sin 1.472 &= 0.995 \\
Q + \cosh 2A \cos 2A &= -0.2735 \\
j \sinh 2A \sin 2A &= j\,2.055 \\
\text{Numerator} &= 2.065\underline{/97.6} \text{ deg.} \\
\sinh 2A \cos 2A &= 0.204 \\
j \cosh 2A \sin 2A &= j\,2.284 \\
\text{Denominator} &= 2.29\ \underline{/84.5} \text{ deg.}
\end{aligned}$$

Therefore,

$$Z = \frac{20{,}500 \times 2.065}{2.29} \underline{/45 \text{ deg.} + 97.6 \text{ deg.} - 84.5 \text{ deg.}}$$

or

$Z = 18{,}500\ \underline{/58.1}$ deg.

and hence

$\therefore r$ eff. $= 18{,}500 \cos 58.1$ deg. $= 9750$ abohms/cm. length

x eff. $= 18{,}500 \sin 58.1$ deg. $= 15{,}700$ abohms/cm. length

On the basis of uniform current distribution the "nominal" reactance is

$$X = 17{,}750 \text{ abohms per cm.}$$

and the d-c. resistance is 4920. The ratio of $\dfrac{r \text{ eff.}}{r_{\text{d-c.}}}$ $= 1.98$ so that the T-shaped copper bar is an effective double squirrel-cage bar, even with a depth of only 9/16 in.

It is interesting to compare these values of resistance

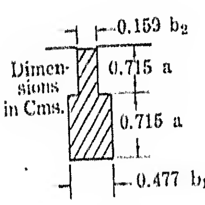

Fig. 24

and reactance with those of the ¼-in. square brass damper bar used in the 220-h. p., 277-rev. per min. synchronous motor calculated in Table I in the body of the paper, and to see what the characteristics of this motor would be if it were equipped with this double squirrel-cage damper bar.

Fig. 25 shows the dimensions of the ¼-in. by ¼-in. square slot actually used in the motor. Dimensions are given in inches. D-c. resistance at 100 deg. cent. = 18,400 abohms per cm. length.

Reactance = 8900 abohms per cm. length.

In addition to the slot reactance there is a tooth tip leakage reactance which in this case amounts to 3000 abohms per cm. This reactance corresponds to the

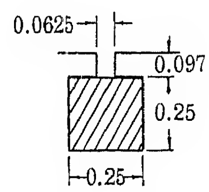

Fig. 25

first term in Equation (28). It must be added to the reactance of both types of bar. Table III gives a comparison of the resistance and reactance of the two bars at 60 cycles, taking the tooth tip leakage into account.

TABLE III

TABLE SHOWING RESISTANCE, REACTANCE, AND POWER FACTOR OF PLAIN BAR AND DOUBLE SQUIRREL-CAGE BAR

Type of bar	60-Cycle resistance	60-Cycle reactance	P. F.
Plain square brass bar........	18,400	11,900	0.84
Double cage copper bar.......	9,750	18,700	0.46

All values given in abohms per cm.

Discussion

R. H. Park: In the treatment of a complex problem such as the starting performance of a synchronous motor, it is necessary to employ simplifying assumptions to facilitate the calculation. At the same time, it is desirable to keep in mind just what assumptions have been employed.

On studying Mr. Putman's paper, I listed the assumptions that I found in it as follows: First, that the machine has a uniform air-gap. Second, that rotor bar reactance and resistance is equal for all rotor bars. Third, that only space fundamental of air-gap flux is considered. Actually, the rotor currents will produce a considerable amount of flux that is not space fundamental. This flux will be leakage reactance flux and will have a good deal to do in the determination of the distribution of rotor-bar currents. Fourth, the numerical value of all rotor-bar currents is assumed equal, even with the field closed. Fifth, the electrical phase angle in time of the rotor bar currents is assumed equal to their electrical space separation. This would be true in an induction motor, but actually, on account of the non-space fundamental air-gap flux, that is, leakage reactance flux, the phase angles will be different. Sixth, the effect of armature resistance is neglected. The effect of armature resistance will be important in determining the torque at half speed. In view of the approximations involved in these assumptions, it is, I think, particularly interesting that Mr. Putman is able to secure results which check tests.

P. L. Alger: Mr. Putman's ways of taking into account the width of pole arc of the machine, and the single-phase reaction of the field winding, are very interesting. And the close checks he gets with test results indicate that his method is at least approximately correct.

However, I feel that some of the bold approximations he has made seriously limit the generality of his conclusions. For example, he assumes the stator resistance to be zero, and thus entirely neglects the dip in torque at half-speed which occurs with any unbalanced rotor. Also, he asumes the current in every squirrel-cage bar to be the same, whereas, as a matter of fact, we know that the outside bars of a squirrel cage always carry more current during the starting period than the middle bars. Finally, he has combined the effects of the field and the squirrel cage by entirely neglecting the action of the squirrel cage in the field axis. That is, he has assumed the field winding to have such low impedance in the direct axis that the squirrel-cage current in this axis is negligible. These approximations are in addition to those he has mentioned in the paper.

Mr. Putman concludes from his study of double squirrel-cage synchronous motors that they are of no practical importance. While there is a measure of truth in this conclusion, there is much to be said on the opposite side of the argument. The difficulty of getting enough space in the pole tip to insert a satisfactory type of double squirrel-cage is the most fundamental part of the problem. The L-bar type of squirrel-cage Mr. Putman employed is not the best for this purpose, since the impedance cannot be made high enough to reduce appreciably the starting current with the field closed. By using an open-circuited, or idle, steel bar above the squirrel cage proper, a higher impedance can be obtained in the same space, and thus a material reduction of starting current can be secured. However, the reduction possible is not great enough to warrant the extended use of this construction.

The primary object of a double squirrel-cage is to reduce the starting current on full voltage sufficiently to avoid the use of a starting compensator. Therefore, all those machines whose starting currents are only about 20 per cent higher than permissible for full-voltage starting can be brought within the permissible class, and so can be made considerably cheaper by the use of the special construction. When the torques are compared on the basis of the same starting current, the two types then give comparable results.

Quentin Graham: I made an experimental investigation several years ago which showed a number of interesting facts concerning synchronous-motor starting performance. Chief among these was the enormous effect of the field winding on the speed—torque curve, a fact which is clearly shown in Mr. Putman's paper, and which, I believe, has not been appreciated fully by designing engineers. A typical set of curves illustrating this point is shown in Fig. 1 herewith. Curve A is the speed—torque characteristic of the motor with its field winding open-circuited so that the squirrel-cage winding furnishes all the torque. If the field winding is closed on itself the torque characteristics are as shown by Curve B. It will be seen that the torque at low speed is about the same but that it increases greatly for low values of slip. Curve C shows that with resistance in the field circuit the cusp is almost entirely removed although the torque is changed very little at the extremities of the curve. By making use of these characteristics, determined first experimentally, we have been able to use relatively high-resistance cage windings with consequent high starting torque and low starting current. The field winding takes care of the torque at low values of slip and the judicious selection of a field starting resistor prevents a dip in the curve at intermediate speeds. While these characteristics have been known and have been explainable in a general way by induction motor theory, Mr. Putman has published the first adequate mathematical treatment of the problem.

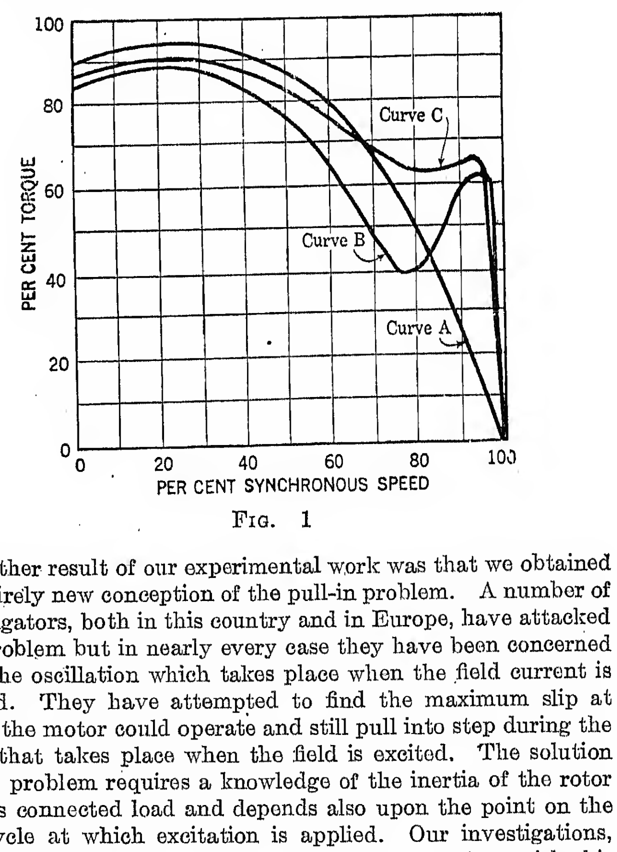

Fig. 1

Another result of our experimental work was that we obtained an entirely new conception of the pull-in problem. A number of investigators, both in this country and in Europe, have attacked this problem but in nearly every case they have been concerned with the oscillation which takes place when the field current is applied. They have attempted to find the maximum slip at which the motor could operate and still pull into step during the surge that takes place when the field is excited. The solution of this problem requires a knowledge of the inertia of the rotor and its connected load and depends also upon the point on the slip cycle at which excitation is applied. Our investigations, however, showed that we need not concern ourselves with this aspect of the pull-in problem except in rare cases. We found that if the motor could be brought to the upper branch of the speed—torque curve, that is, to a speed above the pull-out or unstable point on the curve, the application of excitation would always bring the rotor into synchronism. The problem thus became one of finding the induction motor characteristics rather than one dealing with the purely pull-in phenomenon.

Mr. Alger, in his discussion, has called attention to Mr. Putman's omission of the stator resistance and has pointed out that this may give an error in the torque at half-speed. I have developed the equation for torque including the stator resistance

and have substituted values for a few cases. While there is a slight dip in the curve at half-speed, I have concluded that it is of negligible importance.

H. V. Putman: Before this theoretical investigation was started at all, the company with which I am associated (thanks to the painstaking efforts of Mr. Quentin Graham) has, for a number of years, accumulated a vast amount of experimental data on the starting performance of synchronous motors. These data were of great assistance in building a theoretical structure on which to base calculations of starting performance.

Both Mr. Alger and Mr. Park mentioned the fact that I neglected the stator resistance and Mr. Alger says that I did this without saying anything about it in the paper. I stated very clearly that this assumption was being made in order to simplify the theory. We were well aware of the effect of the stator resistance at half-speed and I stated that Mr. Graham had worked out the theory taking the stator resistance into account. He has calculated curves on this basis which show the dip at half-speed. However, a review of a great many speed-torque curves which we have made, disclosed the fact that none of them shows a distinct dip or cusp at half-speed. At half-speed there are usually a few test points which appear erratic. Sometimes there is a point above the curve, sometimes one below, but we have never been able to obtain a test curve which showed distinctly a dip at half-speed. The dip does exist, but the fact that it can't be obtained experimentally shows that it is so small as to be negligible. This is also borne out by the fact that since we have been building real damper windings, we have never had a case of trouble where a motor stuck at half-speed and refused to come up to full-speed. If there were any appreciable dip in the torque at half speed, it seems likely that, with the increased severity of synchronous-motor applications and hence more severe starting duty, we would have had some cases of sticking at half-speed.

Both Mr. Alger and Mr. Park say I assume the same current in each bar and Mr. Alger says that I neglect the effect of the squirrel-cage in the axis of the field winding. This shows that both Mr. Alger and Mr. Park do not clearly understand the theory of the symmetrical-coordinate method and they have not read my paper carefully. They have this theory mixed up with Blondel's two-reaction theory. One speaks of the direct and transverse axes in the two-reaction theory, but not when dealing with the symmetrical-coordinate method.

What I did assume, was this: There are two fluxes rotating in the gap, one in the positive direction and one in the negative. Both cut the damper bars. Due to the positive flux, there are damper-bar currents set up which are all equal, provided the damper bars all have the same resistance and reactance, and are apart in time phase by the space angle between the bars. These produce a positively rotating m. m. f. which I represent by I_{2pp} and a negatively rotating m. m. f. represented by I_{2np}. Similarly, the negative flux in the gap produces additional damper-bar currents all of which are equal and which in turn produce two more m. m. fs., a negative m. m. f. represented by I_{2nn} and a positive m. m. f. represented by I_{2pn}. Since I_{2pp} and I_{2pn} rotate in the same direction, they combine to make the resultant I_{2p} which is the positively rotating rotor m. m f. Similarly, I_{2np} and I_{2nn} combine to form the negatively rotating rotor m. m. f. From this point on I deal only with m. m. fs. But if one combines the bar currents due to the positive flux, with those due to the negative flux, the combined currents which result are not equal in each bar; neither are they apart in time by the space angle of the bars.

Mr. Alger's statement that I neglect the effect of the damper bars in the axis of the field winding, amounts to the same thing as saying that in an induction-motor diagram, if one represents the rotor-bar current by a single vector I_b, he is neglecting the effect of the bars which constitute a phase at right angles to I_b. But we all know that a polyphase m. m. f. or current can be represented by a single vector and the problem handled as though it were a single-phase, but because we handle it as single-phase it doesn't mean that we neglect the phase at right angles to it. If Mr. Alger will read my paper carefully he will see that I have made no such approximation.

Mr. Park says that my theory assumes that all bars have the same resistance and reactance. This is not necessarily true. My theory begins on the basis of a rotor having a definite rotor resistance, rotor reactance and single-phase action factor, K. It is true that it may be a little more difficult to get the rotor-bar resistance, reactance, and K, if the bars are all different, than it is when they are all alike. I showed in my paper how the value of K is obtained when they are all alike to give a general idea of the problem; however, I did not include in my paper any explanation of the calculation of the several motor constants as explained in one of the foot-notes in my paper. The handling of cases where damper bars of different resistances and reactances are used in the same field pole, is simply a problem in calculating the values of rotor resistance, rotor reactance and K. We often build machines with bars of at least two different materials and usually the bars at the tip of the pole are nearer the surface and

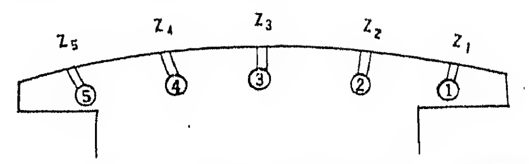

FIG. 2—SYMMETRICAL GROUP OF DAMPER BARS

have less reactance than those in the middle. In all such cases, it is only necessary to calculate an equivalent bar and then proceed as if all bars were like the equivalent bar.

An example calculation of this kind, is as follows: In the accompanying Fig. 2, let Z_1 equal the impedance of bars No. 1 and No. 5. Let β_1 equal phase angle of bars No. 1 and No. 5, that is, $\beta_1 = \tan^{-1} \frac{X_1}{r_1}$ where $Z_1 = \sqrt{x_1^2 + r_1^2}$. Similarly, let Z_2 equal the impedance of bars No. 2 and No. 4 and let β_2 be the corresponding phase angle. Let Z_3 be the impedance of the middle bar and β_3 its phase angle.

Calculate
$$\varphi_1 = \beta_3 - \beta_1$$
$$\varphi_2 = \beta_3 - \beta_2$$

Then calculate
$$X = \left(2 \frac{Z_3}{Z_1} \sin \varphi_1 + 2 \frac{Z_3}{Z_2} \sin \varphi_2 \right)$$
$$Y = \left(1 + 2 \frac{Z_3}{Z_1} \cos \varphi_1 + 2 \frac{Z_3}{Z_2} \cos \varphi_2 \right)$$

Then calculate $B = \sqrt{X^2 + Y^2}$ and $\beta^1 = \tan^{-1} \frac{X}{Y}$

The equivalent bar has an impedance of $\frac{5}{B} Z_3$ and a phase angle of $\beta_3 - \beta^1$.

Small differences in the impedances of the several bars make only a very slight change in K. When it is thought necessary to calculate a new K, we have a fairly elaborate formula involving the several bar impedances, phase angles, and the space angle between the bars. Usually, this is not necessary.

I did not mean to say that the double-squirrel-cage synchronous motor has no practical value. What I did say, is that it is more desirable to limit the inrush by the use of a high-resistance damper rather than by the use of high reactance because this method gives a higher average torque per kv-a. In higher-speed motors where there is a greater depth of pole head, the double squirrel cage can be used to greater advantage and, as Mr. Alger says, is of use in bringing many ratings within the full-voltage starting class.

Synopsis.—The first part of this paper is devoted to the purpose of presenting a clear conception of the internal voltages, currents, heating, and armature reactions as related to the physical structure of the simple converter and as related to the passage of time. These may be styled "space" and "time" relations. "Space" relations are indicated by means of diagrams representing as nearly as possible the physical structure of the converter. "Time" relations are shown by conventional curves and vectors.

The accepted mathematical expressions for voltage ratios, heating effect of currents, and armature reaction imply that certain facts be disregarded. This is done in order to simplify their development.

The mathematical treatment developed in the appendixes to this paper includes most of these disregarded factors and makes it possible to evaluate them.

This treatment is based on the method of "harmonic analysis" by which any regularly repeating function may be represented.

The general theory of the synchronous converter has been given less attention in the technical press than has that of the more widely used purely alternating current machines. Moreover, the synchronous converter has been treated in less detail in our technical colleges and engineering schools. It seems, therefore, that the engineering fraternity in general may not have as clear a conception of phenomena taking place in the converter as in the other types of electrical machines.

It is the purpose of this paper, first, to present a clear and simple explanation of the internal actions and reactions of the synchronous converter without resorting to laborious mathematics; and second, to set forth for those who will be interested the complete mathematical treatment by harmonic analysis.

The subject divides naturally into three parts:
Voltage Relations,
Heating Effect of Current,
Magnetomotive Force Relations.

Voltage Relations

The ratio of effective a-c. voltage for any number of phases may be determined by representing the voltage of each armature coil vectorially as in Fig. 1 where the voltage of the complete armature is represented by a regular polygon of vectors which is so related to the two field poles that the magnitude of the voltage of any coil or any phase is measured by the projection of the vector or vectors upon the axis $(y - y)$ which lies at right angles to the axis of the poles. This axis is usually called the "quadrature axis."

This combination vector diagram and pole drawing is in accord with the physical facts, in that maximum instantaneous voltage is indicated for a given vector (such as c) when it is directly under the center of a pole. Likewise the maximum voltage is generated in a coil when its sides are passing under the center of a pole.

It is evident that the maximum instantaneous voltage across any diameter $(A\,B)$ occurs when that diameter coincides with the "quadrature axis" which is also the brush or neutral axis. Hence the d-c. voltage at the commutator is numerically equal to the maximum instantaneous voltage of an a-c. diameter, and the ratio of effective a-c. diametral voltage to direct current is the ratio of the effective value to the maximum value of the a-c. wave. This ratio is $\frac{1}{\sqrt{2}}$ or 0.707 for the ideal condition of 100 per cent efficiency and a pure fundamental sinusoidal a-c. voltage.

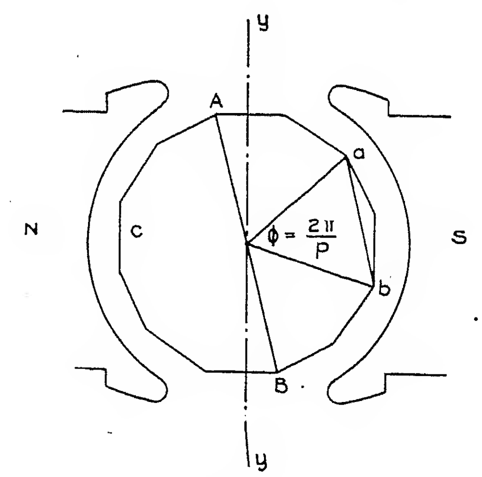

Fig. 1

If the converter has p phases per pair of poles, then each phase covers an angle $\phi = 2\,\pi/p$, and the cord $a\,b$ subtended by this angle is a measure, under ideal conditions, of the maximum a-c. voltage induced in the phase. It is easily seen from the geometry of Fig. 1 that the ratio of the d-c. voltage $A\,B$ to the maximum a-c. phase voltage $a\,b$ is

$$\frac{A\,B}{2\,(A\,B/2)\sin\phi/2} = \frac{1}{\sin\pi/p}$$

or in terms of the effective value of the a-c. voltage it is $\sqrt{2}/\sin\,(\pi/p)$; so that the normal voltage ratio of a

1. Both of the General Electric Co., Schenectady, N. Y.

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

synchronous converter is primarily fixed by the number of phases p. It is well to point out, however, that this result has been arrived at by assuming a sinusoidally distributed field flux passing through zero at infinitely thin brushes; an infinitely distributed ring or full pitch drum winding; zero armature reaction; zero armature impedance; and a magnetic circuit of constant reluctance for all positions of the armature.

These ideal conditions are almost never realized in commercial machines because of practical limitations, some of which will be discussed.

The necessity of providing a neutral zone for commutation and the space requirements of the field coils both demand a shorter pole arc than corresponds to a sinusoidal distribution of the flux. The result is a slightly flattened a-c. voltage wave which has a higher ratio of effective to maximum; the latter always being equal to the d-c. voltage. It will be found that the majority of commutating pole converters have a no-load diametral ratio of approximately 0.725 and, due

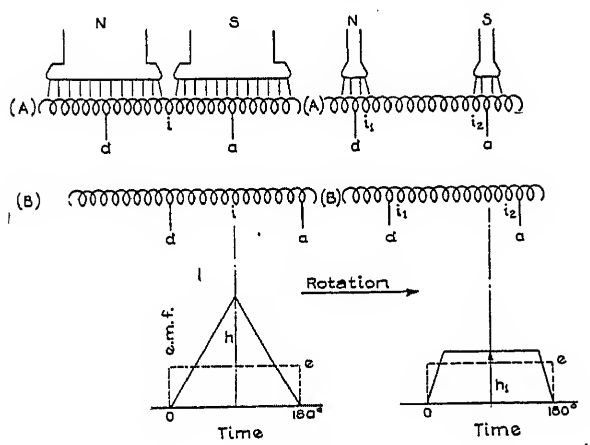

FIG. 2

principally to resistance losses, a full load ratio of 0.74 to 0.75.

The effect upon wave shape of varying the pole face arc can be made plain by considering two extreme cases shown in Fig. 2.

Here is represented poles having an arc of 180 deg. and others, a very short arc. It is assumed that the flux density is constant across each pole face and of such value that the same effective a-c. voltage is generated across a diameter of the armature winding.

It is evident that the diametral phase of winding $d\,i\,a$ in position A under the long arc poles has equal and opposite voltages generated in the two halves $d\,i$ and $i\,a$ so that the total voltage is zero. Now equal voltages are generated in all conductors and the number of conductors under each pole varies directly with time and position of the phase in space and therefore the total voltage of the phase $d\,i\,a$ will be a straight line function of time and space position as shown. The maximum e. m. f., h, is generated when the phase is central with the pole S, position B. The effective a-c. value of this voltage is e and the maximum or d-c. is h which appears continuously between two fixed points between the pole tips where brushes may bear on a commutator connected to the winding.

Now similarly under the short arc poles equal and opposite voltages are generated in $d\,i_1$ and $i_2\,a$ in position A and the resultant voltage is zero. When the phase has moved the distance $d\,i_1$ coils in it will be under the influence only of pole S and the total voltage between d, a will be constant until the tap d reaches the pole S. The net voltage of this diametral phase will be trapezoidal, as shown, with a maximum value h' and the same effective value e as in the previous case.

Thus the effect of increasing the pole arc, keeping the same effective value of a-c. voltage, is greatly to increase the d-c. voltage; and vice versa.

The regulating pole converter uses this principle for varying the d-c. voltage with constant effective a-c. voltage impressed. A variation of the net pole arc is secured by constructing each pole and pole face in two adjacent parts, one larger "main pole" and one smaller "split" or "regulating" pole. The exciting field of the latter may be varied, or even reversed, which results in a net effect equivalent to varying the total pole arc.

There is a number of factors which affect voltage ratio as shown in detail in the appendix. These are:

Number of phases,
Flux distribution or "field form,"
Flux shift relative to brush position,
Flux pulsation caused by armature reaction pulsating m. m. f.,
Flux pulsation caused by variation in reluctance due to position of slots,
Brush shift relative to field flux position,
Brush width determining the number of coils short-circuited,
Brush contact resistance,
Armature coil winding pitch,
Armature coil distribution,
Armature impedance.

HEATING EFFECT OF ARMATURE CURRENT

Before considering the explanation of armature heating, it is advisable to mention the fundamental definition of "motor" and "generator" action.

Generator action in any dynamo-electric machine is the act of current flowing through it in the same direction as, and by means of, the internal "induced" e. m. f.

Motor action in any dynamo-electric machine is the act of current flowing through it in the opposite direction to the internal "induced," and by means of an external impressed e. m. f.

In the converter it is convenient to regard the direct current as due to generator action, and the alternating current as due to motor action. The actual current in any conductor results from superposition of these two.

A bipolar converter, having for convenience a

Gramme ring armature winding, is represented in Fig. 3. The mechanical rotation of the armature is clockwise. Zero time is selected as the instant when the center of the phase $a\ b$ coincides with the center line of the brush.

The voltage generated under each pole in the con-

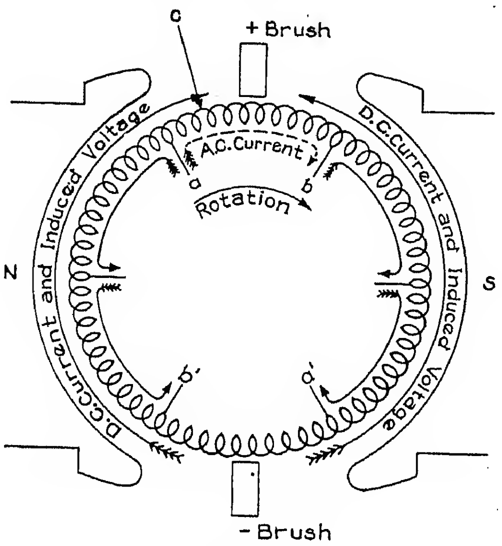

Fig. 3

ductors passing under it is directed from the negative brush toward the positive brush through both of the armature circuits.

The specific case of a six-phase converter is assumed, where the phase $a\ b$ occupies 60 electrical degrees.

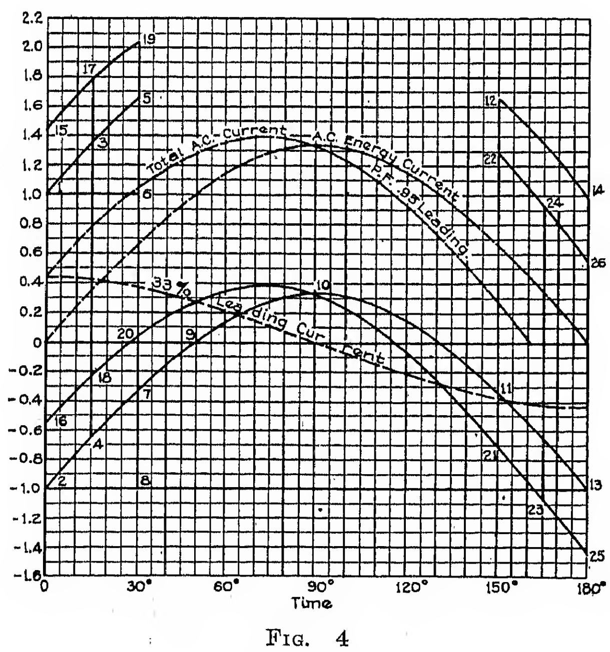

Fig. 4

With the phase in the position of zero voltage, corresponding to zero time in Fig. 4, there is no alternating current at unity power factor. But when the phase moves toward the pole S the voltage will be induced in the direction from the tap b toward a.

Now the a-c. motor, or input current, must flow from a to b in opposition to this induced voltage. At the same time the d-c. generator current is flowing from a to the positive brush in the same direction as that in which the alternating current is just starting to flow and the two currents are added. This condition holds true in any part of the trailing half of the phase which has not yet passed under the brush.

The magnitudes and relations of these currents in time are shown in Fig. 4. The direct current, taken as unity, is represented by the line 1, 6, 8, 13 for the tap coil a which is commutated at point 6 after the 30 deg. of time required for a to rotate to the brush.

The alternating current (dotted curve), since it flows in the same direction, adds to the direct current in coils

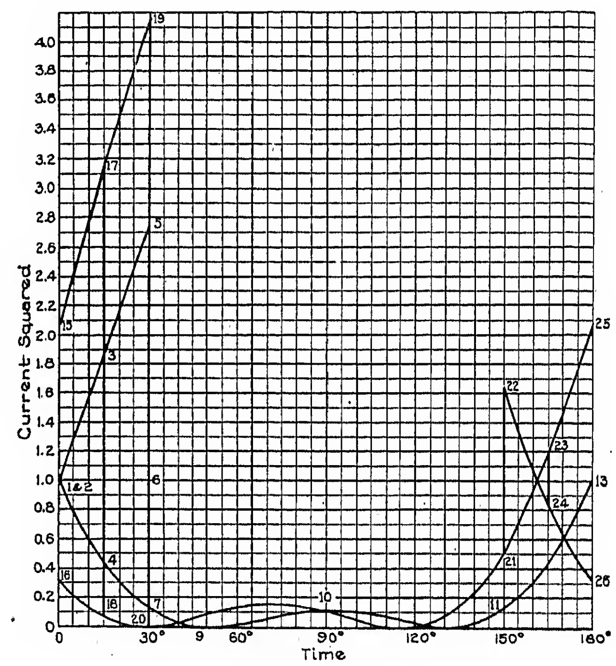

Fig. 5

not yet commutated; hence the current curve of the tap coil a is 1, 3, 5 (commutates), 6, 7, 9, 10, 11, 13.

The heating effect of this current is proportional to its square as shown in the corresponding Fig. 5 by the similarly numbered curve 1, 3, 5, 6, 7, 9, 10, 11, 13. The total or integrated heating is represented by the area under this curve.

In like manner the current in coil c half way between a and the phase center may be traced. This coil will commutate after 15 deg. of time. The current is 1, 3 (commutates), 4, 7, 10, 11, 13, Fig. 4, and the heating similarly numbered in Fig. 5.

The current and heating of the center coil which commutates at zero time is similarly 1, 2, 4, 7, 9, 10, 11, 13.

The current and heating of tap coil b may be traced through in the same manner. The direct current which has already been commutated flows in the opposite direction to the alternating current for 150 deg. of time required for the tap to rotate to the negative brush

The total current follows 2, 4, 7, 9, 10, 11, commutates, and follows 12, 14. One-half cycle or 180 deg. of time then finds tap b at b', Fig. 3. It is evident that this current cycle is the exact equivalent of that shown for tap coil a; similarly, it is evident that any two coils equidistant from the center of the phase are subject to the same heating at unity power factor.

The effect of power factor upon the heat losses is more important in the converter than it is in any machine that carries alternating current alone.

Fig. 4 shows a certain amount of leading reactive

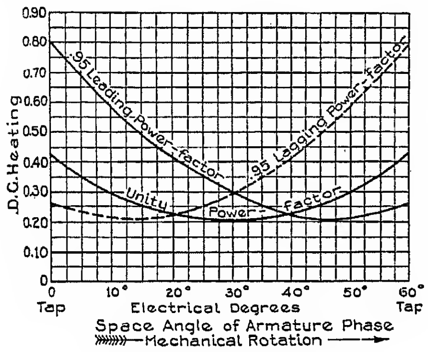

FIG. 6

current which, combined with the same energy current as before, produces the total alternating current shown. It is evident that this leading current has its highest values when the phase $a\ b$ is in the position of zero time, and that this current adds to the direct and alternating energy currents in that part of the phase between the tap a and the d-c. brush.

The current in any coil throughout 180 deg. of time or rotation may be determined as before.

For instance, take the tap coil a. The current is represented by 15, 17, 19 (commutates), 20, 21, 23, 25. The heat loss at any instant of time is represented similarly in Fig. 5.

The current and heating of any coil between tap a and the center of the phase may be traced through the same curves except that commutation will take place sooner at a point between 15 and 19 determined by the distance of the coil from the brush.

The center coil of the phase which is commutated at zero time will carry current and heating indicated by curves 16, 18, 20, 21, 23, 25, Figs. 4 and 5.

The current and heating relations in the other, or leading half of the phase (center to tap b), follow a different course when the power factor is not unity. The tap coil b, for example, has already been commutated, so that the current starts at 16 and for 150 deg. of time follows the same curves 16, 18, 20, 21 (commutates) and then follows 22, 24, 26, Fig. 4.

The heating similarly follows 16, 18, 20, 21, 22, 24, 26 and the total heat is proportional to the area under it.

In like manner any other coil located between tap b and the center of the phase will carry current following the same variation except that it will be commutated later than the tap coil b. This is represented for one such coil by 16, 18, 20, 21, 23 (commutates), 24, 26 in both Figs. 4 and 5.

The averaged total heating in any coil in a phase, expressed as per cent of the loss with direct current alone in the armature, is shown in Fig. 6, for power factor = 1.0, 0.95 leading, and 0.95 lagging. It will be noted that the heat losses at unity power factor are symmetrically distributed while at any power factor other than unity the distribution is not symmetrical. Leading current causes the coils just "ahead" of the tap to overheat while lagging current reverses all these relations and overheats the coils just "behind" the tap. This fact furnishes a means of determining whether a converter armature winding has been damaged by leading or lagging power factor current.

Another important fact shown by these curves is that the heating of the coils near the tap is increased much more rapidly by low power factor than in any other type machine. In this instance of 0.95 power factor the tap heating increases from 0.43 to 0.80 or 85 per cent, whereas in any other device carrying alternating current alone, the increase is only 11 per cent. It may be stated in a general way that the tap coil heating of the converter is increased several times as fast by a change of power factor as in pure a-c. apparatus.

ARMATURE REACTION

Several of the best known textbooks treating of the armature reaction in the synchronous converter

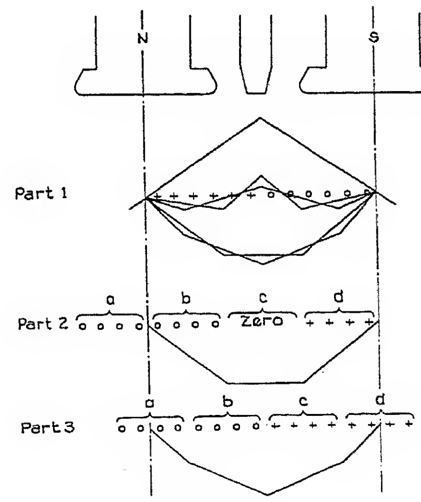

FIG. 7

erroneously apply a "distribution factor" to the d-c. armature reaction, and neglect the factor $4/\pi$ which is the ratio of the sinusoidal component of a square wave to the amplitude of the wave itself. These errors lead to the false conclusion that the a-c. and d-c. armature reactions completely cancel each other in line with the interpoles.

As a matter of fact the armature reaction of a con-

verter consists of a steady component and a series of even $M(p)$ time harmonics. Their effect on commutation and flux distortion requires that they be given due consideration in design.

A conception of the physical relations and magnitude of armature reaction in the converter may be formed by referring to Fig. 7. The direct and alternating currents and their m. m. fs. are considered separately, and then superimposed to form a resultant. A six-phase converter has been chosen, with full pitch, infinitely distributed windings. Thus each phase belt covers 60 electrical degrees and differs by the same amount in time phase from the adjacent belt.

In part I the direct currents are represented as flowing into the plane of the paper under pole N and out of this plane under pole S. According to the usual convention these currents are assumed to be paired so as to constitute turns about the neutral or quadrature axis. The m. m. f. of these direct currents is thus a triangular wave.

In a similar way the m. m. f. distribution due to the alternating current can be obtained, as shown in parts II and III, for two different positions of the armature.

Assuming for convenience unity power factor, and choosing c as reference phase, the currents may be represented as

$i_a = I \sin(\omega t - 120 \text{ deg.}),\ i_c = I \sin(\omega t)$

$i_b = I \sin(\omega t - 60 \text{ deg.}),\ i_d = I \sin(\omega t + 60 \text{ deg.})$

where ωt is the displacement of the midpoint of c from the quadrature axis. Thus for $\omega t = 0$ phase belt c is in the position of zero voltage and current, that is, centered on the neutral axis. The other two currents are

$$i_b = I \sin(0 - 60 \text{ deg.}) = -0.866\, I$$

$$i_d = I \sin(0 + 60 \text{ deg.}) = +0.866\, I$$

Thus the currents i_b and i_d at this particular instant are equivalent to magnetizing turns around the neutral axis, and give rise to trapezoidal distribution of m. m. f.

When the common tap of b and c is on the neutral axis 30 deg. later ($\omega t = 30$ deg.) the currents are.

$$i_a = I \sin(30 \text{ deg.} - 120 \text{ deg.}) = -I,$$

$$i_b = I \sin(30 \text{ deg.} - 60 \text{ deg.}) = -I/2$$

$$i_d = I \sin(30 \text{ deg.} + 60 \text{ deg.}) = +I,$$

$$i_c = I \sin(30 \text{ deg.}) = +I/2$$

At this instant i_a pairs with i_d, and i_b pairs with i to form two bands of magnetizing turns about the neutral axis, and give rise to the polygon distribution of m. m. f. shown in part III.

These two m. m. fs., corresponding to different positions of the armature, may be superimposed on the d-c. diagram in part I and combined with it to produce the corded triple space harmonic of resultant reaction, which oscillates between these two extremes for every 30-deg. rotation of the armature, giving a 6th time harmonic.

These 6th harmonics of m. m. f. are responsible for the appearance of the "tap frequency pulsation" in the external circuit of the converter when the machine is loaded. They also increase the core loss and losses in the amortisseur winding.

There is a steady term of armature reaction under the interpole represented by the average of the two extremes shown in part I, Fig. 7. This must be compensated by extra turns on the interpole. Its small value compared to the d-c. reaction is the reason why interpoles were not adopted for converters until after their application to straight d-c. machines.

Note the presence of the cross magnetizing m. m. f. under the main poles. This demands an increased excitation with load, (due to saturation), which must be supplied either by increased field excitation, or by reactive alternating current and a change of power factor.

It is shown in Appendix III that the resultant reaction under the main poles varies as $\tan\theta$, where $\cos\theta$ is the power factor. It is zero at unity power factor but has a definite value at any other power factor; being opposed to the field flux when due to leading power

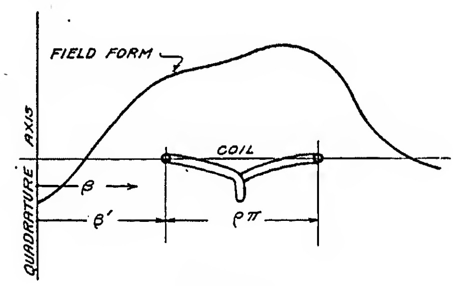

Fig. 8

factor and vice versa when due to lagging power factor.

The mathematical treatment of armature reaction by the method of harmonic analysis is given in Appendix III.

Appendix I

Voltage and Current Ratios

The A-c. Voltage. In Fig. 8 consider the armature coil of pitch ρ and n turns, which at any time t is located an angle β' from the quadrature axis. Let the flux density through which this coil is moving at synchronous speed ωt be specified by the Fourier series.

$$B = \sum_{1}^{\infty}{}^{\kappa} B_\kappa \sin \kappa (\beta + \gamma_\kappa) \qquad (1)$$

The flux included by the coil is

$$\phi = \frac{2\, r\, l}{P} \int_{\beta'}^{\beta' + \rho\pi} B \,.\, d\beta \qquad (2)$$

where

r = air-gap radius

l = effective length of armature stacking

P = number of poles

This flux induces in the coil the voltage

$$e = \frac{-n}{10^8}\frac{d\phi}{dt} = \frac{-4\,r\,l\,n}{P\,10^8}\sum_{1}^{\infty}{}_{\kappa} B_\kappa \sin\frac{\kappa\,\rho\,\pi}{2}\,.$$

$$\cos\kappa\left(\beta' + \gamma_\kappa + \rho\frac{\pi}{2}\right)\cdot\frac{d\beta'}{dt} \qquad (3)$$

But if (β_r) is the position of the coil at $(t = o)$, then since it is moving at synchronous speed

$$\beta' = \beta_r + \omega\,t \text{ so that } \frac{\partial\beta'}{dt} = \omega = 2\,\pi\,f \qquad (4)$$

Substituting (4) in (3)

$$e = \frac{-4\,l\,f\,\tau\,n}{10^8}\sum_{1}^{\infty}{}_{\kappa} B_\kappa \sin\frac{\kappa\,\rho\,\pi}{2}\,.$$

$$\cos\kappa\left(\omega\,t + \beta_r + \gamma_\kappa + \rho\frac{\pi}{2}\right) \qquad (5)$$

where

$$\tau = 2\,\pi\,r/P = \text{pole pitch}$$

The total voltage of a phase belt of c such coils uniformly distributed around the armature by an angle σ between adjacent coils sides is

$$e_p = \frac{-4\,l\,f\,\tau\,n}{10^8}\sum_{1}^{\infty}{}_{\kappa}\sum_{0}^{C-1}{}_{r} B_\kappa \sin\frac{\kappa\,\rho\,\pi}{2}\,.$$

$$\cos\kappa\left(\omega\,t + \beta_o + \gamma_\kappa + \rho\frac{\pi}{2} + r\,\sigma\right) \qquad (6)$$

where β_o is the position of the first coil of the phase

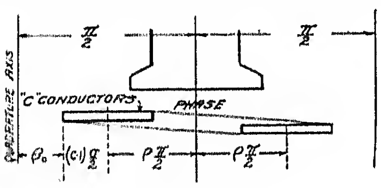

Fig. 9

belt at $t = o$, and r refers to the rth coil after the first so that

$$\beta_r = \beta_o + r\,\sigma \qquad (7)$$

By the geometric method of Appendix IV the r summation may be evaluated, yielding

$$e_p = \frac{-4\,l\,f\,\tau\,n\,c}{10^8}\sum_{1}^{\infty}{}_{\kappa} B_\kappa \sin\frac{\kappa\,\rho\,\pi}{2}\left(\frac{\sin\frac{c\,\kappa\,\sigma}{2}}{c\,.\,\sin\frac{\kappa\,\sigma}{2}}\right)$$

$$\cos\kappa\left[\omega\,t + \beta_o + \gamma_\kappa + \rho\frac{\pi}{2} + (c-1)\frac{\sigma}{2}\right] \qquad (8)$$

If time is counted from the instant that the phase is centrally located with respect to the pole, then it is seen from Fig. 9 that

$$\beta_o = (1-\rho)\frac{\pi}{2} - (c-1)\frac{\sigma}{2} \qquad (9)$$

It is customary to write

$$C_{p\kappa} = \sin\frac{\kappa\,\rho\,\pi}{2} = \text{pitch coefficient of the } \kappa th \text{ harmonic} \qquad (10)$$

$$C_{d\kappa} = \frac{\sin\frac{c\,\kappa\,\sigma}{2}}{c\,.\,\sin\frac{\kappa\,\sigma}{2}} = \frac{\sin\frac{\kappa\,\pi}{p}}{c\,\sin\frac{\kappa\,\pi}{c\,p}} = \text{distribution coefficient of the } \kappa th \text{ harmonic} \qquad (11)$$

where p is the number of phases per pair of poles. If $\sigma \to o$ the distribution is said to be "infinite" and the coefficient C_{dk} approaches its limiting value

$$(C_{d\kappa})_{\sigma\to 0} = \frac{\sin\frac{\kappa\,\pi}{p}}{\frac{\kappa\,\pi}{p}} \qquad (12)$$

For lower values of k, Equations (11) and (12) are practically identical, so that in subsequent expressions, where the higher harmonics may be neglected, Equation (12) will be used, since it facilitates the calculations.

By (9), (10), and (11), Equation (8) may be written

$$e_p = \frac{-4\,l\,f\,\tau\,n\,c}{10^8}\sum_{1}^{\infty}{}_{\kappa} B_\kappa\,C_{p\kappa}\,C_{d\kappa}\cos\kappa\left(\omega\,t + \gamma_\kappa + \frac{\pi}{2}\right) \qquad (13)$$

and the fundamental component of e_p is

$$e_1 = \frac{4\,l\,f\,\tau\,n\,c}{10^8} B_1\,C_{p1}\,C_{d1}\sin(\omega\,t + \gamma_1) \qquad (14)$$

As a matter of convenience in the argument of this discussion let us introduce the notation

$$M\,(p) = \text{multiple of } p \qquad (15)$$

It is of special importance to notice that the $\kappa = M\,(p)$ harmonics do not contribute to the terminal voltage of the phase, since by (11) the coefficient $C_{d\kappa}$ is zero for these harmonics.

If the fundamental is the only component present in the a-c. voltage applied at the slip rings, then such harmonic currents will flow as will consume by their impedance drops and their armature reaction, those harmonic generated voltages which are not wiped out by the winding coefficients C_{dk} and $C_{p\kappa}$. If resistance be neglected and if the flux contributed by the armature reactance and reaction be considered as part of the *resultant* field form, then we may say that

The resultant field form can contain only those harmonics for which

$$\left.\begin{array}{ll}\text{(a)} & C_{pk} = 0 \text{ or} \\ \text{(b)} & C_{dk} = 0 \text{ (includes all the } M\,(p) \text{ harmonics)}\end{array}\right\} \qquad (16)$$

and this statement holds, within its limitations, for a machine loaded or unloaded.

In commercial machines the pitch ρ is near unity, so that the *even* harmonics are wiped out thereby, and the neutralizing currents are therefore composed only of *odd*

time harmonics, even though the field form contains very large even space harmonics.

In practise, the a-c. line voltage is nearly a pure sinusoid, but almost without exception there is a transformer bank between the line and the converter. The transformer may usually be considered as short-circuited at its primary terminals to all harmonics, since the impedance of the connected system is very low. The harmonic currents are then limited by the combined impedance of the transformer and converter, and the voltage drops in the transformer due thereto appear as a harmonic voltage across the slip rings. Thus due to the presence of the transformer the resultant field form may contain other harmonics than those allowed by (**16**), but they are of no great importance. They affect both the a-c. and d-c. voltages.

The D-c. Voltage. Fig. 10 shows the brush b shifted an angle ψ from the quadrature axis. Since the coils

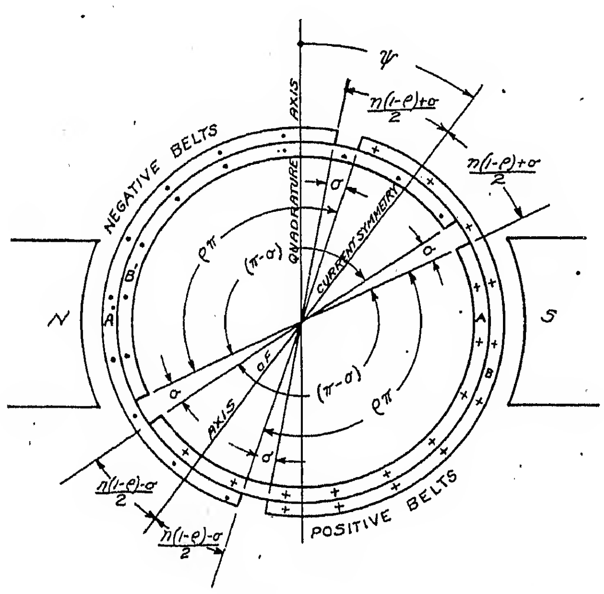

FIG. 10

have a pitch ρ the mean position of the belt of conductors connecting adjacent brushes extends from

$$\left(\psi - \rho\,\frac{\pi}{2} + \frac{\pi}{2} + \frac{\sigma}{2}\right) \text{ to } \left(\psi - \rho\,\frac{\pi}{2} + \frac{3\,\pi}{2} - \frac{\sigma}{2}\right) \tag{17}$$

The belt contains π/σ conductors. Its instantaneous position will vary periodically by half the angle σ between coil sides either side of the mean position specified above. This variation, which is partly responsible for the "tooth ripple" observed in the voltage wave, will be neglected in this discussion.

Equation (**8**) gives the voltage induced in a belt of c conductors at any instant t. By substituting

$$\left.\begin{aligned} \omega\,t &= 0 \\ c &= \pi/\sigma \\ \beta_o &= \psi - \rho\,\frac{\pi}{2} + \frac{\pi}{2} + \frac{\sigma}{2} \end{aligned}\right\} \tag{18}$$

we obtain the equation for the d-c. voltage.

$$E_{DC} = \frac{+\,4\,l\,f\,\tau\,n}{10^8}\sum_1^{\infty}{}_{\kappa}\,B_\kappa\,C_{p\kappa}\left(\frac{\sin\dfrac{\kappa\,\pi}{2}}{\sin\dfrac{\kappa\,\sigma}{2}}\right)\cdot\cos\kappa\,(\psi + \gamma_\kappa) \tag{19}$$

Here the $M\ (p)$ harmonics are not wiped out by distribution, but contribute to the d-c. voltage. But the even harmonics are completely wiped out by the distribution factor $\sin\dfrac{\kappa\,\pi}{2}$.

The Voltage Ratio. The ratio of the direct current to the effective value of the fundamental of the a-c. voltage, as obtained from Equations (**14**) and (**19**), is

$$\frac{E_{DC}}{E_1} = \frac{\sqrt{2}\cos(\psi + \gamma_1)}{\sin\dfrac{\pi}{p}}$$

$$+\,\sqrt{2}\sum_2^{\infty}{}_{\kappa}\,\frac{B_\kappa\,C_{p\kappa}\,\sin\dfrac{\kappa\,\pi}{2}\,\sin\dfrac{\sigma}{2}}{B_1\,C_{p1}\sin\dfrac{\pi}{p}\,.\,\sin\dfrac{\kappa\,\sigma}{2}}\cos\kappa\,(\psi + \gamma_\kappa)$$

$$= \sqrt{2}\,\Delta/\sin\,(\pi/p) \tag{20}$$

Equation (**20**) is more specifically written, according to (**16**), by substituting m for κ and dropping the limits of summation, where m is any harmonic for which $\kappa = M\ (p)$.

An inspection of this equation shows that the voltage ratio of a synchronous converter is fixed by the following conditions:

a. The number of phases p in the ratio $\sqrt{2}/\sin\,(\pi/p)$, called the *normal* ratio of the synchronous converter.

b. The brush shift ψ, limited because of sparking for shifts large enough to affect the ratio more than a few per cent.

c. The flux shifts γ_1 and γ_m have the same effect, theoretically, as the brush shift ψ, but are more feasible practically since the brush may be left in the artificial neutral zone of the commutating poles, and sparking thereby avoided.

d. Superposition of those flux harmonics of odd order which are multiples of the number of phases per pair of poles. The voltages due thereto are cancelled out in the phase by the distribution of the winding, but appear in the d-c. voltage and thus change the ratio. Other harmonics in the flux may be used to change the ratio, but not so effectively, since they change both the a-c. and d-c. induced voltages, and consequently, they cause harmonic currents to flow which tend to neutralize the flux harmonics by armature reaction and reactance and increase the transformer heating, but may or may not increase the converter heating.

Note that the even multiples of p harmonics are

ineffective since they are cancelled out entirely in the d-c. voltage by the factor $\sin m\,\pi/2$. For this reason it is impossible to vary the voltage of a two-phase, four-phase, or two n-phase machine by superposition of multiple of p harmonics. However the voltage of a six-phase machine may be varied by superimposing the odd multiple of (3) harmonics, provided that the transformer connections are open-circuited to the flow of the third harmonic current and its multiples.

Such connections are equivalent to the use of a six-phase converter as a duplex three-phase machine.

Items c and d constitute the regulating pole method of voltage variation.

e. The armature winding factors are the angle σ between adjacent coil sides, the per cent pitch ρ and the pitch coefficients $C_{\rho 1}$ and $C_{\rho m}$. In commercial machines σ is usually less than 12 deg., and $1.00 > \rho > 0.95$.

In addition to the above there are several other influences on the voltage ratio which do not appear in the equation. They are:

f. The brush short-circuits the voltage across its bearing arc, but this decrease of net voltage is too small to be of any practical importance.

g. The armature impedance and brush resistance drops change the voltage ratio with the load.

h. The armature reaction contains a steady term and a series of even multiple of p harmonics. The steady term is of little practical importance, but the harmonics of armature reaction in conjunction with g cause the so-called "tap frequency pulsations" to appear in the terminal voltages.

i. The oscillation about its mean position of the belt of conductors between brushes, and the variation in reluctance of the magnetic circuit due to the passage of the slots under the poles, cause a "tooth frequency pulsation" to appear in the voltage. This tooth frequency pulsation is high enough to prove objectionable on account of telephone interference when the feeders run parallel to telephone lines. It may be eliminated by spiralling the armature slots.

In present-day practise it has been found more satisfactory for operating and economic reasons to vary the terminal voltage of the converter rather than change its ratio by flux distortion. This may be accomplished by the following means:

j. Tap changing transformers or voltage regulators.

k. Booster converters, in which a small alternator is connected in series with the converter. The voltage is controlled by manipulacion of the booster field excitation. In smaller machines the booster is usually a separate machine with a revolving field, but in the larger sets it is made integral with the converter proper and has a revolving armature. Direct-current boosters are not as satisfactory since they have the disadvantage of a commutator capable of carrying the full converter output.

l. Field controlled converters, in which a change in the excitation changes the power factor. The reactive component of current flowing through the external reactance of the transformers or of separate reactors, changes the voltage at the converter slip rings, and thus the d-c. voltage.

Current Ratio. The current ratio of the synchronous converter follows from the law of conservation of energy

$$\text{d-c. output} = \text{a-c. input} \times \text{efficiency} \tag{21}$$

$$\therefore E_{DC}\, I_o = p\, E_1\, I_1\, (1 - \zeta) \cos\theta \tag{22}$$

where

$\cos\theta$ = power factor

I_1 = eff. value of a-c. current

ζ = rotational losses as per cent of a-c. input.

$$\therefore I_1 = \frac{E_{DC}}{E_1}\,\frac{I_o}{p\,(1-\zeta)\cos\theta} = \frac{\sqrt{2}\,\Delta\, I_o}{p \sin\dfrac{\pi}{p}\,(1-\zeta)\cos\theta} \tag{23}$$

The effective value of the slip ring current is the vector sum of the currents in the two phases connected to that ring. Its absolute value, therefore, is

$$I_1' = I_1 \left| \epsilon^{j0} + \epsilon^{j\left(\pi - \frac{2\pi}{p}\right)} \right| = 2\, I_1 \sin\frac{\pi}{p}$$

$$= \frac{2\sqrt{2}\,\Delta\, I_o}{p\,(1-\zeta)\cos\theta} \tag{24}$$

Appendix II

Armature Heating

On the assumption of linear commutation and a brush overlap of b radians the direct current in the layer

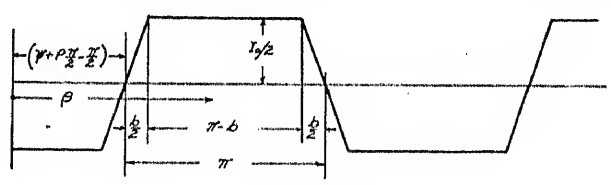

Fig. 11

of conductors between adjacent brushes is a trapezoidal wave as shown in Fig. 11. The Fourier series of this wave reckoned from the quadrature axis is

$$i_{dc} = \frac{4\, I_o}{\pi\, b} \sum_{1}^{\infty}{}_{\kappa} \frac{\sin(2\kappa - 1)\, b/2}{(2\kappa - 1)^2} \sin(2\kappa - 1)$$

$$\left(\beta - \psi + \rho\frac{\pi}{2} - \frac{\pi}{2}\right) \tag{25}$$

The alternating current in a phase is, in general,

$$i_{ac} = \sum_{1}^{\infty}{}_{m}\, I_m \sin m\,(\omega\, t + \theta_m) \tag{26}$$

If the phase belt has c coils of pitch $\rho\,\pi$, uniformly distributed by the angle σ, then at any time t the position with respect to the quadrature axis of the $(r+1)$ th coil of the belt is, by Fig. 9,

$$\beta = \left[\omega\, t + \frac{\pi}{2}(1-\rho) - (c-1)\frac{\sigma}{2} + r\,\sigma\right] \tag{27}$$

The substitution of (27) in (25) thus specifies the direct current in the $(r + 1)$ *th* coil at any instant. The resultant current in this coil is the difference of the alternating and direct current, and is

$$i_{r+1} = \sum_{1}^{\infty}{}_m I_m \sin m\,(\omega\, t + \theta_m)$$

$$- \frac{4\, I_o}{\pi\, b} \sum_{1}^{\infty}{}_\kappa \frac{\sin\,(2\,\kappa - 1)\, b/2}{(2\,\kappa - 1)^2} \sin\,(2\,\kappa - 1)$$

$$\cdot \left[\omega\, t - \psi - (c - 1)\,\frac{\sigma}{2} + r\,\sigma\right] \quad (28)$$

The average loss per cycle for this $r + 1$th coil is

$$W_{r+1} = \frac{1}{\pi} \int_0^\pi R\, i_{r+1}^2\, d\,(\omega\, t) \quad (29)$$

where

R = resistance of the coil.

The substitution of (28) in (29) yields integrals of the following types

$$\int_0^\pi \sin^2 a\, x\, .\, d\, x = \pi/2 \qquad \int_0^\pi \cos^2 a\, x\, .\, d\, x = \pi/2$$

$$\int_0^\pi \sin a\, x\, .\, \cos a\, x\, .\, d\, x = 0 \quad \int_0^\pi \sin a\, x\, .\, \cos b\, x\, .\, d\, x = 0$$

$$\int_0^\pi \sin a\, x\, .\, \sin b\, x\, .\, d\, x = 0 \quad \int_0^\pi \cos a\, x\, .\, \cos b\, x\, .\, d\, x = 0$$

$$a \neq b \quad (30)$$

If, now, $2\,s - 1$, denotes those harmonics having the same order in both the m and κ series; that is, those for which

$$m = (2\,\kappa - 1) = (2\,s - 1) \quad (31)$$

then by the relations of (30) it is easy to show that (29) becomes

$$W_{r+1} = \frac{R}{2} \sum_{1}^{\infty}{}_m I_m^2$$

$$+ \frac{R}{2} \left(\frac{4\, I_o}{\pi\, b}\right)^2 \sum_{1}^{\infty}{}_\kappa \frac{\sin^2\,(2\,\kappa - 1)\, b/2}{(2\,\kappa - 1)^4}$$

$$- R \left(\frac{4\, I_o}{\pi\, b}\right) \sum{}_s I_{(2s-1)} \frac{\sin\,(2\,s - 1)\, b/2}{(2\,s - 1)^2}$$

$$\cos\,(2\,s - 1)\,(\lambda_{2s-1} + r\,\sigma) \quad (32)$$

where

$$\lambda_{2s-1} = \left[- (c - 1)\,\frac{\sigma}{2} - \psi - \theta_{2s-1}\right] \quad (33)$$

The last summation of (32) can not, in general, be evaluated since its limits and arguments are all indefinite. But the second summation on the right of (32) can be evaluated by the methods of analysis shown in Appendix V. It is

$$\frac{R}{2} \left(\frac{4\, I_o}{\pi\, b}\right)^2 \sum_{1}^{\infty}{}_\kappa \frac{\sin^2\,(2\,\kappa - 1)\, b/2}{(2\,\kappa - 1)^4}$$

$$= \frac{R\, I_o^2}{4} \left(1 - \frac{2\, b}{3\,\pi}\right) \quad (34)$$

$$\text{for } \pi \geq b \geq 0$$

Since, in practise, b is of the order of ¼ radian it is seen that the effect of brush over lap is to reduce the losses in a conductor by the order of 3 per cent of the total armature current heating. It is therefore of no importance. Obviously, since we have shown the effect of brush over lap to be insignificant for any conductor it will also be negligible for the whole armature heating. Let us then, for simplicity, pass at once to the limit by allowing $b \to 0$ in our equations. Then (32) reduces to

$$W_{r+1} = \frac{R}{2} \sum_{1}^{\infty}{}_m I_m^2 + \frac{R\, I_o^2}{4}$$

$$- 2\, R\, \frac{I_o}{\pi} \sum{}_s I_{(2s-1)} \frac{\cos\,(2\,s - 1)\,(\lambda_{2s-1} + r\,\sigma)}{(2\,s - 1)} \quad (35)$$

The average heating of the whole armature is

$$W = \sum_{0}^{c-1}{}_r \frac{W_{r+1}}{c} = \frac{R}{2} \sum_{1}^{\infty}{}_m I_m^2 + \frac{R\, I_o^2}{4}$$

$$- 2\,\frac{R\, I_o}{\pi\, c} \sum{}_s \sum_{0}^{c-1}{}_r I_{(2s-1)} \frac{\cos\,(2\,s - 1)\,(\lambda_{2s-1} + r\,\sigma)}{(2\,s - 1)} \quad (36)$$

Effecting the r summation as shown in Appendix IV, we obtain

$$W = \frac{R}{2} \sum_{1}^{\infty}{}_m I_m^2 + \frac{R\, I_o^2}{4}$$

$$- \frac{2}{\pi} R\, I_o \sum{}_s I_{(2s-1)} \frac{C_{d(2s-1)}}{(2\,s - 1)} \cos\,(2\,s - 1)\,[\psi + \theta_{2s-1}] \quad (37)$$

where

$$C_{d(2s-1)} = \frac{\sin\,(2\,s - 1)\, c\,\sigma/2}{c\, .\, \sin\,(2\,s - 1)\,\sigma/2}$$

It is very interesting to note from Equation (37) that the total heating may be reduced by introducing harmonic currents of proper phase angle, θ_{2s-1}, such that

$$\frac{2\, I_o\, I_{2s-1}}{\pi\,(2\,s - 1)} C_{d(2s-1)} \cos\,(2\,s - 1)\,[\psi + \theta_{2s-1}] > \frac{I^2_{2s-1}}{2} \quad (38)$$

This inequality is a maximum for $[\psi + \theta_{2s-1}] = 0$ or π corresponding to $C_{d(2s-1)} = (+)$ or $(-)$

$$I_{2s-1} = \frac{2\, I_o\, C_{d(2s-1)}}{\pi\,(2\,s - 1)} \quad (39)$$

Since the sinusoidal component of the a-c. current bears a fixed ratio to the d-c. current, it is not possible to meet conditions (39) with the fundamental. Therefore, segregating it, we have as the equation of minimum armature heating,

$$W_{min} = \frac{R I_1^2}{2} + \frac{R I_o^2}{4} - \frac{2}{\pi} I_o I_1 C_{d1} \cos [\psi + \theta_1]$$

$$- \frac{2}{\pi^2} R I_o^2 \sum_2^\infty {}_s \frac{C^2_{d(2s-1)}}{(2s-1)^2} \tag{40}$$

One way to cause such currents to flow would be to introduce their order into the field form with proper phase and amplitude. The $M(p)$ harmonics could not, of course, be introduced by this method, as was pointed out in Appendix I. As an example, suppose we have a six-phase converter with transformer connections open-circuited to the third harmonics and its multiples. Let us assume infinite distribution and consider the effect of introducing fifth and seventh harmonic currents in conformity with the "best compromise" conditions of Equation (39). Then

$$C_{d5} = 0.966 \times \frac{12}{5\pi}, C_{d7} = 0.966 \times \frac{12}{7\pi} \tag{41}$$

Therefore by (40)

$$W = R \left\{ \frac{I_1^2}{2} + \frac{I_o^2}{4} (1 - 0.022) - \frac{2}{\pi} I_1 I_o C_{d1} \cos [\psi + \theta_1] \right\} \tag{42}$$

where the saving is $0.022 \, R \, I_o^2/4$, entirely negligible.

In the case of a particular conductor the conditions to be satisfied are

$$\left. \begin{aligned} \lambda_{2s-1} + r\sigma &= 0 \\ I_{2s-1} &= \frac{2 I_o}{\pi (2s-1)} \end{aligned} \right\} \tag{43}$$

If these relations hold for every odd harmonic from (1) to (∞) the heating in that particular conductor would be zero.

But by Equation (22) this would require that

$$I_1 = \frac{2 I_o}{\pi} = \frac{2 I_o}{p \, . \sin \frac{\pi}{p} \, (1 - \zeta) \cos \theta} \tag{44}$$

which is obviously possible only in the case $p \to \infty$, $\theta = 0$, and $\zeta = 0$; that is:

a. an infinite number of phases,
b. unity power factor,
c. zero losses.

In this theoretical discussion of heat reduction by superposition of harmonic currents we have assumed the possibility of their introduction. Practically, however, the difficulties encountered are enormous.

If the a-c. harmonics be neglected we have from (22), (35) and (36)

$$W_{r+1} = \frac{R I_o^2}{4} \left\{ 1 + \frac{8 \Delta^2}{p^2 \sin^2 \frac{\pi}{p} (1 - \zeta)^2 \cos^2 \theta} - \frac{16 \Delta \cos(\lambda_1 + r\sigma)}{\pi p \sin \frac{\pi}{p} (1 - \zeta) \cos \theta} \right\} \tag{45}$$

$$W = \frac{R I_o^2}{4} \left\{ 1 + \frac{8 \Delta^2}{p^2 \sin^2 \frac{\pi}{p} (1 - \zeta)^2 \cos^2 \theta} - \frac{16 \Delta C_{d1} \cos [\psi + \theta_1]}{\pi p \sin \frac{\pi}{p} (1 - \zeta) \cos \theta} \right\} \tag{46}$$

The usual text-book expressions are obtained herefrom by introducing the following simplifying assumptions.

1. Normal voltage ratio, $\Delta = 1$
2. 100 per cent pitch, $\rho = 1$
3. Infinite distribution, $\sigma = 0, c = \infty$
4. $\tau = r\sigma - (c - 1) \frac{\sigma}{2}$ = position of a coil from middle of the phase belt

$$W_{r+1} = \frac{R I_o^2}{4} \left\{ 1 + \frac{8}{p^2 \sin^2 \frac{\pi}{p} (1 - \zeta)^2 \cos^2 \theta} - \frac{16 \cos(\tau - \theta)}{\pi p \sin \frac{\pi}{p} (1 - \zeta) \cos \theta} \right\} \tag{47}$$

$$W = \frac{R I_o^2}{4} \left\{ 1 + \frac{8}{p^2 \sin^2 \frac{\pi}{p} (1 - \zeta)^2 \cos^2 \theta} - \frac{16}{\pi^2 (1 - \zeta)} \right\} \tag{48}$$

The sensitivity of the heating to the power factor ($\cos \theta$) requires that the converter be run at or near unity power factor.

It is obvious from Equation (47) that the heating is a maximum at one or the other of the outside conductors of the phase belt; that is, at the "tap" coils. At unity power factor it is the same for both tap coils, but at any other power factor it is increased at one tap and decreased at the other.

Appendix III

Armature Reaction

Polyphase Armature Reaction. Each armature coil of n turns, pitch $\rho\pi$, and instantaneous current i gives rise to the rectangular wave of m. m. f. shown in Fig. 12 whose Fourier series is

$$F_1 = \frac{4}{\pi} n i \sum_1^\infty {}_\kappa \frac{\sin \kappa \pi/2}{\kappa} \sin \kappa \rho \frac{\pi}{2} . \sin \kappa \alpha \tag{49}$$

where α is the space angle measured on the armature.

The total m. m. f. of a phase belt of c such coils uniformly distributed by the angle σ is

$$F_p = \frac{4}{\pi} n\, i \sum_{0}^{c-1}{}_{r} \sum_{1}^{\infty}{}_{\kappa} \frac{\sin \kappa\, \pi/2}{\kappa} \sin \kappa\, \rho \frac{\pi}{2}\,.$$

$$\sin \kappa\, (\alpha - r\, \sigma) \qquad (50)$$

Evaluating the r summation by the method of Appendix IV,

$$F_p = \frac{4}{\pi} n\, i \sum_{1}^{\infty}{}_{\kappa} \frac{\sin \kappa\, \pi/2}{\kappa} \sin \kappa\, \rho \frac{\pi}{2}\,.$$

$$\frac{\sin \kappa\, c\, \sigma/2}{\sin \kappa\, \sigma/2} \sin \kappa \left[\alpha - (c-1)\frac{\sigma}{2}\right] \qquad (51)$$

The displacement angle $\kappa\,(c-1)\,\sigma/2$ may be eliminated by choosing the reference axis at an angle

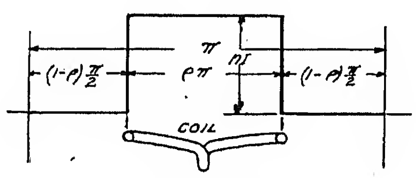

FIG. 12

$(\rho - 1)\,\pi/2$ from the midpoint of the phase belt. Then by (10), (11) and (20) we get

$$F_p = \frac{4}{\pi} n\, c \sum_{1}^{\infty}{}_{\kappa} \sum_{1}^{\infty}{}_{m} \frac{\sin \kappa\, \pi/2}{\kappa} C_{\rho\kappa}\, C_{d\kappa}\, I_m \sin m$$

$$(\omega\, t + \theta_m) \sin \kappa\, \alpha$$

$$= \frac{4}{\pi} n\, c \sum_{1}^{\infty}{}_{\kappa} \sum_{1}^{\infty}{}_{m} \frac{\sin \kappa\, \pi/2}{\kappa}$$

$$C_{\rho\kappa}\, C_{d\kappa}\, I_m \,\{\cos\,[\kappa\, \alpha - m\,(\omega\, t + \theta_m)\,] - \cos\,[\kappa\, \alpha + m\,(\omega\, t + \theta_m)\,]\,\} \qquad (52)$$

In this expression the angles for which

$$\left.\begin{aligned} \cos\,[\kappa\, \alpha - m\,(\omega\, t + \theta_m)\,] &= 1 \\ \cos\,[\kappa\, \alpha + m\,(\omega\, t + \theta_m)\,] &= 1 \end{aligned}\right\} \qquad (53)$$

are

$$\left.\begin{aligned} \alpha &= m\,(\omega\, t + \theta_m)/\kappa \\ \alpha &= -\,m\,(\omega\, t + \theta_m)/\kappa \end{aligned}\right\} \qquad (54)$$

and these angles move around the armature with the velocities

$$\left.\begin{aligned} d\,\alpha/d\,t &= m\,\omega/\kappa \\ d\,\alpha/d\,t &= -\,m\,\omega/\kappa \end{aligned}\right\} \qquad (55)$$

That is, the pulsating m. m. f. of amplitude

$$\left(\frac{4}{\pi}\, C_{\rho\kappa}\, C_{d\kappa}\, I_m/\kappa\right) cn$$

has been decomposed into two traveling waves of half this amplitude rotating in opposite directions at equal speeds.

If the machine has p phase belts per pair of poles, supplied by a balanced symmetrical p phase system of polyphase currents, then both the time and space angles between adjacent phase belts will differ by the angle $2\,\pi/p$. Thus to specify the m. m. f. of the qth phase belt, decrease both α and $\omega\, t$ in (52) by the angle $2\,\pi\, q/p$. The total m. m. f. for all p phases then is

$$F = \frac{2}{\pi}\, c\, n \sum_{0}^{p-1}{}_{q} \sum_{1}^{\infty}{}_{\kappa} \sum_{1}^{\infty}{}_{m} \frac{\sin \kappa\, \pi/2}{\kappa}\, C_{\rho\kappa}\, C_{d\kappa}\, I_m$$

$$\left\{ \cos\left[\kappa\left(\alpha - \frac{2\,\pi\, q}{p}\right) - m\left(\omega\, t - \frac{2\,\pi\, q}{p} + \theta_m\right)\right] - \cos\left[\kappa\left(\alpha - \frac{2\,\pi\, q}{p}\right) + m\left(\omega\, t - \frac{2\,\pi\, q}{p} + \theta_m\right)\right] \right\}$$

$$= \frac{2}{\pi}\, c\, n \sum_{1}^{\infty}{}_{\kappa} \sum_{1}^{\infty}{}_{m} \frac{\sin \kappa\, \pi/2}{\kappa}\, C_{\rho\kappa}\, C_{d\kappa}\, I_m$$

$$\left\{ \cos\,[\kappa\, \alpha - m\,(\omega\, t + \theta_m)\,] \sum_{0}^{p-1}{}_{q} \cos\,(m - \kappa)\, \frac{2\,\pi\, q}{p} \right.$$

$$- \cos\,[\kappa\, \alpha + m\,(\omega\, t + \theta_m)\,] \sum_{0}^{p-1}{}_{q} \cos\,(m + \kappa)\, \frac{2\,\pi\, q}{p}$$

$$- \sin\,[\kappa\, \alpha - m\,(\omega\, t + \theta_m)\,] \sum_{0}^{p-1}{}_{q} \sin\,(m - \kappa)\, \frac{2\,\pi\, q}{p}$$

$$\left. - \sin\,[\kappa\, \alpha + m\,(\omega\, t + \theta_m)\,] \sum_{0}^{p-1}{}_{q} \sin\,(m + \kappa)\, \frac{2\,\pi\, q}{p} \right\} \qquad (56)$$

But by Equations (101) and (102)

$$\sum_{0}^{p-1}{}_{q} \cos\,(m \pm \kappa)\, \frac{2\,\pi\, q}{p} = \begin{cases} p \text{ if } (m \pm \kappa) = M(p) \text{ or } 0 \\ 0 \text{ if } (m \pm \kappa) \neq M(p) \text{ or } 0 \end{cases} \qquad (57)$$

$$\sum_{0}^{p-1}{}_{q} \sin\,(m \pm \kappa)\, \frac{2\,\pi\, q}{p} = 0 \qquad (58)$$

Hereby Equation (56) reduces to

$$F = \frac{2}{\pi}\, p\, c\, n \sum_{1}^{\infty}{}_{\kappa} \sum_{1}^{\infty}{}_{m} \frac{\sin \kappa\, \pi/2}{\kappa}\, C_{\rho\kappa}\, C_{d\kappa}\, I_m$$

$$\{\cos\,[\kappa'\, \alpha - m\,(\omega\, t + \theta_m)] - \cos\,[\kappa''\, \alpha + m\,(\omega\, t + \theta_m)]\} \qquad (59)$$

where

$$\left.\begin{aligned} k' &= \text{any value of } k \text{ for which } \pm\,(m - k) = M(p) \text{ or } 0 \\ k'' &= \text{any value of } k \text{ for which } (m + k) = M\,(p) \end{aligned}\right\} \qquad (60)$$

It is to be understood that the summation is carried out with respect to these particular values κ' and κ'' of κ only.

For a single-phase machine κ' and κ'' include every integer value, and each may therefore be replaced by κ. It is then the equation of two traveling waves of equal amplitude rotating in opposite directions at equal

speed. Their combination gives a standing wave of twice the amplitude. This means that in the single-phase machine there is no rotating component of armature reaction with respect to the armature.

Equation (59) gives the armature reaction with respect to the armature. It is necessary, however, to have it with respect to the field. Let time be counted from the instant that the phase is in its mid-position about the pole. Now the armature is running backwards at synchronous speed $w\,t$ relative to the poles (since in our convention positive rotation is the direction of rotation of the fundamental rotating field of armature reaction); so that the armature reaction stationary in space at any angle β from the quadrature or interpolar axis is given by the substitution

$$\alpha = \omega\, t + \beta \qquad (61)$$

Then (59) becomes

$$F = \frac{Z}{\pi} \sum_{1}^{\infty}{}_m \sum_{1}^{\infty}{}_\kappa \frac{\sin \kappa\, \pi/2}{\kappa} C_{p\kappa}\, C_{d\kappa}\, I_m$$

$$\{\cos [(\kappa' - m)\, \omega\, t + \kappa'\, \beta - m\, \theta_m] - \cos [(\kappa'' + m)\, \omega\, t + \kappa''\, \beta + m\, \theta_m] \} \qquad (62)$$

where

$Z = 2\, p\, c\, n$ = total conductors per pair of poles. (63)

By the definitions of κ' and κ'' it is seen from (62) that

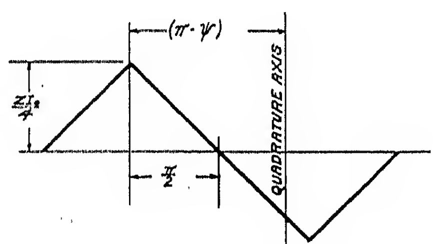

FIG. 13

the only sets of terms that contribute to the polyphase armature reaction are:

a. Those of constant magnitude, defined by $(\kappa' - m) = 0$

b. The $M\,(p)$ time harmonics, defined by $(\kappa' - m) = \pm M\,(p)$ and $(\kappa'' + m) = M\,(p)$. (64)

Terms of the form $\kappa' - m = - M\,(p)$ are cancelled out by corresponding terms in $\kappa'' + m = M\,(p)$. All even values of κ are wiped out by the factor $\sin \kappa\, \pi/2$. Therefore the only terms that need be considered are those for which $\kappa > m$ and odd.

The components of m. m. f. in line with the interpoles and main poles are referred to as the quadrature and direct components respectively. They are given by $\beta = 0$ and $\beta = \pi/2$ respectively, and are, for the fundamental current,

$$F_Q = \frac{Z\, I_1}{\pi} \sum_{2}^{\infty}{}_\kappa \frac{\sin \kappa\, \pi/2}{\kappa} C_{p\kappa}\, C_{d\kappa}$$

$$\{\cos [(\kappa' - 1)\, \omega\, t - \theta_1] - \cos [(\kappa'' + 1)\, \omega\, t + \theta_1] \} + \frac{Z\, I_1}{\pi} C_{p1}\, C_{d1} \cos \theta_1 \qquad (65)$$

$$F_D = \frac{Z\, I_1}{\pi} \sum_{2}^{\infty}{}_\kappa \frac{\sin^2 \kappa\, \pi/2}{\kappa} C_{p\kappa}\, C_{d\kappa}$$

$$\{\sin [(\kappa'' + 1)\, \omega\, t + \theta_1] - \sin [(\kappa' - 1)\, \omega\, t - \theta_1] \} + \frac{Z\, I_1}{\pi} C_{p1}\, C_{d1} \sin \theta_1 \qquad (66)$$

The average over a pole pitch is

$$F_{av} = \frac{1}{\pi} \int_{-\pi/2}^{\pi/2} F\, d\, \beta = \frac{2}{\pi^2} Z\, I_1\, C_{p1}\, C_{d1} \cos \theta_1$$

$$+ \frac{2}{\pi^2} Z\, I_1 \sum_{2}^{\infty}{}_\kappa \frac{\sin^2 \kappa\, \pi/2}{\kappa^2} C_{p\kappa}\, C_{d\kappa}$$

$$\{\cos [(\kappa' - 1)\, \omega\, t - \theta_1] - \cos [(\kappa'' + 1)\, \omega\, t + \theta_1] \} \qquad (67)$$

The D-c. Armature Reaction. It is convenient to consider the top layer of conductors connecting adjacent brushes as a "phase belt," having its returns in the bottom layer of conductors an angle $\rho\, \pi$ ahead. The d-c. armature reaction may then be calculated as for two such "phases," displaced by 180 deg. in space from each other, and carrying currents in opposite directions; thus, in a sense, also 180 deg. out of phase in time. Equation (52) gives the armature reaction of a phase belt carrying a current i. This equation can be applied to determine the d-c. armature reaction, if the tooth pulsations and brush overlap be neglected, and the following substitutions made:

$$\left.\begin{aligned} I_o &= \text{d-c. brush current} \\ i &= I_o/2 \text{ for the first belt} \\ i &= - I_o/2 \text{ for the second belt 180 deg. from the first.} \\ c\, n &= Z/4 \text{ conductors per belt} \\ C_{d\kappa}' &= \frac{\sin \kappa\, \pi/2}{(Z/4\, n) \sin (2\, \kappa\, n\, \pi/Z)} \\ &\simeq \frac{\sin \kappa\, \pi/2}{\kappa\, \pi/2} \text{ for } \frac{Z}{4\, n} \text{ large} \end{aligned}\right\} \qquad (68)$$

Then the armature reaction for the two belts is

$$F' = \frac{Z\, I_o}{2\, \pi} \sum_{1}^{\infty}{}_\kappa \frac{\sin \kappa\, \pi/2}{\kappa} C_{p\kappa}\, C_{d\kappa}'$$

$$[\sin \kappa\, \alpha' - \sin \kappa\, (\alpha' - \pi)]$$

$$= \frac{Z\, I_o}{\pi} \sum_{1}^{\infty}{}_\kappa \frac{\sin \kappa\, \pi/2}{\kappa} C_{p\kappa}\, C_{d\kappa}' \sin \kappa\, \alpha' \qquad (69)$$

where α' is reckoned from an angle $(\rho - 1)\, \pi/2$ behind the midpoint of the belt. But from Fig. 10 it is seen that the origin of α' is at an angle $\psi + \pi/2$ ahead of the quadrature axis, so that

$$\alpha' = \beta - \psi - \pi/2 \tag{70}$$

Equation (69) then becomes

$$F' = \frac{Z\,I_o}{\pi}\sum_{1}^{\infty}{}_{\kappa}\frac{\sin^2\kappa\,\pi/2}{\kappa}\,C_{p\kappa}\,C_{d\kappa}'\cos\kappa\,(\beta - \psi + \pi) \tag{71}$$

For infinite distribution and unity pitch (71) reduces to

$$F' = -\frac{2\,Z\,I_o}{\pi^2}\sum_{1}^{\infty}{}_{\kappa}\frac{\cos(2\,\kappa - 1)\,(\beta - \psi)}{(2\,\kappa - 1)^2} \tag{72}$$

By Equation (110), Appendix V, the value of this triangular wave over a certain range of its angle is

$$F' = -\frac{Z\,I_o}{4}\left\{1 - \frac{2}{\pi}(\beta - \psi)\right\} \tag{73}$$

$$\text{for } 0 > (\beta - \psi) > -\pi$$

Hereby the quadrature and direct components of d-c. armature reaction are

$$F_Q' = F'\Big]_{\beta=0} = -\frac{Z\,I_o}{4}\left(1 - \frac{2\,\psi}{\pi}\right) \tag{74}$$

$$F_D' = -F'\Big]_{\beta=-\pi/2} = \frac{Z\,I_o}{4}\,\frac{2\,\psi}{\pi} \tag{75}$$

The Resultant Armature Reaction. The resultant armature reaction is the sum of the a-c. and d-c. reactions as given by Equations (62) and (71). It is

$$F_R = \frac{Z}{\pi}\sum_{1}^{\infty}{}_{\kappa}\sum_{1}^{\infty}{}_{m}\frac{\sin\kappa\,\pi/2}{\kappa}\,C_{p\kappa}\,C_{d\kappa}\,I_m$$

$$\{\cos[(\kappa' - m)\,\omega\,t + \kappa'\beta - m\,\theta_m] - \cos[(\kappa'' + m)\,\omega\,t + \kappa''\beta + m\,\theta_m]\}$$

$$+\frac{Z}{\pi}\sum_{1}^{\infty}{}_{\kappa}\frac{\sin^2\kappa\,\pi/2}{\kappa}\,C_{p\kappa}\,C_{d\kappa}'\,I_o\cos\kappa\,(\beta - \psi + \pi) \tag{76}$$

Or for 100 per cent pitch, infinite distribution and the fundamental current only

$$F_R = \frac{Z}{\pi^2}\sum_{1}^{\infty}{}_{\kappa}\frac{\sin^2\kappa\,\pi/2}{\kappa^2}\left\{I_1\,p\sin\frac{\kappa\,\pi}{p}\right.$$

$$(\cos[(\kappa' - 1)\,\omega\,t + \kappa'\beta - \theta_1]$$

$$\left.-\cos[(\kappa'' + 1)\,\omega\,t + \kappa''\beta + \theta_1]) - 2\,I_o\cos\kappa\,(\beta - \psi)\right\} \tag{77}$$

The quadrature and direct components are given by substituting $\beta = 0$ and $\beta = \pi/2$ respectively; or can be obtained by adding the corresponding components of the a-c. and d-c. reactions from Equations (65), (66), (74), and (75). Thus, using (23)

$$F_{RQ} = \frac{Z\,I_o}{(1 - \zeta)}\left\{\frac{2\cos\theta_1}{\pi^2\cos\theta}\,\Delta - \left(\frac{\pi - 2\,\psi}{4\,\pi}\right)(1 - \zeta)\right.$$

$$+\frac{2}{\pi^2}\,\frac{\Delta}{\cos\theta}\sum_{2}^{\infty}{}_{\kappa}\frac{\sin\kappa\,\pi/p\,.\,\sin^2\kappa\,\pi/2}{\kappa^2\sin\pi/p}$$

$$\left.(\cos[(\kappa' - 1)\,\omega\,t - \theta_1] - \cos[(\kappa'' + 1)\,\omega\,t + \theta_1])\right\} \tag{78}$$

$$F_{RD} = \frac{Z\,I_o}{(1 - \zeta)}\left\{\frac{2\sin\theta_1}{\pi^2\cos\theta}\,\Delta + \frac{\psi}{2\,\pi}(1 - \zeta)\right.$$

$$+\frac{2}{\pi^2}\,\frac{\Delta}{\cos\theta}\sum_{2}^{\infty}{}_{\kappa}\frac{\sin\kappa\,\pi/p\,.\,\sin\kappa\,\pi/2}{\kappa^2\sin\pi/p}$$

$$\left.(\sin[(\kappa' - 1)\,\omega\,t - \theta_1] - \sin[(\kappa'' + 1)\,\omega\,t + \theta_1])\right\} \tag{79}$$

Since k is always odd, and since $\kappa \pm 1 = M\,(p)$ by the definitions of k' and k'', it follows that

$$\frac{\sin\kappa\,\pi/p}{\sin\pi/p} = \frac{\sin[M\,(p) \pm 1]\,\pi/p}{\sin\pi/p} = \pm 1 \tag{80}$$

where the $-$ sign is to be associated with k'' and the $+$ sign with k'.

Except in the case of the booster and regulating pole types of converters, the distortion of the field flux is negligible, so that the voltage is practically zero at the instant that the phase is central with the pole. It is evident, therefore, that the angle θ_1 is nearly the same as the power factor angle θ. Then for the simple converter (78) and (79) simplify to

$$F_{RQ} = \frac{Z\,I_o}{(1 - \zeta)}\left\{\frac{2}{\pi^2}\,\Delta - \left(\frac{\pi - 2\,\psi}{4\,\pi}\right)(1 - \zeta)\right.$$

$$+\frac{2\,\Delta}{\pi^2\cos\theta}\sum_{2}^{\infty}{}_{\kappa}\frac{\sin^2\kappa\,\pi/2}{\kappa^2}$$

$$\left.\times\,(\cos[(\kappa' - 1)\,\omega\,t - \theta] + \cos[(\kappa'' + 1)\,\omega\,t + \theta])\right\} \tag{81}$$

$$F_{RD} = \frac{Z\,I_o}{(1 - \zeta)}\left\{\frac{2}{\pi^2}\,\Delta\tan\theta + \frac{\psi}{2\,\pi}(1 - \zeta)\right.$$

$$+\frac{2\,\Delta}{\pi^2\cos\theta}\sum_{2}^{\infty}{}_{\kappa}\frac{\sin\kappa\,\pi/2}{\kappa^2}$$

$$\left.\times\,(\sin[(\kappa' - 1)\,\omega\,t - \theta] + \sin[(\kappa'' + 1)\,\omega\,t + \theta])\right\} \tag{82}$$

Now $k \pm 1$ is always even, and since k' and k'' are

only particular values of k it follows that the harmonics of armature reaction are always even and $M\ (p)$. Also, for every $k' - 1$ term there is a $k'' + 1$ term of the same order, because for every value of $M\ (p)$ values of k can be chosen such that $k' - 1 = M\ (p) = k'' + 1$.

Thus the armature reaction of a converter consists of a steady term and a series of even $M\ (p)$ harmonics. The pulsations in the m. m. f. due to these harmonics show up in the oscillograms as the so-called "tap ripple." This ripple is not present at zero load because the armature reaction is then zero. In the case of the quadrature reaction these pulsations occur under the interpole and seem to have some influence on commutation.

For unity power factor and zero brush shift the steady term of the direct component of armature reaction disappears; but contrary to general opinion the quadrature component does not vanish under these conditions.

Chief interest lies in the quadrature component since it acts on the neutral zone and must be compensated by extra turns on the interpoles. As an instance, take a six-phase converter for which $\zeta = 0,\ \theta = 0,\ \psi = 0$, and $\Delta = 1$. Then its quadrature component of armature reaction is

$$F_{6\phi} = Z\, I_o \{ 0.037 + 0.013 \cos 6\ \omega\, t + 0.003 \cos 12\ \omega\, t + 0.001 \cos 18\ \omega\, t + \ldots \} \qquad (83)$$

Thus a 6th harmonic pulsation exists of about ⅓ the magnitude of the steady term. Due to this pulsation the armature reaction varies from about 10 per cent to 20 per cent of the d-c. armature reaction. Of course the ordinary series winding of the interpole does not neutralize these pulsations of m. m. f.

In design the average armature reaction over a pole arc is used as a criterion of the demagnetizing effect of the armature. If $2\ \lambda$ is the pole arc, then by (77) the average m. m. f. over this arc is

$$F_\lambda = \frac{1}{2\ \lambda} \int_{\pi/2 - \lambda}^{\pi/2 + \lambda} F_R\, d\,\beta$$

$$= \frac{Z}{\lambda\ \pi^2} \sum_{1}^{\infty}{}_{\kappa} \frac{\sin \kappa\, \pi/2}{\kappa^3} C_{p\kappa} \sin \kappa\, \lambda \left\{ I_1\, p \sin \frac{\kappa\, \pi}{p} \,.\, (\sin [(\kappa'' + 1)\ \omega\, t + \theta_1] - \sin [(\kappa' - 1)\ \omega\, t - \theta_1]) - 2\, I_o \sin \kappa\, \psi \right\} \qquad (84)$$

For zero brush shift, normal voltage ratio, full pitch, fundamental only, and Equation (23) this reduces to

$$F = \frac{2}{\pi^2} \frac{Z\, I_o}{(1 - \zeta)} \frac{\sin \lambda}{\lambda} \tan \theta$$

$$= \frac{4}{\pi^3} \frac{Z\, I_o}{(1 - \zeta)} \tan \theta \frac{\sin a\, \pi/2}{a} \qquad (85)$$

where

$$a = \left(\frac{\text{pole arc}}{\text{pole pitch}} \right) \qquad (86)$$

For $a = 2/3$ this gives,

$$F_{2/3} = 0.1675 \frac{Z\, I_o}{(1 - \zeta)} \tan \theta = 0.67 \frac{Z\, I_o \tan \theta}{4\ (1 - \zeta)} \qquad (87)$$

Appendix IV

The Distribution Summations

The distribution of the armature coils leads to the two following definite series:

$$y_1 = \sum_0^{c-1}{}_r \sin n\ (x \pm r\ \sigma) \text{ and } y_2 = \sum_0^{c-1}{}_r \cos n\ (x \pm r\ \sigma) \qquad (88)$$

Expanding,

$$y_1 = \sum_0^{c-1}{}_r (\sin n\, x \,.\, \cos n\, r\, \sigma \pm \cos n\, x \,.\, \sin n\, r\, \sigma)$$

$$= \sin n\, x \sum_0^{c-1}{}_r \cos n\, r\, \sigma \pm \cos n\, x \sum_0^{c-1}{}_r \sin n\, r\, \sigma$$

$$= B \sin n\, x \pm A \cos n\, x$$

$$= \sqrt{A^2 + B^2} \sin \left(n\, x \pm \tan^{-1} \frac{A}{B} \right) = C \sin\ (n\, x \pm \beta) \qquad (89)$$

Likewise

$$y_2 = C \cos\ (n\, x \pm \beta) \qquad (90)$$

where

$$\left. \begin{aligned} A &= \sum_0^{c-1}{}_r \sin n\, r\, \sigma, \quad C = \sqrt{A^2 + B^2} \\ B &= \sum_0^{c-1}{}_r \cos n\, r\, \sigma, \quad \beta = \tan^{-1} (A/B) \end{aligned} \right\} \qquad (91)$$

The A and B summations may be evaluated geometrically from Fig. 14, where the vectors have unit length so that their projections on the x and y axes are the *cosine* and *sine* respectively of their direction angles $n\, r\, \sigma$. The figure has been drawn for four vectors, but the argument holds for any number of vectors, c. From the figure the following relations are evident.

$$R = 1/2 \sin \frac{n\, \sigma}{2} \qquad (92)$$

$$\alpha = (\pi - c\, n\, \sigma)/2 \qquad (93)$$

$$\gamma = (\pi - n\, \sigma)/2 \qquad (94)$$

$$\beta = \alpha - \gamma = (c - 1) \frac{n\, \sigma}{2} = \tan^{-1} (A/B) \qquad (95)$$

$$C = 2\, R \cos \alpha = \frac{\cos\ (\pi - c\, n\, \sigma)/2}{\sin n\, \sigma/2} = \frac{\sin c\, n\, \sigma/2}{\sin n\, \sigma/2} \qquad (96)$$

Therefore

$$y_1 = \sum_{0}^{c-1}{}_r \sin n\,(x \pm r\,\sigma) = \frac{\sin c\,n\,\sigma/2}{\sin n\,\sigma/2}\sin n \left[x \pm (c-1)\frac{\sigma}{2}\right] \quad (97)$$

$$y_2 = \sum_{0}^{c-1}{}_r \cos n\,(x \pm r\,\sigma) = \frac{\sin c\,n\,\sigma/2}{\sin n\,\sigma/2}\cos n \left[x \pm (c-1)\frac{\sigma}{2}\right] \quad (98)$$

Now if $\sigma = 2\,\pi/c$

$$\frac{\sin c\,n\,\sigma/2}{\sin n\,\sigma/2} = \frac{\sin n\,\pi}{\sin n\,\pi/c} = 0 \text{ if } n \neq M\,(c) \text{ or } 0 \quad (99)$$

But if $n = M\,(c)$ or 0 the fraction is an indeterminate

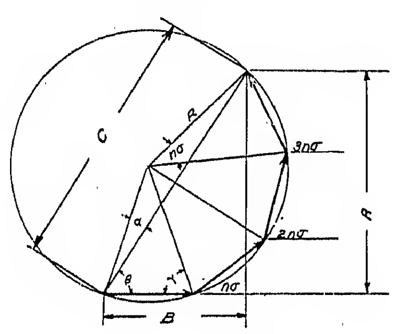

FIG. 14

which must be evaluated by differentiating numerator and denominator, thus

$$\left.\frac{\sin n\,\pi}{\sin n\,\pi/c}\right]_{n=M(c)} = \frac{D_n \sin n\,\pi}{D_n \sin n\,\pi/c} = \frac{c\,\pi \cos n\,\pi}{\pi \cos n\,\pi/c} = \pm\, c \quad (100)$$

Then in the limiting case of $x = 0$ and $\sigma = 2\,\pi/c$

$$\sum_{0}^{c-1}{}_r \sin n\,r\,\sigma = \frac{\sin n\,\pi}{\sin n\,\pi/c}\sin n\,(c-1)\frac{\pi}{c}$$

$$= \frac{\sin n\,\pi}{\sin n\,\pi/c}\left(\sin n\,\pi \,.\, \cos\frac{n\,\pi}{2} - \cos n\,\pi \,.\, \sin\frac{n\,\pi}{c}\right)$$

$$= 0 \quad (101)$$

$$\sum_{0}^{c-1}{}_r \cos n\,r\,\sigma = \frac{\sin n\,\pi}{\sin n\,\pi/c}\cos n\,(c-1)\frac{\pi}{c}$$

$$= \frac{\sin n\,\pi}{\sin n\,\pi/c}\left(\cos n\,\pi \,.\, \cos\frac{n\,\pi}{c} + \sin n\,\pi \,.\, \sin\frac{n\,\pi}{c}\right)$$

$$\left.\begin{aligned} &= 0 \text{ if } n \neq M\,(c) \text{ or } 0 \\ &= c \text{ if } n = M\,(c) \text{ or } 0 \end{aligned}\right\} \quad (102)$$

Appendix V

SUMMATION OF THE SERIES $\displaystyle\sum_{1}^{\infty}{}_n \frac{\sin^2 (2\,n-1)\,x/2}{(2\,n-1)^4}$

The Fourier Series of a periodic function is

$$f\,(x) = a_o + \sum_{1}^{\infty}{}_n\,(a_n \cos n\,x + b_n \sin n\,x) \quad (103)$$

where

$$\left.\begin{aligned} a_o &= \frac{1}{2\,\pi}\int_{-\pi}^{\pi} f\,(x)\,.\,d\,x \\ a_n &= \frac{1}{\pi}\int_{-\pi}^{\pi} f\,(x)\,.\,\cos n\,x\,.\,d\,x \\ b_n &= \frac{1}{\pi}\int_{-\pi}^{\pi} f\,(x)\,.\,\sin n\,x\,.\,d\,x \end{aligned}\right\} \quad (104)$$

For the case of the trapezoidal wave of unit amplitude shown in Fig. 15 we find that

$$f\,(x) = \frac{8}{\pi}\sum_{1}^{\infty}{}_n \frac{\sin (2\,n-1)\,b/2\,.\,\sin (2\,n-1)\,x}{b\,(2\,n-1)^2} \quad (105)$$

If $b = 0$ it becomes a square wave:

$$f_1\,(x) = \frac{4}{\pi}\sum_{1}^{\infty}{}_n \frac{\sin (2\,n-1)\,x}{(2\,n-1)} = 1 \text{ for } \pi > x > 0 \quad (106)$$

If $b = \pi$ it becomes a triangular wave:

$$f_2\,(x) = \frac{8}{\pi^2}\sum_{1}^{\infty}{}_n \frac{\sin (2\,n-1)\,\pi/2\,.\,\sin (2\,n-1)\,x}{(2\,n-1)^2} \quad (107)$$

The sum of the required series can be obtained by three successive integrations between the definite

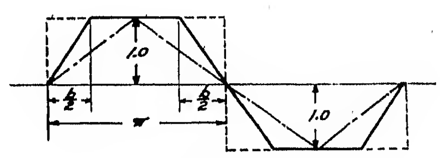

FIG. 15

limits of 0 and x of the square wave equation, and using the triangular wave equation to evaluate an intermediate series introduced by the first integration. Thus:

$$\int_0^x 1\,.\,d\,x = \int_0^x \frac{4}{\pi}\sum_{1}^{\infty}{}_n \frac{\sin (2\,n-1)\,x}{(2\,n-1)}\,.\,d\,x$$

$$\therefore -\,x = \frac{4}{\pi}\sum_{1}^{\infty}{}_n \frac{\cos (2\,n-1)\,x}{(2\,n-1)^2}$$

$$= \frac{4}{\pi} \sum_{1}^{\infty}{}_{n} \frac{1}{(2n-1)^2} \tag{108}$$

But substituting $x = \pi/2$ into the triangular wave of unit amplitude, Equation (**105**), we get

$$f_2\left(\frac{\pi}{2}\right) = \frac{8}{\pi^2} \sum_{1}^{\infty}{}_{n} \frac{1}{(2n-1)^2} = 1 \tag{109}$$

since $f_2(x) = 1$ at $x = \pi/2$. Therefore (**108**) becomes

$$\frac{\pi}{2} - x = \frac{4}{\pi} \sum_{1}^{\infty}{}_{n} \frac{\cos(2n-1)x}{(2n-1)^2} \tag{110}$$

$$\int_0^x \int_0^x \left(\frac{\pi}{2} - x\right) dx$$

$$= \int_0^x \int_0^x \frac{4}{\pi} \sum_{1}^{\infty}{}_{n} \frac{\cos(2n-1)x}{(2n-1)^2}\, dx \tag{111}$$

$$\frac{\pi x^2}{4} - \frac{x^3}{6} = \frac{4}{\pi} \sum_{1}^{\infty}{}_{n} \frac{1-\cos(2n-1)x}{(2n-1)^4}$$

$$= \frac{8}{\pi} \sum_{1}^{\infty}{}_{n} \frac{\sin^2(2n-1)x/2}{(2n-1)^4} \tag{112}$$

Therefore the required series is

$$\sum_{1}^{\infty}{}_{n} \frac{\sin^2(2n-1)x/2}{(2n-1)^4} = \frac{\pi^2 x^2}{32} - \frac{\pi x^3}{48} \tag{113}$$

List of Symbols

b = Brush width expressed in electrical radians
B_κ = Amplitude of flux density for the κth harmonic
c = Coils per phase belt
$C_{p\kappa}$ = Pitch factor of the κth harmonic
$C_{d\kappa}$ = Distribution factor of the κth harmonic
e = Instantaneous voltage induced in a coil
e_p = Instantaneous voltage induced in a phase
E_{dc} = D-c. induced voltage
E_1 = Effective value of the fundamental of a-c. induced voltage
F = Polyphase armature reaction
F' = D-c. armature reaction
F_R = Resultant armature reaction
(Subscript D for direct component. Subscript Q for quadrature component.)
i_{ac} = Instantaneous a-c. phase current
I_1 = Fundamental of a-c. current (eff. value)
I_m = Amplitude of the mth harmonic of a-c. current
I_0 = D-c. brush current
m = Time harmonic of the a-c. current
$M(\ )$ = Multiple of ( )
n = Number of turns per coil
p = Number of phases per pair of poles
r = Index for the $(r+1)$th conductor in a phase belt
R = Resistance of an armature coil
t = Time counted from instant when the phase is centrally located with respect to the poles
Z = Total number of conductors per pair of poles
α = Space angle measured on the armature
β = Space angle measured on the field
γ_κ = Flux shift of the κth harmonic of flux distribution
Δ = Distortion factor of the converter
ζ = Rotational losses as fraction of the a-c. input
θ_m = Phase angle of the mth time harmonic of a-c. current
θ = Power factor angle
κ = Space harmonic
κ' = Any value of κ for which $\pm(m-\kappa) = M(p)$ or 0
κ'' = Any value of κ for which $(m+\kappa) = M(p)$
ρ = Pitch expressed as a fraction
τ = Position of a coil from the middle of the phase belt
σ = Distribution angle of the coils
ψ = Brush shift from neutral position
ω = $2\pi f = 2\pi$ (frequency).

Discussion

E. B. Shand: From the standpoint of practical design calculations, I believe that the formulas in the complex forms given are not generally applicable, due to the fact that the accuracy of design calculations is limited by a number of factors not considered in the paper. An instance of this may be found in Equation (**20**) for voltage ratio. This expression may be simplified very greatly by introducing coefficients obtained directly from the converter field form without going through the process of actual harmonic analysis, which have a greater degree of accuracy than those of the calculated field form.

The expressions for the armature-loss constants vary from those ordinarily employed in that the effect of non-sinusoidal alternating currents is included. In working with converters the difficulty in determining actual armature losses is due to the fact that the phase relations between the alternating and direct currents within the armature are not expressed completely by the phase angle of the currents at the collector rings, due to the internal phase displacement within the converter itself. This difference in loss may be greater than 50 per cent in certain cases. Certain data and the manner of estimating the armature losses under these conditions have already been published.[1] I believe that Equations (**45**) and (**46**) should be modified to allow for these conditions.

In the discussion of armature reaction, it is stated that "the 6th harmonics of m. m. f. are responsible for the 'tap-frequency pulsation' in the external circuit of the converter when it is loaded." In my own experience with converters I have often found this pulsation to be just as great with no load on the converter when the reaction should be negligible, as with full load. This would preclude the generality of the above statement. In cases given some investigation, it has been found that the pulsation was due mainly to the fact that the converter with its 3rd and 5th, (etc.) harmonics in the generated voltage wave had been connected to a power system of low impedance and with a voltage closely approximating a sine wave. The harmonics had therefore to be absorbed to a large extent within the converter itself by pulsating fluxes produced by harmonic currents. These pulsating fluxes generated the voltage variations found in the d-c. voltage and which naturally must repeat themselves with

1. "Operation of Synchronous Converters at Reduced Voltages", *Electrical Journal*, Dec. 1924.

every tap. These harmonic currents are particularly apparent when the converter is operating at very light loads.

One more comment might be applied to the paper in a general way. Its usefulness would probably be increased if the symbols used in the appendices were more completely defined.

Quentin Graham: I note that the authors have not discussed the average heating, or total loss, of all coils in the converter. They have shown very clearly how the heating of individual coils varies with coil position and power factor and might easily have gone a step further and included the average heating or loss. The latter is important if the efficiency is to be

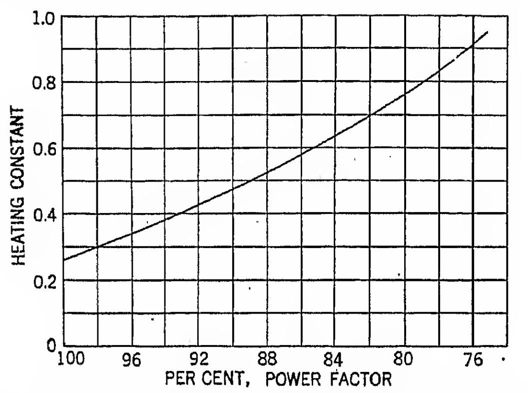

FIG. 1—CURVE SHOWING AVERAGE HEATING OR LOSS CONSTANT FOR 6-PHASE SYNCHRONOUS CONVERTERS WITH EQUAL INPUT AND OUTPUT

calculated under various conditions. I am submitting herewith a curve, Fig. 1, which shows the average heating constant for six-phase converters with the assumption of no rotationa losses, and another set of curves, Fig. 2, shows the variation of the heating constant for six-phase converters under conditions of varying power factor and varying ratio of d-c. to a-c. power. The authors' equations contain a factor which depends upon this ratio although it is defined in terms of efficiency or rotational losses. If the ratio of d-c. to a-c. power is allowed to vary through a wide range as in Fig. 2 the results are applicable to cases in which mechanical power is either put into or taken out of the shaft. Such curves are useful in connection with booster converters, for example, in which the booster machine is coupled to the converter shaft.

It is interesting to note that the minimum heating or loss does not occur when the input and output are equal, but that a small amount of power put in through the shaft is necessary to reach the minimum point on the curve. As the power factor becomes lower the minimum point recedes farther from the point of pure converter operations.

L. V. Bewley: The equations in this paper were derived to show explicitly the several factors which influence the characteristics of the converter, and were not intended to be directly applicable to routine design calculations.

The angles θ_m and θ refer to the displacement of the currents in the phase belts. The heating is a minimum when $\theta = 0$; although, as Mr. Shand points out, the external power factor of the machine will be lagging under these conditions due to its internal reactances.

The tap-frequency pulsation is caused by the harmonics of armature reaction and by a variation in the impedance drop of the alternating currents between brushes due to the transition of the phase belt across the brush. If the field form contains only the fundamental and M (p) flux harmonics and if there are no harmonics in the applied voltage, then the tap-frequency pulsation varies with the alternating current, and is zero at no-load. But if the field form contains other than the M (p) flux harmonics, or if there are harmonics in the applied voltage, then one component of the tap-frequency pulsation will be practically independent of the load. In many machines this latter condition predominates. The effects of the variation of the resistance in causing these pulsations has been very fully discussed by Mr. Neville in the November, 1917 issue of the *Electrician*, London, England. We have to thank Mr. Shand for bringing this question up in the discussion.

The average heating of the whole armature, which Mr. Graham asks about, is given in Equations (**36**), (**37**), (**38**), (**39**), (**40**), (**46**) and (**48**).

Equation (**23**), which gives the current ratio, contains a factor, ζ, which takes care of the rotational losses of the machine. The booster converter may be considered as included in our equations if ζ is taken as positive when the booster generates and as negative when the booster motors.

Also, in addition to what Mr. Graham brings up, if you want to carry things further and take up consideration of the variable-ratio or split-pole converter, the distortion of the flux causes motor or generator action depending upon whether the distortion factor Δ is less than, or greater than, unity. This is easily seen by averaging the armature reaction from the center of a main pole to the center of the next adjacent main pole. This average armature reaction, which is a measure of the torque, involves the expression $[\Delta/(1 - \zeta) - \cos \psi]$; it thus depends upon the distortion of the field form, the mechanical torque on the shaft, and the relative shift between flux and brush. Our equations are therefore rather general and easily extensible to other types of converters, although we specified that the scope of the paper was confined to consideration of the simple converter.

T. T. Hambleton: I agree entirely with Mr. Shand that the complication involved in the formula which we have developed would render it unsuitable for ordinary everyday use. The formula we already have in use is good enough.

There is another point of interest in addition to those mentioned by Mr. Graham relative to armature heating. This is a comparison of the increase in armature copper loss of the converter and other machines carrying only alternating current as the power factor is lowered.

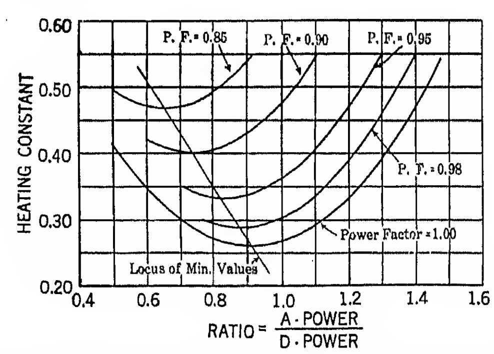

FIG. 2—CURVE SHOWING AVERAGE HEATING OR LOSS CONSTANT FOR 6-PHASE SYNCHRONOUS CONVERTERS FOR VARIOUS VALUES OF POWER FACTOR AND RATIOS OF A-C. TO D-C. POWER

For values of the abscissa above 1.0 the converter performs some mechanical work (either externally or in overcoming rotational losses). For values below 1.0, some power is put in through the shaft.

A curve may be drawn using power factor as ordinates and per cent increase in copper loss as abscissas. A few points on these curves are as follows:

Power factor	Converter heating (tap coil), per cent	A-c. machine heating (all coils), per cent
1.00	100	100
0.97	165	106
0.95	190	111
0.90	248	123
0.80	375	156

This shows why the converter is essentially a unity-power-factor machine and illustrates the danger of departing from specified power factors.

Constant-Current Regulating Transformer Characteristics

Special Tests Show Radical Differences From Conventional Assumptions

BY H. C. LOUIS[1]
Member, A. I. E. E.

and

A. ALBAUGH[1]
Associate, A. I. E. E.

Synopsis.—It has generally been assumed that the total losses of a constant-current regulating transformer remain practically constant for all loads. Performance and test calculations have accordingly heretofore been made according to well-known conventional methods from the segregated losses determined from test or design data, assuming total losses constant. Extensive tests described in the paper show, however, that these losses are not necessarily even approximately constant, but for some transformers vary greatly with the load, the total losses at light loads greatly exceeding those at full load.

The tests further show that the increased losses produce increased temperature rises at light loads, which may be sufficiently excessive to endanger the apparatus, although the same transformer may be able to carry full load with normal temperature rise.

The increased total losses and temperature rises at light loads are shown to be due largely to the increase of stray load losses with decrease of load, caused mainly by the leakage flux inducing excessive circulating currents in the laminations and structural parts of the transformer, such as the cage. Exploring coils and iron filings were used to investigate the amount and direction of the leakage flux.

Performance specifications should be based on the actual total losses for all loads and not on the conventional assumption of constant total losses, as has been done in the past.

It is pointed out that the characteristics described depend somewhat on the design, other features besides liberality in the use of materials being of importance. Consequently, measures should be taken by designers to correct these undesirable characteristics as much as possible. Users not only desire the most highly efficient apparatus consistent with cost, but must have apparatus of the highest reliability under all possible conditions, which cannot be expected of constant-current transformers endangered by excessive temperatures at light loads. The characteristics discussed are, therefore, not only of theoretical interest, but also of considerable practical interest to both designer and user.

THE general theoretical principles usually accepted and applied to performance calculations and tests of moving-coil constant-current transformers have been based on certain conventional assumptions which have heretofore been generally accepted without question. It has generally been assumed that the total losses of a constant-current transformer remain practically constant for all loads, that is, for all coil positions.

The reasons for this are based on simple fundamental considerations. Inasmuch as the applied voltage remains constant for all loads, and the resultant magnetic flux nearly so, it seems reasonable to assume that the core loss should also remain practically constant. Furthermore, inasmuch as the current in both primary and secondary remains practically constant, changes of load being changes in secondary voltage effected by variation of leakage reactance with position of the coil producing power factor changes only in current, the copper losses should also be practically constant. It was also assumed that the stray load losses did not vary greatly with the load.

The more exact reasoning leading to the assumption of constant losses is that the iron loss and copper loss both vary somewhat, but in such a way as to keep the total losses practically constant. Under the condition of full load, the magnetic leakage is a minimum, the entire magnetic circuit is excited to nearly its maximum density, and the core loss a maximum. At reduced loads, more of the flux passes across the open space between the legs, thus reducing the flux in parts of the core, consequently, decreasing the core loss. So the core loss would be greatest at heavy loads, and slightly lower at light loads. Considering the copper loss, the $I^2 R$ component remains constant, but the eddy current component is less at full load and slightly greater at light loads. On this basis the total losses would be practically constant for all loads.

Performance and test calculations were therefore formerly made according to well-known conventional methods from segregated losses determined from test or design data. The segregated losses were determined under conditions corresponding to full load, and the values thus determined used as the losses for other loads as well as for full load.

Actual Characteristics Differ Greatly from Theoretical

Tests made by the writers, however, showed that the total losses were not necessarily even approximately constant, but for some transformers varied greatly with the coil position and consequently the load. In most cases the losses at light loads were found to greatly exceed those at full load. This condition is contrary to the usual performance of most electrical machinery. This increase of losses with decrease of load is plainly shown in Fig. 1.

This deviation of actual performance from that conventionally assumed is not only of theoretical interest but of great practical significance to both manufacturer and operator. It means that the losses at light

1. Both of the Consolidated Gas, Electric Light and Power Co., Baltimore, Md.

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

loads are much greater than supposed, consequently the cost of supplying these losses appreciably increases the cost of current supplied to series lamps. It makes it desirable for users to operate constant-current transformers close to full load but this is not always practical under actual conditions.

Standard tests and manufacturers' guarantees have been based on the assumption of constant losses. This has given misleading fictitious values for the losses and efficiences at the lower loads. Referring to Fig. 1, at

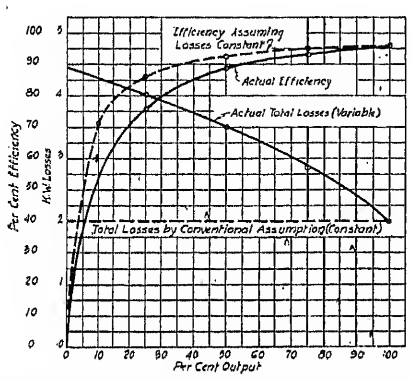

FIG. 1—ACTUAL AND CONVENTIONALLY ASSUMED VARIATION OF TOTAL LOSSES IN A CONSTANT-CURRENT TRANSFORMER WITH LOAD

full load the losses are two kw. and the efficiency 96 per cent according to both methods. At one-quarter load, the actual loss is four kw., that is, twice that assumed by the conventional method, and the actual efficiency is 76 per cent as against 86 per cent based on the conventional method.

TEMPERATURE CHARACTERISTICS UNUSUAL

Another consideration which is exceedingly important is the effect on the temperature rise of the transformer. The increased losses will produce increased temperatures at light loads, which may not only exceed the temperature guarantees, but may endanger the apparatus. Conventional temperature tests on constant-current transformers were formerly made under conditions corresponding to full load. Tests made by us, however, showed that temperature rises were higher at light loads than at full load due to the greater losses at light load. Transformers which have satisfactorily passed the standard temperature tests may develop excessive temperatures at light loads. This is shown in Fig. 2. This condition is contrary to our usual experience with electrical apparatus, which is that temperature rises are ordinarily greater at heavy loads than light loads.

Due to the arrangement of circuits, changing load conditions and necessary spare capacity allowances, it is not always practical to run all constant-current transformers at full load, but many of these must be run at light loads. Consequently, some of these may overheat and ultimately break down, even though they may be able to operate satisfactorily at full load without reaching excessive temperatures. The transformer of Fig. 2 shows a temperature rise in the iron of 55 deg. cent. at full load, which does not exceed the normal allowable limit. At one-half load the rise is 86.5 deg. cent. and at one-quarter load the rise is 93.5 deg. cent. which greatly exceeds the allowable limit.

FACTORS AFFECTING THESE CHARACTERISTICS

This variation of losses with load is more marked in some transformers than in others, depending somewhat on the design. As some of the older transformers were designed along very liberal lines, this variation was so small comparatively, as to justify the assumption of constant losses. The variation is most marked, however, in modern designs in which materials are worked to the limit, a condition typical of modern design in general, brought on by economic necessity and the stress of competition.

Liberality in the use of materials is not the only factor affecting the performance as described, but there are other factors which play an important part. We made a number of tests trying to analyze some of these, and to find some of the underlying causes and provide a theory to account for some of the particular characteristics described.

STRAY LOAD LOSSES

The results of our tests indicate that the stray load losses are mainly responsible for the effects described. The leakage fluxes vary greatly in amount with the load, causing the stray load losses to increase greatly with decrease of load. In some cases these may equal or exceed the total of the other losses. In most elec-

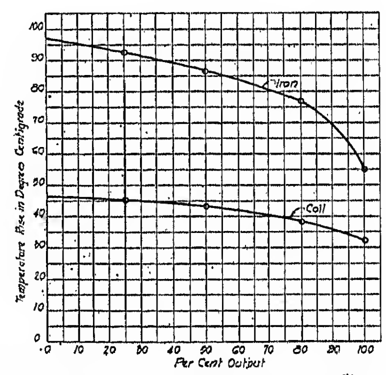

FIG. 2—EFFECT OF LOAD ON TEMPERATURE RISE OF CONSTANT-CURRENT TRANSFORMERS

trical apparatus the stray load losses, which are small at light loads and greatest at heavy loads, are usually considerably less than the other losses.

The direction of the leakage flux has a very important bearing. As shown in detail later on, the leakage flux leaves the laminations not only by the edges, but a large proportion of it leaves from the sides perpendicular to the plane of the laminations, producing a heavy eddy current loss in these, with consequent heating. Furthermore, this is the part of the leakage flux which is most likely to encounter in its path metallic struc-

tural parts of the transformer, thus producing eddy currents in these parts. Fluxes leaving in the direction of the edges will produce comparatively small losses of this nature.

The total effect will therefore depend greatly upon the distribution of leakage flux resulting from the design. As the leakage flux increases with decrease of

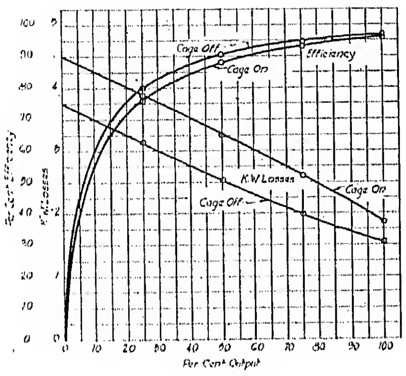

FIG. 3—EFFECT OF CAGE ON OPERATION OF CONSTANT-CURRENT TRANSFORMER

load, a transformer in which much of the leakage flux passes from the sides of the laminations will show greatly increased losses of this nature at light loads.

A marked example of losses in structural parts of a constant-current transformer was the stray load loss in the protective cage, which was greatest at light loads, tests showing the large value of ¾ kw. When the cage was removed, this cage loss was eliminated. Fig. 3 shows how the cage affected the total losses and the efficiency for various loads.

This marked variation of large stray load losses with

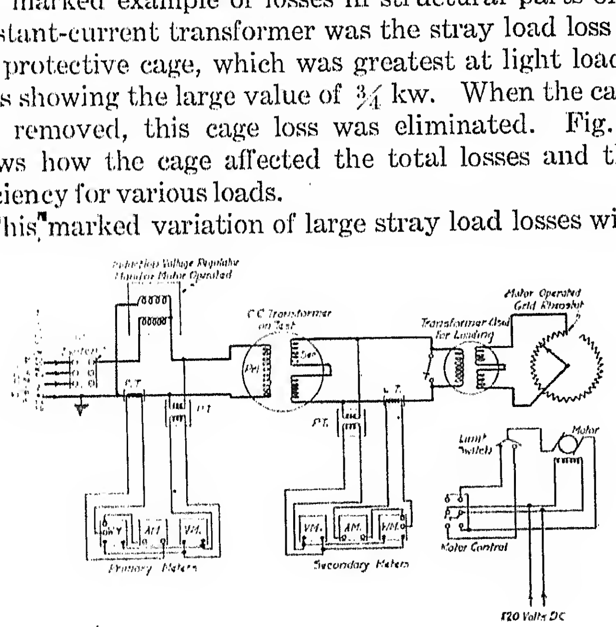

FIG. 4—WIRING DIAGRAM OF CONSTANT-CURRENT TRANSFORMER TEST SHOWING METER CONNECTIONS AND METHOD OF LOADING

load will therefore largely account for the great variation of total losses with load characteristic of some constant-current transformers. When the stray load losses are comparatively small the conventional assumption of constant losses is reasonably correct. However, when these are comparatively large the total losses will increase noticeably with decrease of load.

EFFICIENCY AND LOSS TESTS

Efficiencies and losses were determined by input—output method, tests being made on different makes and sizes of transformers at various loads and voltages. The scheme of connections used during the tests is shown in Fig. 4. This gave good control of voltage and load. Due to the use of transformers in the secondary circuit, the power factor in this circuit was slightly less than unity. The main effect of this was to materially reduce the maximum capacity of the transformer.

However, as long as the secondary power factor was kept nearly constant throughout a particular test from no load to full load, the characteristics of the transformer were not altered.

The transformers tested were rated at 6.6 secondary amperes and at either 2300 or 2540 volts primary. Most of the tests were made on 60-cycle transformers at an actual frequency of 62.5 cycles, this being the frequency of our nominal 60-cycle system. A few tests were also made on 25-cycle transformers.

Readings were taken of voltage, current and kw. on both primary and secondary side, meters being read as

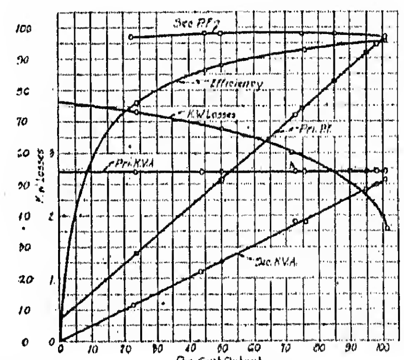

FIG. 5—TYPICAL PERFORMANCE CURVES OF CONSTANT-CURRENT TRANSFORMER

closely as possible. Although absolute accuracy is not claimed for the instruments used and methods of measurement they were of sufficient practical accuracy for the purpose. This was shown by the general consistency of the loss measurements, and by the fact that the temperature runs gave results in line with the loss measurements. For example, as wattmeters are more subject to error at low power factors than at high power factors, the wattmeters on the primary side would tend to show higher losses at light loads than full load, due to the much lower power factors. However, not only was the actual possible error due to this cause far from being large enough to account for the great increase of losses shown by our results, but the greatly increased temperature rises actually measured proved that these represented actual additional losses rather than errors of measurement.

Efficiencies, power factors, and losses were calculated from the readings. Fig. 5 shows typical performance curves determined by actual test.

Temperature Tests

Temperature tests were also made on different makes and sizes of transformers under various conditions of load and voltage, to determine the effect of the load carried upon the temperature rise of various parts. These temperature runs were made with the same scheme of connections as for the efficiency tests shown in Fig. 4, that is, with test conditions the same as actual load conditions.

Temperatures were measured by means of ther-

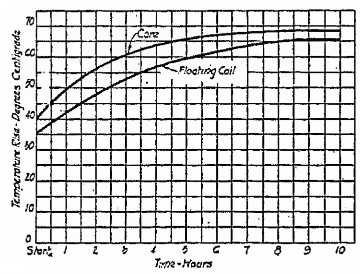

Fig. 6—Maximum Temperature Rise in Constant-Current Transformer Operating at One-Quarter Load

mometers and thermocouples placed in numerous locations on the iron core and the primary and secondary coils. The maximum iron temperatures were found to be on the center leg of the iron core, on the side parallel to the sides of the laminations, somewhere between the primary and secondary coils. Typical temperature rise curves are shown on Fig. 6. It will be noted that the floating coil of this transformer shows a temperature rise of 65 deg. cent. at 1/4 load, whereas it had previously shown a temperature rise of only 55 deg. cent. at full load.

Exploring Coils used to determine the Amount and Characteristics of the Leakage Flux

Exploring coils consisting of several turns of small wire were wound around each of the three legs of the transformer. These coils were so arranged that they could be moved up and down the core. The voltage induced in these windings is a measure of the amount of flux at that particular point in the iron core. Moving the exploring core further up and further down the coil showed a change in voltage in the coil which represents an increase or decrease in magnetic flux in that core. The results obtained with the use of these exploring coils are shown in Fig. 7. It can be noted from the curves on Fig. 7 that the rate of change of flux throughout the entire distance between the primary and secondary coils is practically uniform. This means that the leakage flux leaving a narrow section near one coil, say on short circuit, is practically the same as the flux leaving a similar narrow section near the other coil. It was found from these tests that the flux per unit section between the primary and secondary coils was the same regardless of the position of the moving coil, provided, of course, that the primary voltage and secondary current and power factor were held constant.

To determine the amount of leakage flux leaving the core perpendicular to the core laminations, exploring coils were wound on the face of the sides on both the center leg and the two outside legs of the iron core. The voltage obtained on these cores is an indication of the amount of flux entering or leaving that portion of the circuit. When reduced to a unit area basis, it was found that the leakage flux leaving the center core perpendicular to the laminations was, in most cases, 45 per cent or more of the total leakage flux. The total leakage flux entering the two outside legs perpendicular to the laminations was only 25 per cent of the total transformer leakage flux.

The fact that so much flux leaves the center core perpendicular to the laminations accounts for the high temperatures found on that portion of the iron core and for at least some of the increased losses with decreased load, this being due to the fact that much more leakage flux occurs at no load than at full load.

Using a small exploring coil about one in. in diameter, the passage of the flux from the center leg to the outside leg was traced. With this coil it was found that a considerable portion of the leakage flux passes through the region normally occupied by the expanded metal protecting cage around the outside of the transformer. The amount of this leakage flux is sufficient to cause considerable induced currents in the screen. Careful

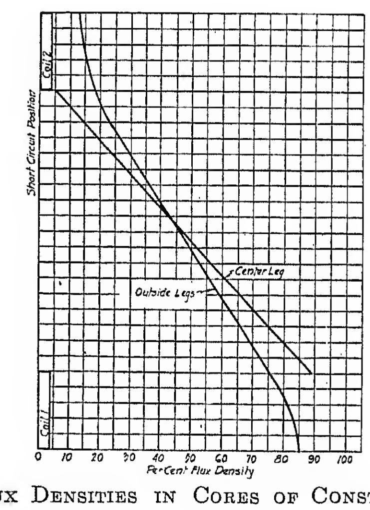

Fig. 7—Flux Densities in Cores of Constant-Current Transformer when Short-Circuited

measurements made on different transformers showed that in maximum conditions, the loss in the cage may amount to as much as 20 per cent of the total losses measured. This maximum loss occurs at short circuit when the leakage flux is greatest. As the load increases and the coils come closer together the loss in the screen is decreased slightly.

Flux Distribution Shown by Iron Filings

The flux distribution was also studied by means of iron filings spread on paper placed around the core. Photographs of these were taken, Figs. 8 and 9 showing preroductions. These show the flux distribution in the

air-gap between the center leg and outer legs of the core for two different transformers under load. The iron filings show how the flux leaves the center core and travels to the outside legs. Both of these show that not only does the flux pass from the edges of the center core to the outside legs, but a large amount of flux leaves the center core practically perpendicular to the laminations. On the other hand, on the outside legs, the greater proportion of this same part of the leakage flux passes around and enters at the extreme outside edges. That is, the leakage flux path to the outside legs is

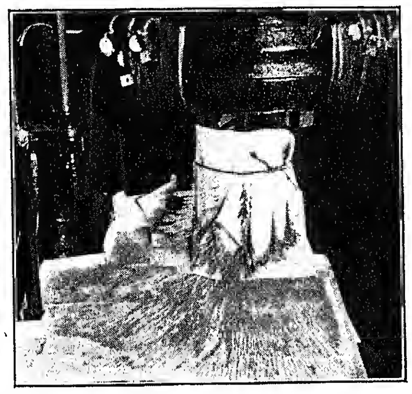

Fig. 8—Direction of Leakage Flux in Constant-Current Transformer under Load Illustrated by Means of Iron Filings

mainly to the inner and outer edges, the proportion of flux entering perpendicular to the laminations being considerably less than that in the center leg of the core.

Conclusions

1. The results prove conclusively that the total losses of a constant-current moving-coil transformer are not constant, but may vary greatly with the load, increasing with decrease of load.

2. The increased losses at light loads may be sufficient to cause excessive and dangerous temperature rises in a transformer at light loads, although the same transformer may be able to carry full load with normal temperature rise.

3. This increase of total losses and increased temperature rises at light loads are due largely to the increase of stray load losses with decrease of load, caused mainly by the leakage flux passing from the core perpendicular to the sides of the laminations. These induce excessive circulating currents not only in the laminations themselves but in structural parts of the transformer, such as the cage.

4. Performance specifications, in order to be correct, should be based on the actual total losses for all loads. The conventional methods hitherto used based on constant total losses give highly misleading results. More attention should be given to the framing of specifications which should include such details as are necessary to show the true characteristics of the transformer, and to enable its fitness for particular operating conditions to be determined.

Some constant-current transformers are equipped with a light-load tap, which accomplishes reduction of secondary voltage by a change of ratio. This reduces the leakage flux and resulting stray load losses for a given load. While such a tap can be used to advantage under some conditions, tap changing is not always practical, such as under changing load conditions due to shifting of circuits. Specifications should not only cover the performance for the reduced capacity tap as well as for full winding, but should also clearly indicate on which each part is based. Some specifications do not indicate whether the performance at light loads is based on the full winding or on the reduced capacity tap.

5. Measures should be taken by designers to correct as far as possible the undesirable characteristics described. Aside from a more liberal use of materials, it should be possible to accomplish much by other design features A few possibilities are here suggested. The loss in the metallic cage can be eliminated by replacing this by a non-metallic guard. Losses in the laminations can be reduced by making these narrower. The use of a cruciform core, if practical, would also reduce the losses in the laminations by providing edges for the flux to leave in all directions thereby reducing to a minimum the flux leaving perpendicular to the sides of the laminations.

In this connection it is desired to point out that the extra cost of a properly designed constant-current transformer may be offset by the savings which will

Fig. 9—Second Illustration of Leakage Flux by Means of Iron Filings Showing How This Leaves the Sides as well as the Inside and Outside Edges of the Laminations

result from reduced losses. It may also be possible to get the desired characteristics without materially increasing the cost of the transformer.

Aside from the savings in losses, continuity of service, which is of special importance in street lighting service, requires reliability in operation of all equipment supplying this service. Such service is endangered by using transformers which may break down due to heating on light loads.

Discussion

E. D. Treanor: The authors' criticism of the conventional method of stating the characteristics of constant-current transformers is possibly justified in that this method was indefinite and allowed the possibility of misinterpretation by the purchaser and of neglect by the manufacturer. The assumption that the losses remain essentially constant at all loads was of course known to be not strictly accurate, but the method was of long standing and thought to be satisfactory for transformers which were usually operated near full load or on taps which approximate full-load conditions. It was a convenient assumption because it simplified and reduced the costs of tests and gave accurate results at the point of usual loading.

It seems to me that the most important point in the paper is the viewpoint that there is sufficient use of such transformers at quite low loads to justify more attention to light-load losses, as it is suggested that better characterisics may even justify increased cost if they cannot be obtained without it. On this basis the suggestions for improvement made by the authors and other possible methods should of course be studied to determine whether they are feasible economically on transformers which are now in somewhat limited use. It would seem quite difficult to prove that it is economical to operate constant-current transformer at half load or less even at the assumption that the losses remain constant.

Where the general data of the company with which I am affiliated have been made on the so-called theoretical basis, this has been very plainly stated, but in order to avoid any possibility of confusion such data will in the future be placed on the basis of input-output measurements and it will be shown where the data are based on normal windings and where on taps.

One other point is suggested as a possible danger from increasing light-load losses, that is, high temperature in coils or core structure. These transformers have not as yet been specifically covered by standardization rules of the Institute. Temperature limits, of course, should be considered with reference to the particular apparatus involved and the location of the heated portions with respect to insulation. Until such rules are laid down, the best guides would seem to be general information on other apparatus and experience on particular transformers. The maximum temperature reported at extremely low loads, while undesirably high, should not be injurious to the transformers which have been carefully designed to keep organic material from exposure to points of maximum temperature on metallic parts. The temperatures shown are not generally representative of modern designs.

There should be no difficulty in covering desired characteristics in losses and temperature by specifications so definite that no confusion can arise. However, when operating conditions compel the use of constant-current transformers at so much less than their normal load that the taps provided will not give reasonable characteristics, it would seem that the economical thing would be to provide transformers of a proper rating even if the larger transformer has the same losses at all loads.

J. B. Gibbs: It is well known that constant-current regulating transformers depend for their operation on the leakage flux between coils. This knowledge has enabled us to design and build regulators which operate satisfactorily and even to predict with good accuracy the reluctance of the average path which the magnetic leakage flux must follow. It has remained, however, for the authors of this paper to make a detailed study of the path of the leakage flux and of its effect on the regulator operation.

The ampere-turns in the winding of a constant-current regulator, or of any other transformer for that matter, cause a difference in magnetic potential between different parts of the iron circuit. This in turn causes a leakage flux to pass from one part to the other through the air space between the coils. The amount of this leakage flux depends upon the ampere-turns which produce it and on the length and area of the average path which it must traverse. If a constant-current regulator is to go to short circuit without an increase in secondary current, the designer must make the total leakage flux when the coils are at their position of maximum separation as great as the total flux induced in the regulator. The leakage leaves from the central core of the regulator in every direction, and quite a large part of it leaves in a direction perpendicular to the plane of the laminations. This part, of course, must pass directly through the outer laminations and it sets up considerable losses. The losses naturally depend upon the amount of iron affected, that is, upon the distance between the primary and secondary coil, and they are greater, as the authors have pointed out, under no-load condition. Under certain conditions, the temperature of the iron may be relatively high, especially under the no-load condition. The highest temperatures are usually confined to small parts of the iron, though, and it should be pointed out that the coils of this type of transformer are not wound on the iron; they are wound on a heavy insulating tube, and this is further separated from the iron by an air space. I never have heard of a case of damage to the coils on account of the temperature of the iron. In fact, all our tests seem to indicate that although the iron at certain points may become hot, the wire nearest to

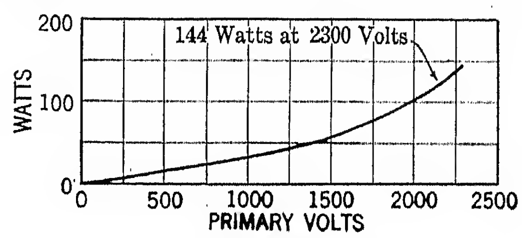

Fig. 1

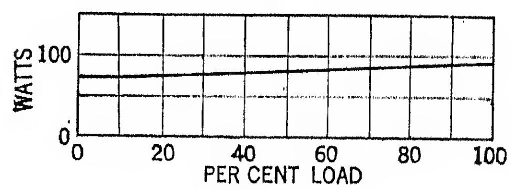

Fig. 2

that iron is relatively cool. As to the coils themselves, the temperature test on such regulators is usually made with the secondary coil short-circuited and full voltage applied to the primary, which is the worst condition, as this paper shows. So that if the temperature test shows the coils at a safe temperature, you may be reasonably sure that the operating condition will show them at a still lower temperature. The authors' remarks about temperature as applied to commercial constant-current regulators seem to me rather unduly alarming.

The most desirable operating condition, as every one recognizes, is with full load on the regulator. This results in the highest efficiency and the highest power factor. The present paper shows also that it results in the lowest temperature. All these three factors operate in the same direction. Sometimes the condition of the circuits demands that the regulator be operated at less than full load. If this is done, efficiency and power factor are sacrificed to a certain extent and the temperature is increased above what it might be, but it is not increased to a point where a good commercial regulator will be endangered either in operation or in life.

W. B. Kouwenhoven: As Messrs. Louis and Albaugh show, the losses are mainly caused by the leakage flux. This leakage flux will naturally produce a high temperature in the iron, but it is a surprise to me that the temperature of the secondary winding should be as high as shown by the authors. I should like to know how the temperature of this winding was measured. Owing to the small current in the secondary, the size of the con-

ductor is relatively small and I should expect that the eddy currents set up in this conductor by the leakage flux would be small.

A. F. Hamdi: During the summer of 1925 we were testing some constant-current transformers and it had been our habit to use the over-all method for getting efficiency. We did not use the accepted A. I. E. E. method, which means calculating the efficiency from the losses. The A. I. E. E. rules apply specifically to constant-potential transformers and were not suited for this purpose; and the paper and also the previous speakers have pointed out why those rules do not cover constant-current transformers. We hope that in the future revision of the standards, this thing will be taken care of.

In our tests the errors in efficiency were not quite as much as pointed out by the authors, namely, in Fig. 1 of the paper we find about a 10-per cent difference at 25-per cent load. In our tests we found discrepancies of about 1½ to 5 per cent in various transformers. The transformers we tested were oil-cooled, 10-kv-a. modern transformers.

I should like to ask the actual magnitude of the stray-load losses. In our case we found that the total losses varied by less than 20 per cent, whereas the stray-load losses themselves varied by over 100 per cent; in other words, they were about 100 watts at full load and went up to about 225 watts at light load.

I should like to discuss an empirical method which we have used for efficiency calculations, which apparently gives very good results. On a test of six transformers, we have been able to come within better than 1 per cent of the over-all method.

One thing, of course, to be kept in mind is that the entire core of the constant-current transformer is not excited to the same flux density.

In the new method we have assumed, arbitrarily, that one-half of the core is excited to a flux density corresponding to the primary voltage, while the other half is excited to a flux density corresponding to the secondary voltage. The total core loss at any load can therefore be obtained from the accompanying Fig. 1, which represents core losses at various voltages with open-circuited secondary. Fig. 2 represents the total core losses obtained from Fig. 1, following the above assumption.

Taking for instance the case of full load, the core loss is 95 watts, made up of 72 watts (half the core loss occurring at primary voltage—2300 volts) and 23 watts (half the core loss occurring at full load secondary voltage—1335 volts). Similarly at no load, the core loss is taken to be only 72 watts, as there is practically no voltage across the short-circuited secondary.

The next thing to calculate is the stray-load loss. This can be obtained from the short-circuited impedance test made with the two extreme positions of the coils: first with the coils locked close together and second with the coils away from each other as far as possible, corresponding to the full-load and the no-load positions respectively.

From the two values of losses so measured we obtain the stray-load losses by subtracting the d-c. $I^2 R$ losses involved and also the core losses which are obtained from Fig. 1. This last step is essential because contrary to the case of constant-potential transformers considerable voltage is necessary to perform a short-circuit test on constant-current transformers.

The two values of stray-load losses so obtained are plotted in Fig. 3. The straight line joining them gives the stray-load losses at various loads, if we assume that the coil displacement is a straight-line function of the load. This assumption is really fair, because the stray-load losses actually vary as the curve in dotted line superimposed on the straight line in Fig. 3.

The total losses of the transformer can therefore be obtained by adding to the d-c. $I^2 R$ losses (constant for all loads) the core losses as obtained from Fig. 2 and the stray-load losses as obtained from Fig. 3.

The efficiency is then calculated in the usual manner.

H. C. Louis and A. Albaugh: The question of loading constant-current transformers is a very serious one, especially when circuits are growing. In this case, it is necessary to provide certain spare capacity in the transformers. This capacity, of course, will vary with the assumed ultimate size of the circuit. So that to prepare for the final condition, transformers of apparently excessive size are often used.

Another reason is that when station-type transformers are used, it is highly advantageous to have them all of the same size, thereby providing the greatest standardization and flexibility. Some of the circuits for these transformers, therefore, will be more heavily loaded than others.

Regardless of the loading of these transformers, it is important that their characteristics be thoroughly understood by operators and designers and the main object of this paper is to present the most important of those characteristics.

Mr. Treanor mentioned that the temperatures shown in the curves are not generally representative of modern designs. The temperatures shown are fairly representative of the latest design station-type air-cooled constant-current transformers. However, oil-cooled transformers have lower temperature due to the presence of the cooling oil.

The advantage of taps on constant-current transformers is questionable. Some of our tests show that although operating on a lower capacity tap, the transformers do not have a higher efficiency than when operating at the same load on the full-

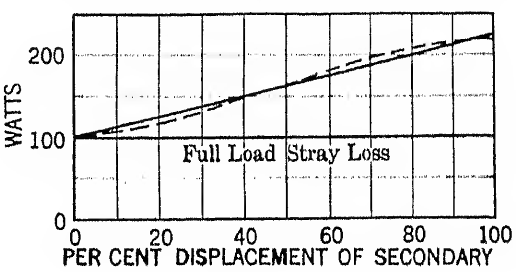

Fig. 3

capacity tap. At light loads on the low-capacity tap, losses were found to be actually higher than on the full-rating connection. The main advantage of the tap is the slightly higher power factor obtained.

Mr. Gibbs mentions that temperature tests are usually made with the secondary coils short-circuited and full primary voltage applied. Under these conditions, the temperature rise will be a maximum, but considerable care must be taken in these tests to locate the hottest parts, especially in oil-cooled transformers. The hot-spot temperatures of these transformers may be sufficiently high to cause sludging and for this reason, should be located.

Dr. Kouwenhoven's question about the temperature rise in the coils, is an interesting one. Undoubtedly, the great amount of leakage flux causes eddy-current losses in the copper conductors which will vary somewhat with the load and thus affect the temperatures. However, the copper temperature variation noted was mainly due to radiation and convection of heat from the iron core. The temperature of the coils on the transformers tested was measured by means of thermometers and thermocouples applied directly to the coils. Temperatures by rise of resistance measurements were taken but as these gave only the average temperatures and not the maximum temperatures, they were not used in the paper.

In reference to the losses, we have made some attempts to segregate them but the results were not very satisfactory. The stray-load losses at full load on 50-kw. air-cooled station-type transformers amount to approximately 400 watts out of a total loss of about 1800 watts, while at short circuit, the stray-load losses amount to 2400 watts out of a total of 3500 watts. Of course, we are not certain of these values and do not put much dependence in them. They were worked up only in order that we might reach some conclusion for the apparent increase in losses of the transformer with decreased load.

Additional Losses of Synchronous Machines

BY C. M. LAFFOON[1] and J. F. CALVERT[1]
Associate, A. I. E. E. Non-member

Synopsis.—*In the case of high-speed turbine generators, the most reliable means of determining the losses under actual operating conditions is to measure the weight and temperature rise of the cooling medium and to estimate the small part of the losses which is dissipated from the frame to the surrounding medium. The temperature rise of the cooling medium can be obtained by means of temperature detectors located at the inlet and outlet sections of the generator. In order to obtain reliable values of the average temperature rise for the machine, it is necessary to have approximately uniform velocities at both inlet and outlet sections and to measure the temperature rise at a large number of incremental sections.*

The volume of cooling medium passing through the machine can be determined by (a) introducing a definite amount of heat energy into the cooling medium and measuring its temperature rise, or (b) measuring the mean velocity head at the outlet section of a properly designed stock.

Loss tests were made on five 3600-rev. per. min. turbine generators when operated as synchronous condensers. In the case of these machines, the additional losses including the increase in core loss at full kv-a. and zero per cent power-factor load varied from 3 to 22 per cent of the total losses. This corresponds to approximately 0.14 to 1.0 per cent of the generator input. The additional losses as measured under sustained short-circuit conditions were from 5 to 10 per cent less than the corresponding values for full kv-a. at zero per cent power factor.

It is suggested that data can be obtained for predetermining the magnitude of the total additional losses by measuring the loss in each structural part and determining graphically the magnetizing flux which produces it. The magnetizing flux distributions at different parts of the machine were plotted for different ampere-turn relations.

Additional studies are being made on methods of calculating the magnitude of the additional losses and the increase in core loss with load.

The losses of a synchronous machine, when operating under no-load conditions, can be obtained with a satisfactory degree of accuracy by measuring: (a) the electrical power required to drive it; (b) the mechanical counter torque developed by it; or (c) the retardation of the rotor when the driving power is suddenly removed. In general, the particular test method which should be used depends on the type of machine under consideration and the local conditions which are associated with it. In the case of a high-speed steam turbine generator, it is preferable to operate it as a synchronous motor and measure the electrical input. The power factor of the load can be adjusted to unity, practically, so that the electrical input measurements can be made very accurately. This method eliminates the necessity of correcting for the coupling, and for motor losses when a separate driving motor is used. It has an outstanding limitation when applied to steam turbine generators, however, in that such machines are not usually adapted for self-starting as induction motors, but must be brought up to speed synchronously with an isolated generator set. In connection with large steam driven turbine generators, it is well to call attention to the fact that the direct-connected auxiliary generator furnishes a satisfactory means of driving the main generator and thus makes it relatively easy to measure the magnitude of its no-load and short-circuit losses. In the case of low-speed generators, the excitation loss is an appreciable percentage of the total losses; consequently, a direct-connected exciter, when available, can be used as a source of driving power for determining the no-load and short-circuit losses. With larger water-wheel driven generators which have large fly-wheel effect, the retardation method offers a satisfactory means of determining the no-load and short-circuit losses[2].

Various satisfactory methods have been derived for separating the total measured value of the no-load losses into the two principal components of (a) windage and friction, and (b) iron loss. Since the total value of the no-load losses can be accurately determined and segregated into the respective components, it is a relatively simple matter to estimate the magnitude of the no-load loss components quite accurately, provided the loss constants are based on test results from similarly proportioned machines. Obviously, this method of calculation is limited by the actual test data which are available. With the more analytical and scientific method of calculating the losses, it is necessary to make an exhaustive study of the effect of the different variables involved and then determine the necessary constants from tests on actual machines or models which reproduce the conditions that exist in the machine. A large number of such investigations has been and is being made by different individuals, organizations, and manufacturing companies, so that, so far as the no-load losses of synchronous machines are concerned, the field is being rather thoroughly investigated.

Synchronous Machines Under Load Conditions

When a synchronous machine delivers or receives current at constant terminal voltage and definite power-factor conditions, the flux and ampere-turn relations are appreciably different from the conditions which exist at no-load on account of the leakage reactance and demagnetizing action of the armature winding. Consequently, the armature current not only introduces other losses, but the iron and excitation losses are higher than at no-load. The friction and windage losses can be considered, for all practical

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

2. See Bibliography, 1.

purposes, constant at all loads, provided the air and speed conditions are not changed. The losses introduced by the armature current are the armature copper loss based on d-c. resistance and the additional losses which are produced in the materials of the main magnetic and electric circuits and in materials which are in close proximity to the armature winding. The excitation loss under different load conditions can be calculated or measured with a satisfactory degree of accuracy. The d-c. resistance of the armature winding can be satisfactorily measured under load conditions and thus the d-c. armature copper loss can be obtained. The question of increased copper loss due to the non-uniform distribution of the current in the armature conductors has been thoroughly investigated by different writers, and it can be assumed that this portion of the additional loss can be calculated with a satisfactory degree of accuracy.[3] The question of increased iron loss due to load will be considered in a later article. Several studies have been made by European writers in regard to the calculation and measurement of generator losses under load conditions.[4] But the data which were obtained apply particularly to machines of European design proportions. The design proportions and construction of European machines are widely different from present American designed machines and the additional losses are probably widely different in the two types of machines. The principal purposes of this article are (a) to discuss methods of measuring the losses of high speed synchronous machines under load conditions; (b) to give results of loss measurements on four, 3600-rev. per. min. turbine generators; and (c) to segregate the losses into the different components so as to ascertain the magnitude of the total additional losses.

Methods of Measuring the Losses of Steam Turbine-Driven Generators under Load Conditions

The loading-back and calorimeter methods are the two outstanding means of measuring the losses of high-speed synchronous machines under different load conditions. In the loading-back method two duplicate machines, which are electrically and mechanically coupled together, are driven at synchronous speed. When one unit operates as a motor and the other as a generator at definite current, voltage and power-factor conditions, the only power required from an external source is that which is necessary to supply the losses of the two units. With this method of test, the total losses of the two machines can be measured with a satisfactory degree of accuracy, but there is question in regard to the division of the losses on account of the fact that the two machines do not have the same excitation and consequently do not have the same internal flux conditions. This method has the further limitation in that two machines are required and a complicated coupling or frame shifting mechanism is required if it is desired to operate at different power factors.

3. See Bibliography, 2, 3, 4.

4. See Bibliography, 5, 6, 7.

With the calorimeter method, the losses of the machine are determined by measuring the weight and temperature rise of the cooling medium. Obviously this method is only applicable to machines with forced ventilation, such as rotating machines and water- or oil-cooled transformers. When such an electric machine is operating at any given load condition, and constant temperatures have been reached, a major portion of the losses within the frame is carried away by the cooling medium, and the remainder is dissipated to the medium surrounding the frame of the machine. In the case of steam turbine driven generators, the magnitude of the loss to the cooling medium can be measured quite accurately and the small part of the loss which is dissipated from the frame to the surrounding medium can be estimated with a sufficient degree of accuracy to make this method the most reliable one for this class of machines. If the machine has a closed circuit ventilating system and the surface type of cooler for the cooling medium of the generator, the loss given up by the cooling medium can be obtained by measuring the weight and temperature rise of the water passing through the surface cooler. In addition to estimating the loss dissipated from the frame of the machine, it is necessary in this case to estimate the portion of the loss which is lost by the cooling medium in passing from the outlet of the machine to the inlet of the cooler, and also the loss dissipated from the frame of the cooler. With these three corrections to make, instead of one, the magnitude of the error in the estimated portion of the losses is probably three times as great as in the previous case. Moreover, the energy transferred from the cooling medium to the water cannot be measured with as great accuracy as that from the machine to the cooling medium on account of the fact that (a) the temperature rise of the cooling water is only about one-fourth of that of the cooling medium in passing through the machine and hence, for the same numerical error in the temperature rise, the percentage error would be four times as great; and (b) equally reliable measurements of the temperature rise of the cooling water cannot be made on account of the difficulty of getting a sufficient number of accurate-reading temperature detectors in intimate contact with the water at the inlet and outlet sections of the cooler. In general, the direct measurement for determining the weight and temperature rise of the cooling medium is the simplest and most reliable calorimeter method of determining the total losses of steam driven turbine generators under any load condition.

Measurement of the Temperature Rise of the Cooling Medium

The temperature rise of the cooling medium can be obtained by measuring its temperature at the inlet and discharge sections of the machine or by measuring it

directly by means of differentially connected temperature detectors. The measurement of the temperature rise of the cooling medium would be very easy to make if the temperature were constant at both inlet and discharge sections. In actual machines, neither the temperatures nor the velocities of the cooling medium are uniform at either the inlet or discharge sections of the generator. Consequently, in order to determine the average temperature rise of the machine, it is necessary (a) to divide the inlet and outlet sections into a large number of incremental sections and measure the temperature and the volume of the cooling medium which flows across each incremental section; or (b) to obtain uniform velocities at both inlet and outlet sections and then obtain the temperature at a sufficient number of incremental sections so that a simple algebraic average can be used. The latter is the preferable method to use on account of the fact that the velocity variable of the cooling medium is eliminated and the temperature rise can be obtained at a sufficient number of incremental sections by measuring the difference in e. m. fs. induced in thermocouple junctions or the difference in potential drops across resistance elements. Satisfactory results can be obtained by either type of detector provided the necessary precautions are exercised, and the choice of method will depend to a large extent on general preference and previous experience. When the thermocouple type of detector is used, the number of junctions in series can be chosen such that the indicating instrument operates at the most accurate part on its scale. Rubber insulation should be used on the wires between junctions in order to eliminate erratic results due to short circuits and grounds which are usually experienced when less reliable insulation is used. If the inlet air temperature periodically fluctuates over an appreciable range, the measured temperature rises will also be irregular because the pulsations are damped out or absorbed by the generator and do not appear to an appreciable extent in the outlet air temperature. The variation in inlet air temperature must be corrected for by taking a relatively large number of readings, or the temperature detectors must be compensated so that a close average temperature rise can be obtained. In order to damp out variations in the temperature rise after the machine has reached constant temperatures, thermal storage capacity should be added to the detector located at the inlet air section. From a theoretical consideration, the heat storage capacity of the detectors which are located at the inlet air section should be equivalent to that of the machine but actually the mass of the heat storage materials for the inlet detectors cannot be made very large without obstructing the air flow. Marked improvement can be obtained, however, by making the heat storage capacity of the detectors located in the inlet air stream as large as practical, without obstructing or seriously disturbing the air flow. In order to obtain sufficient thermal storage capacity in the inlet detectors, and yet not interfere with the air flow, a satisfactory procedure is to measure the temperature rise between two arbitrarily chosen incremental sections at the inlet and discharge by means of a set of thermocouples connected in differential series. Correction for the variation in temperature at both the inlet and discharge section can be made by measuring the temperature variation of all other points of each section with respect to the arbitrarily chosen reference points, by means of another set of thermocouples connected in differential series but which have no appreciable thermal storage capacity.

Measurement of Weight or Volume of the Cooling Medium

The calorimeter method can also be used to measure the volume of the cooling medium which passes through the machine. If a known amount of power is absorbed by the cooling medium and the corresponding temperature rise is measured, the volume of the cooling medium can be calculated from its specific heat constant, barometric pressure, and absolute temperature. If air is used as the cooling medium the volume can be calculated from the following formula[5].

$$V = \frac{0.177\,(273 + T_1)}{B}\;\frac{W}{T_2} \qquad (1)$$

where V = the mean volume in the meter in cu. ft, per min.,

T_1 = the mean temperature in deg. cent.,

B = room barometric pressure, and approximately the mean static pressure in the meter in inches of mercury,

W = watts input to the air,

T_2 = temperature rise of the air in deg. cent. due to W.

In order that satisfactory values of air volume be obtained with this method of measurement, the following conditions and requirements must be fulfilled:

a. Either uniform air velocities or uniform air temperatures must exist in the air stream at the sections where the temperature detectors are located,

b. The heat input to the air stream should be uniform over its entire cross-section, or else the air must be thoroughly mixed after heating so that uniform air temperature will exist at the outlet section,

c. The temperature of the heating elements must be sufficiently low, and the lead arrangements such that the percentage of heat radiated and conducted from these elements is negligible as compared to percentage of heat input which is convected away by the air stream,

d. The walls surrounding the air stream at the place where the heat is introduced should be insulated so that a negligible percentage of the heat input is dissipated to the surrounding atmosphere,

e. A sufficient length of time should elapse, after the heat is applied, before making the temperature rise

5. See Bibliography, 8.

measurements, in order for the walls, bus bars, and wiring connections to reach constant temperatures,

f. The degree of accuracy in measuring the temperature rise of the air should be comparable with the accuracy of the temperature rise measurement of the generator under load conditions.

The volume of the cooling medium can also be obtained by measuring its velocity head at the discharge section. This necessitates the discharge of the cooling medium from the machine from a nozzle or stack which must be designed so that the velocities of the cooling medium at the outlet are practically uniform and the direction of flow is normal to the outlet section. When the cooling medium is discharged directly into a large room, the discharge velocity heads for the incremental section of the outlet section can be measured with an impact tube and an inclined pressure gage. From these velocity head measurements the respective velocities can be calculated in feet per minute for any specific cooling medium. The derivation of the formula for air as the cooling medium is as follows:

- p = velocity head in inches of water for any incremental section,
- a = area of any incremental section in sq. ft.,
- v = velocity in ft. per min. for any incremental section,
- q = volume in cu. ft. per min. for any incremental section,
- θ = air temperature in deg. cent.,
- T = $273 + \theta$ = absolute air temperature,
- K = constant,
- α = density of air in lb. per cu. ft.,
- β = barometric pressure.

Subscript o indicates values corresponding to standard air conditions which are assumed to be 25 deg. cent. or 298 deg. cent. absolute temperature, and a barometric pressure of 29.92 in. of mercury. Subscript 1 indicates values applying to an actual test condition, and subscript i indicates values applying to intake air conditions.

$$v_0 = \frac{1}{\sqrt{K\,\alpha_0}}\sqrt{p_0} = 4030\sqrt{p_0}$$

for any incremental section,

$$v_1 = \frac{1}{\sqrt{K\,\alpha_1}}\sqrt{p_1}$$

$$\alpha_1 = \frac{\alpha_0\,T_0\,\beta_1}{T_1\,\beta_0}$$

$$q_1 = a\,v_1$$

$$q_1 = 4030\sqrt{\frac{T_1\,\beta_0}{T_0\,\beta_1}}\sqrt{p_1}$$

$$= 6 \times 10^3\sqrt{\frac{273 + \theta_1}{\beta_1}}\sqrt{p_1}$$

Then the total volume Q_1 at the outlet, is

$$Q_1 = \sum_1^n q_1 = 6 \times 10^3\sqrt{\frac{273 + \theta_1}{\beta_1}}\sum_1^n \sqrt{p_1} \qquad (2)$$

Since the variations in temperature of the outlet air are small, practically no error in the total volume is introduced by considering T_1 constant for all of the incremental sections. The total volume in terms of intake condition is

$$Q_i = Q_1\frac{T_i}{T_1} = \frac{6 \times 10^3\,(273 + \theta_i)}{\sqrt{\beta_1}\,(273 + \theta_1)}\sum_1^n \sqrt{p_1} \qquad (3)$$

Since it is necessary to measure the temperature rise of the air passing through the machine, it is desirable to have the temperature at the outlet of the stack the same as at the outlet of the machine. The loss of heat energy from the walls of the stack can be made inappreciable by applying a sufficient amount of cork and felt insulation.

In comparing these two methods of measuring the volume of air passing through steam driven turbine generators, both require practically uniform velocities at particular sections. The calorimeter method requires special wiring, and considerable care in the thermocouple measurements. The velocity head readings at the outlet section of the stack can be easily obtained and consistently repeated. The number of points at which these pressures are read can be increased indefinitely and thus the accuracy of the results can be made as high as it is advisable to go. The number of thermocouple junctions cannot be increased beyond a particular value without restricting the air flow. The stack is simple to build, more sturdy, easier to maintain, and in general gives more consistent results than the calorimeter method of measuring air volumes. Both methods will give reliable results provided the elements are properly designed and the necessary precautions exercised in making the measurements.

Loss Measurements on High Speed Turbine Generators

Temperature and loss measurements were made on five three-phase, 3600-rev. per. min., 80-per cent power-factor turbine generators with rating characteristics as indicated in Table I. The generators were operated as synchronous condensers, and the losses were determined by the calorimeter method for several different kv-a. loads. The power factor varied from 100 per cent at no-load to approximately zero per cent at 100-per cent kv-a. load.

The loss from the generator to the cooling air was calculated by the following formulas:[6]

$$K\,W_1 = \frac{Q_a\,\theta \times 10^{-3}}{1.765} \qquad (4)$$

$K\,W_1$ = Loss to the air in kw.

6. See Bibliography, 8.

TABLE I

Generator number	Rating		Remarks
	Kv-a.	Volts	
1	2500	600	Generator had same fan as generator No. 2. One conductor per slot type of stator winding.
2	3125	2400	Stator end plates of magnetic material.
3	3125	2400	Same as generator No. 2 except non-magnetic end plates.
4	6250	2400	Axial system of ventilation. Armature punchings of medium loss steel.
5	6250	2400	Multiple path radial system of ventilation. Larger fan than on generator No. 4. Armature punchings of low loss silicon steel.

Q_a = Air volume in cu. ft. per min. at standard temperature and barometric pressure conditions.

θ = Average temperature rise of the cooling air in deg. cent.

The loss dissipated from the frame by natural convection was calculated on the basis of a dissipation

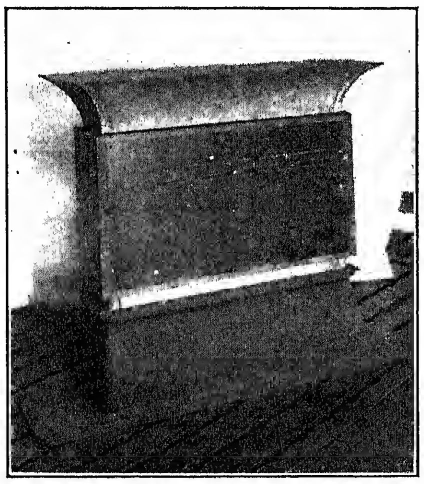

FIG. 1—CALORIMETER

constant of 0.012 watts per sq. in. per deg. cent. temperature difference between the surface of the machine and the surrounding air.

$$K W_2 = 0.012 - S\,(\theta_s - \theta_a) \qquad (5)$$

where

$K W_2$ = Loss in kw. dissipated from the surface of the frame,

S = Effective dissipating surface of the frame in sq. in.,

θ_s = Average temperature of the frame surface in deg. cent.,

θ_a = Average temperature of the surrounding air in deg. cent.

The total loss within the frame of the generator is the sum of the two losses as defined above.

The temperature rise of the cooling air for all of the machines was measured by means of thermocouples located at the inlet and outlet sections and connected in differential series. The volumes of cooling air for machines Nos. 1 to 4 inclusive were determined by the calorimeter method and Equation (1). Fig. 1 shows the type of calorimeter which was used to make the measurements. The volume of cooling air for generator No. 5 was determined from the velocity head measurements at the outlet of a discharge stack and the calculations were made by using Equation (3). Fig. 2 shows the stack as assembled on this generator for the test.

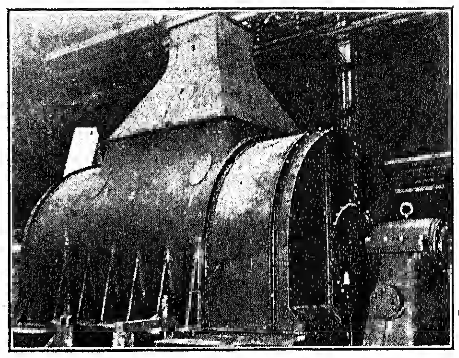

FIG. 2—DISCHARGE STACK ON GENERATOR

SEPARATION OF THE LOSSES

The total losses within the frame were separated into the following components:

a. Air friction and fan loss,
b. Iron loss at no-load,
c. Field copper loss,
d. Armature copper loss based on the d-c. resistance,
e. Additional loss.

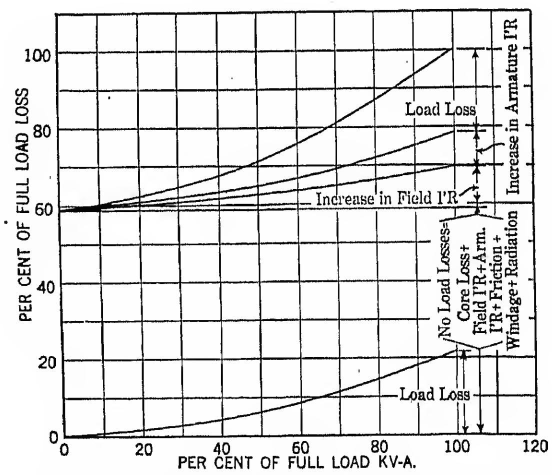

FIG. 3—SHOWING RATIO OF LOSS TO LOAD

(Generator No. 1, 2500-kv-a., 600-volt, three-phase, 60-cycle, 3600-rev. per min.)

The total losses of the machine at no-load and full voltage conditions, as obtained by the calorimeter method, checked very closely with the results which were obtained from the electric input measurements when the machines were operated as synchronous motors at no-load and 100 per cent power factor. The iron loss was separated from the total no-load loss by measuring the kw. input to the machine when operated

as a synchronous motor at 100 per cent power factor for several values of impressed voltage, and then extending a curve of either the voltage or a function of the voltage vs. total kw. loss to the zero voltage line.

The field copper loss was calculated from the measurements of the field current, and the voltage at the collector rings after constant temperature conditions were reached. The armature copper loss, based on the d-c. resistance of the winding, can be calculated with good approximation by estimating the average temperature of the winding from readings of imbedded temperature detectors on the ends and buried parts of the coils. A closer approximation can be obtained by measuring the resistance of the winding immediately at the end of each test run. By plotting the values of resistance against time and extending the curve back to the instant of time corresponding to the end of the test, the resistance of the winding at the final operating condition can be determined with a good degree of accuracy.

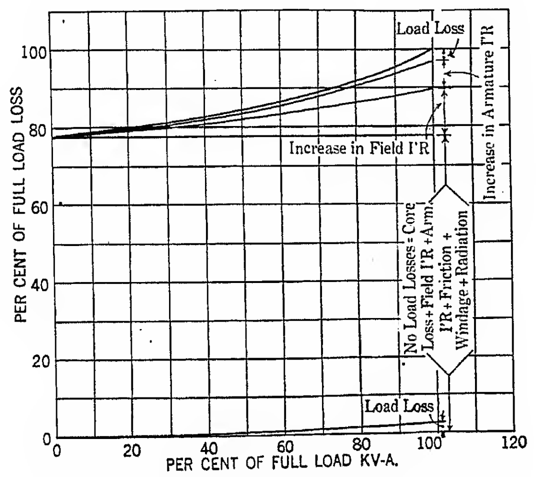

FIG. 4—SHOWING RATIO OF LOSS TO LOAD

(Generator No. 2, 3125-kv-a., 3300-volt, three-phase, 60-cycle, 3600-rev. per min.)

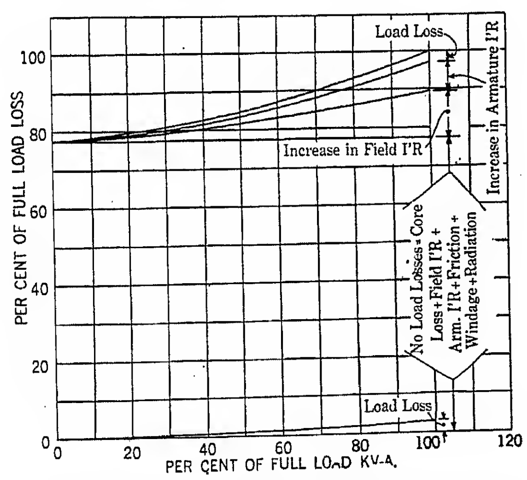

FIG. 5—SHOWING RATIO OF LOSS TO LOAD

(Generator No. 3, 3125-kv-a., 2300-volt, three-phase, 60-cycle, 3600-rev. per min.)

Both methods were used in determining the armature copper losses of these generators. The additional loss was obtained by subtracting the sum of the above losses, items *a* to *d* inclusive, from the total value of the measured loss within the frame for each generator. The total losses within the frame and the segregated components are given in Figs. 3, 4, 5, 6 and 7, as a function of the per cent kv-a. load for all of the generators. Fig. 8 shows the variation of the additional losses as a function of the per cent kv-a. load at zero per cent power factor for all of the machines. The total and segregated values of the generator losses are given in Table II for both full kv-a. load at zero per cent power factor, and for sustained short-circuit conditions with full-load current flowing in the armature winding.

It can be seen from the data in Table II that the additional loss varies from approximately 3 to 22 per cent of the total loss for these machines. Hence, if the total loss represents 4.5 per cent of generator input,

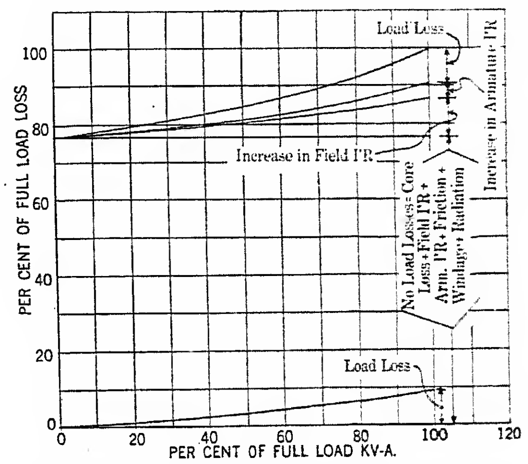

FIG. 6—SHOWING RATIO OF LOSS TO LOAD

(Generator No. 4, 6250-kv-a., 2400-volt, three-phase, 60-cycle, 3600-rev. per min.)

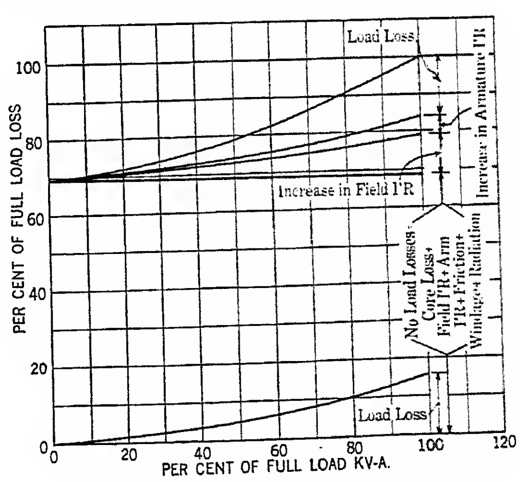

FIG. 7—SHOWING RATIO OF LOSS TO LOAD

(Generator No. 5, 6250-kv-a., 2400-volt, three-phase, 60-cycle, 3600-rev. per min.)

TABLE II

Generator number	Rating in per cent			Generator Losses Expressed in Per Cent				
	Kv-a.	Volts	Amp.	Total	Fan + friction + iron	Field copper	Armature copper	Additional
1	100	100	100	100	56.35	12.9	8.91	21.84
	..	0	100	59.5	28.0	3.06	8.48	20.0
2	100	100	100	100	74.2	15.6	7.39	2.80
	..							
3	100	100	100	100	74.0	15.56	7.55	2.9
	..							
4	100	100	100	100	73.8	12.7	3.92	9.5
	..	0	100	50.2	35.0	1.87	3.92	9.4
5	100	100	100	100	66.5	12.5	5.28	15.6
	..	0	100	68.4	46.8	2.48	5.15	14.0

the additional loss in the case of these machines would represent from 0.14 to 1.0 per cent of the total kw. input. The highest percentage additional loss occurred for machine No. 1, which had a 600-volt stator winding with only one conductor per slot. The one-conductor-per-slot type of winding usually results in a relatively large per cent additional loss on account of the higher current per slot and the greater concentration of current in the end connections of the winding. This loss handicap for low-voltage windings cannot ordinarily be eliminated without departing appreciably from the design proportions which are satisfactory for the more desirable higher voltages. Such changes usually result in increased development and manufacturing costs, and consequently, from the standpoint of generator costs alone, the use of special low-voltage windings should not be encouraged.

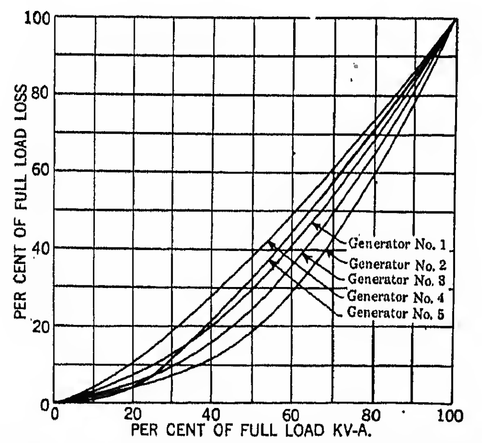

FIG. 8—LOAD LOSS IN PER CENT OF FULL LOAD LOSS VS. PER CENT OF FULL LOAD FOR FIVE GENERATORS

The additional loss of the machines at full kv-a. and approximately zero per cent power factor is of the same order of magnitude as the additional losses of the machine under sustained short-circuit conditions. The additional loss for full kv-a., full voltage conditions includes the increase in iron loss over the no-load values, whereas the additional loss at short-circuit conditions includes only the iron loss due to a magnetizing flux which depends on the magnitude of the leakage reactance.

TEMPERATURE LOAD CURVES

Thermocouples were located on the stator end bells, end plates, finger plates which support the stator teeth, and on the surface of the stator teeth near the finger plates. The final temperature rises which were obtained at these points are plotted against per cent kv-a. load as shown by the curves in Figs. 9 to 13. The outstanding points in connection with these curves are as follows:

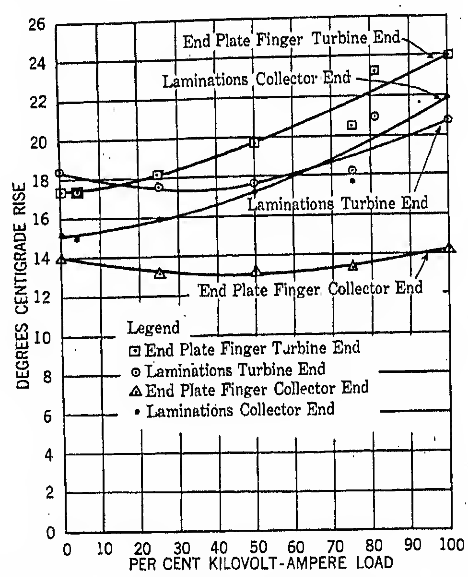

FIG. 9—TEMPERATURE RISES ABOVE INGOING AIR OF END-PLATE FINGERS AND LAMINATIONS (Generator No. 1)

a. The final temperatures which were reached at full kv-a. load were very low. The temperature rise did not exceed 20 deg. cent. at any of the points on any machine. The temperature rise of finger plates was practically the same as for the adjacent stator tooth laminations. On the basis of these results, it can be concluded that the additional loss in these parts of these machines must not be very large.

b. In all cases, the temperature rise decreased slightly as the load increased from zero to approximately 25 per cent of the full load kv-a. rating. While this is of little or no practical importance, it is of interest from a theoretical standpoint because it shows that the resultant flux in these parts due to the stator and rotor m. m. fs. is smaller than at no-load due to the field acting alone.

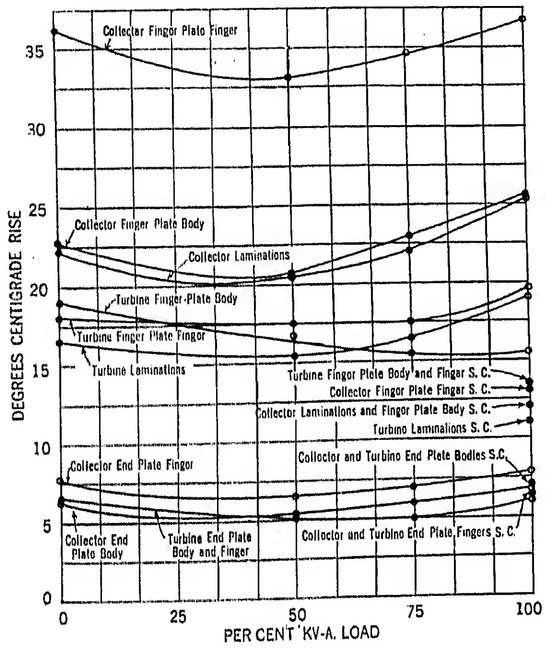

FIG. 10—TEMPERATURE RISE ABOVE INGOING AIR OF FINGER PLATES, END PLATES AND LAMINATIONS, MAGNETIC END PLATES (Generator No. 3)

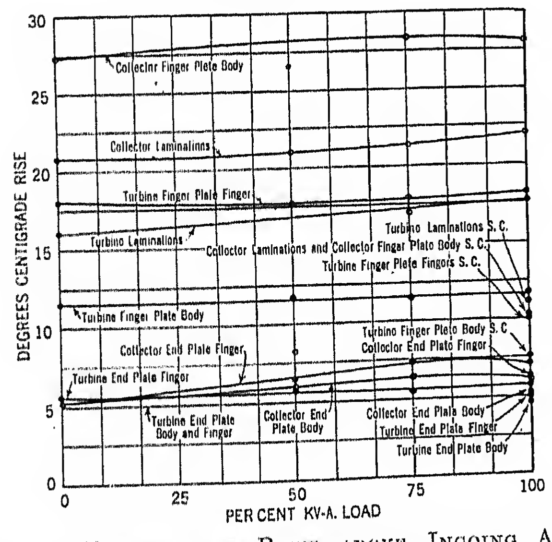

FIG. 11—TEMPERATURE RISES ABOVE INGOING AIR OF FINGER PLATES, END PLATES AND LAMINATIONS, NON-MAGNETIC END PLATES (Generator No. 3)

MEASUREMENT OF THE LOSSES IN DIFFERENT PARTS OF THE MACHINE

In order to predetermine the magnitude of the additional loss of a synchronous machine, it is necessary to know the relative proportions of the loss that exist in the different parts of the machine and also how these loss components depend on the different variable factors. While the calorimeter method is quite satisfactory for measuring the total value of the additional losses of a high speed synchronous machine, it is not applicable for measuring the loss that occurs in the different parts of the machine, due to the fact that the loss in each part represents a too small percentage of the total value of the measured loss. A satisfactory method for determining the proportion of the additional loss which occurs in each part of the machine should measure the loss in that part alone and not measure it in combination with other losses of considerably greater magnitude. Such tests can be made on models which represent the different parts of the magnetic circuit and which are artificially subjected to the electric

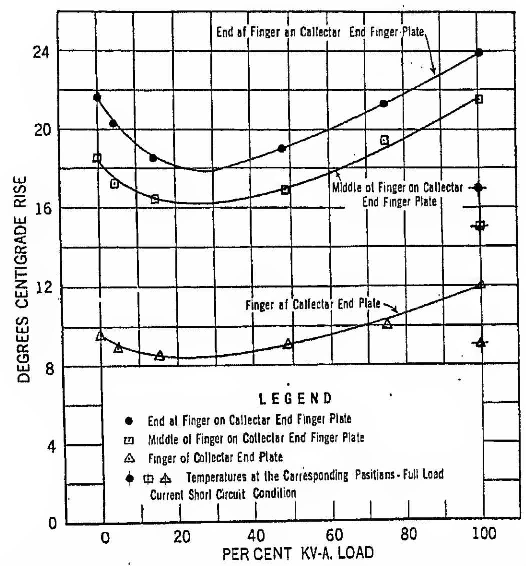

FIG. 12—TEMPERATURE RISES ABOVE INGOING AIR OF FINGER PLATES, END PLATES AND LAMINATIONS (Generator No. 4)

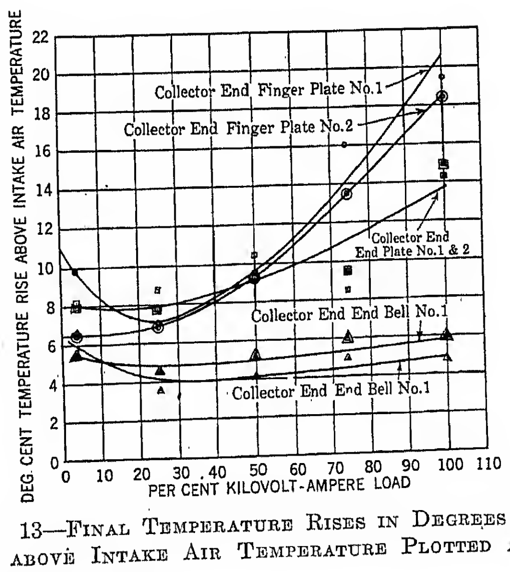

FIG. 13—FINAL TEMPERATURE RISES IN DEGREES CENTIGRADE ABOVE INTAKE AIR TEMPERATURE PLOTTED AGAINST PER CENT KV-A. LOAD

and magnetic conditions as exist in the machine. Such loss measurements can be made quite accurately, but in most cases it is difficult to reproduce the actual magnetic conditions which exist at different load and operating conditions. The losses which occur in the different parts of the machine due to any change in operating conditions can be obtained by measuring the energy absorbed by these parts when the machine is operating at constant temperatures and the change in operating condition is suddenly made. Under steady

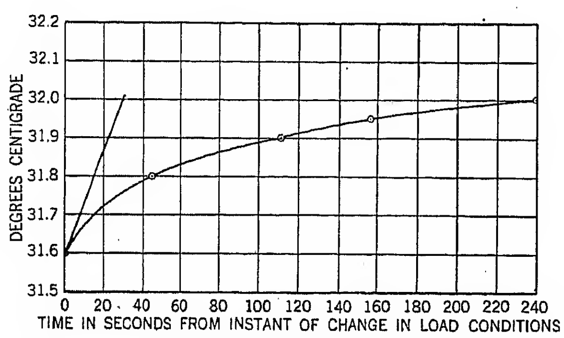

Fig. 14—Temperature Rise of Iron vs. Time

Couple No. 2—Location, turbine end lamination --- $\frac{d\theta}{dt}$ in deg. cent. per sec., 0.01365 --- C, 55.8 ---- watts per cu. in., 0.761

conditions, the heat flowing to any section plus the heat generated in that section must equal the heat flowing away from the section, since there is no change in stored energy under steady temperature conditions. When the load is suddenly increased there is an instantaneous increase in the heat generated in the section. Since there must be a change in the temperature gradient before there can be any change in the heat flow, all of the increase in the generated energy in each section must be stored, at the first instant after the sudden change in load is made. The slope of the temperature time curve for the particular section is proportional to the rate at which energy is stored in it. The increase in loss in watts per cubic inch equals the slope in degrees centigrade per second, at the instant the load change is made, times the specific heat constant of the material in watt-seconds, per cubic inch, per degree centigrade. In order to check the feasibility of obtaining such temperature time curves, thermocouples were located at various points on a machine, and temperature readings were obtained for sudden load changes by means of a reliable potentiometer and a very sensitive galvanometer. The curve in Fig. 14 shows the change in temperature of the stator tooth laminations with respect to time when the load on generator No. 5 was changed from no-load, no-voltage condition to no-load, full-voltage condition. The rate of change of temperature with respect to time at zero time is 0.01365 deg. cent. per sec., and with a specific heat constant of 55.8 watt-seconds per cu. in. per deg. cent., the loss in the stator teeth at the surface is 0.761 watt per cu. in. Since the density of the magnetizing flux in the stator teeth can be readily calculated, the loss constant can be obtained for the teeth with any kind of laminated iron as actually built in the machine. In a like manner, this method of measuring the loss and the analytical method of determining the magnetizing flux can be applied to all parts of the machine so that reliable loss constants can be obtained in terms of the different variable factors.

General Theory of Flux Distribution in Air Parts of the Magnetic Circuit

In the first determination of the magnitude and distribution of the flux in the air parts of the magnetic circuit of a high speed turbine generator, the iron parts were assumed to have infinite permeability. Later approximations were made, when necessary, to consider the effect of saturation. In laying out the flux fields, a family of orthogonal lines will be shown at right angles to the flux lines. Since the flux lines close and do not cross each other, the orthogonal lines, which are at right angles to flux lines, must always converge at the magnetomotive force centers. With a given set of magnetomotive forces and boundary conditions, it is assumed that the correct flux distribution is obtained when the stored energy in the magnetic circuit is a maximum. Uniform current densities are also assumed to exist at all sections of the electric conductors.

According to the accepted interpretation, the magnetomotive force produces closed lines of force or flux around the magnetic centers. There is no force,

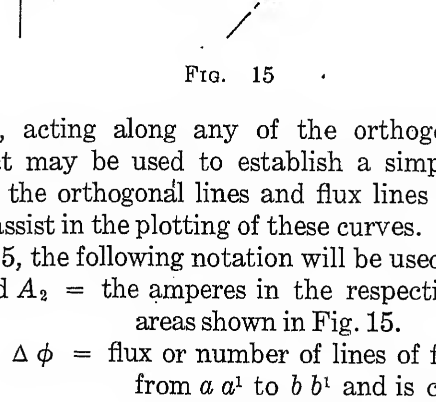

Fig. 15

however, acting along any of the orthogonal lines. This fact may be used to establish a simple relation between the orthogonal lines and flux lines which will greatly assist in the plotting of these curves. Referring to Fig. 15, the following notation will be used:

A_1 and A_2 = the amperes in the respective shaded areas shown in Fig. 15.

$\Delta\phi$ = flux or number of lines of force going from $a\,a^1$ to $b\,b^1$ and is constant in value along this tube. This tube is to be considered of negligible width so that there is no difference in ampere turns acting on this circuit or path in the direction $a^1 - a$, $b^1 - b$, etc.

l_1 and l_2 = the lengths of the path in the parts shown.

$\Delta\, d_1$ and $\Delta\, d_2$ = the corresponding mean widths.

H_1 and H_2 = mean field intensity along l_1 and l_2.

The work done in moving a unit pole around the path o, m, p, o linking A_1 is all done along m, p or l_1. Similarly in moving a unit pole around o, p, n, o in linking A_2, the work is all done along p, n or l_2.

Then:

$$H_1\, l_1 = \frac{4\,\pi}{10}\, A_1 \tag{4}$$

$$H_2\, l_2 = \frac{4\,\pi}{10}\, A_2 \tag{5}$$

and since

$$\Delta\,\phi = H_1\,\Delta\, d_1 = H_2\,\Delta\, d_2 \tag{6}$$

by substituting Equation (6) in (4) and (5),

$$\Delta\,\phi\,\frac{l_1}{\Delta\, d_1} = \frac{4\,\pi}{10}\, A_1 \tag{7}$$

$$\Delta\,\phi\,\frac{l_2}{\Delta\, d_2} = \frac{4\,\pi}{10}\, A_2 \tag{8}$$

Let

$\Delta\, P_1$ and $\Delta\, P_2$ = the respective permeances in the two parts of the circuit shown above.

Then

$$\Delta\, P_1\, \alpha\, \frac{\Delta\, d_1}{l_1} \tag{9}$$

$$\Delta\, P_2\, \alpha\, \frac{\Delta\, d_2}{l_2} \tag{10}$$

Then

$$\frac{\Delta\, P_2}{\Delta\, P_1} = \frac{A_1}{A_2} = \frac{\text{area}_1}{\text{area}_2} \tag{11}$$

Since all the values in Equation (11) can be easily estimated, graphical solutions for the flux distributions can be made fairly readily, where mathematical solutions would become too complicated in most irregularly shaped fields existing in electrical machines. As mathematical solutions would probably have to be based on the same assumption as this one, namely, iron paths of infinite permeability, even the increased accuracy in determining the field probably would be unwarranted in many cases on the basis of this assumption.

While the foregoing theory of flux distribution applies specifically to the magnetomotive force of the armature or field winding acting alone, it can be extended to cover cases in which there are magnetomotive forces in both elements of the machine. In applying it to an actual machine, the magnitude and distribution of the flux were determined for several different parts of the magnetic circuit, as shown in the following figures:

a. Fig. 16 shows the flux distribution in a portion of the air-gap with the field winding excited to give normal voltage, but with no current in the armature windings.

b. Fig. 17 shows the flux distribution in the air-gap when the machine is operating at 100 per cent kv-a., 100 per cent voltage, and zero per cent power factor.

c. Figs. 18 and 19 show the flux distribution in the air-gap when the generator is delivering 100 per cent kv-a. at 100 per cent voltage and power factor.

d. Fig. 20 shows the flux distribution in the air space between the end bells and the machine at the centerline of the poles for 100 per cent kv-a., 100 per cent voltage and zero per cent power factor. The instantaneous values of the currents in the three phases of the armature winding were 0, 86.6, and 086.6 per cent, respectively, of the maximum value at full load. Fig. 21 shows the flux distribution in the space as indicated by iron filings. The rotor was stationary, but its relative position with respect to the stator winding was the same as above. Both elements were supplied with d-c. values of the same magnitudes as the above instantaneous current values. The arrangement of the filings checks very closely with the flux distribution as obtained by the graphical analysis.

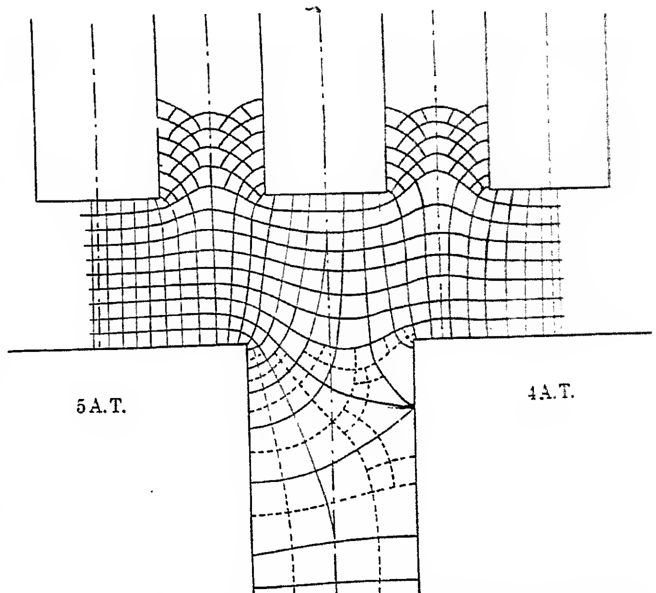

Fig. 16—Flux Distribution in the Air-Gap and Rotor Slot with Relative M. M. Fs. of 5 and 4 Ampere-Turns Across Gap Due to Rotor Winding and Zero M. M. F. Due to Stator Winding

e. Figs. 24 and 25 show the magnetomotive force diagram due to the end connections of the armature winding of a 3600-rev. per min. turbine generator, for specific instantaneous values of current. In obtaining these diagrams, it was assumed that the magnetomotive force acts at right angles to the end winding surface determined by the end connections. The results which have already been obtained from preliminary experi-

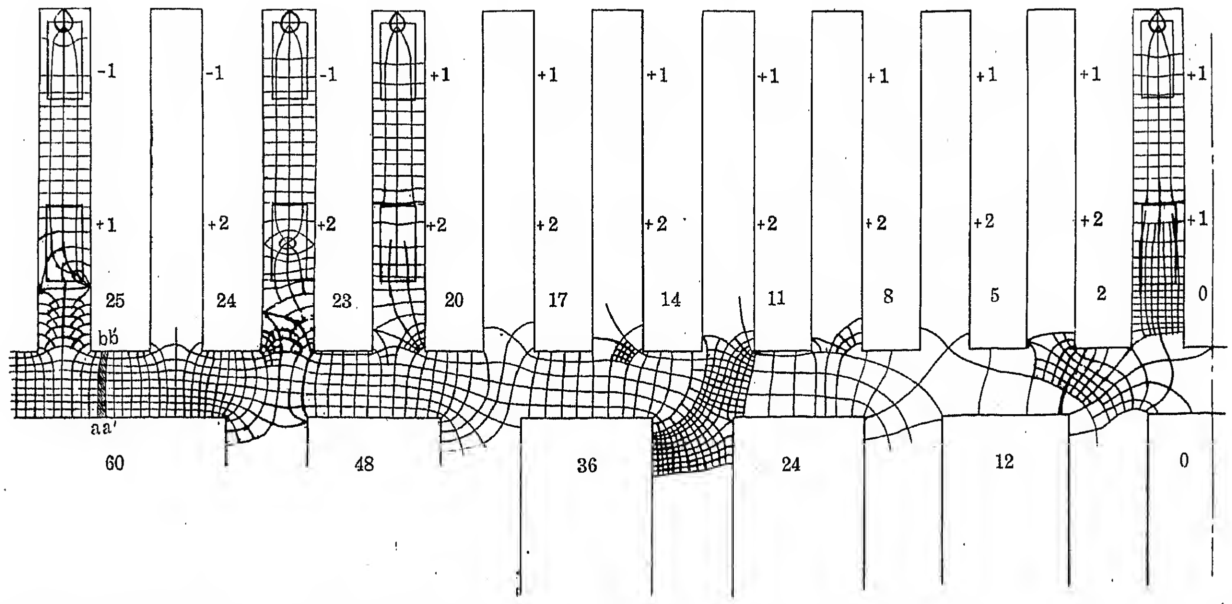

FIG. 17—TOTAL FIELD AMPERE-TURNS PER POLE EQUAL 31,824 AND ARE TAKEN AS PROPORTIONAL TO 60 IN THESE CALCULATIONS. PER INCH PERPENDICULAR TO THE SHEET FLUX PER TUBE $a - a'$ TO $b - b'$ EQUALS $3.19 \times \frac{31824 \times 4}{60} = 6768$ LINES

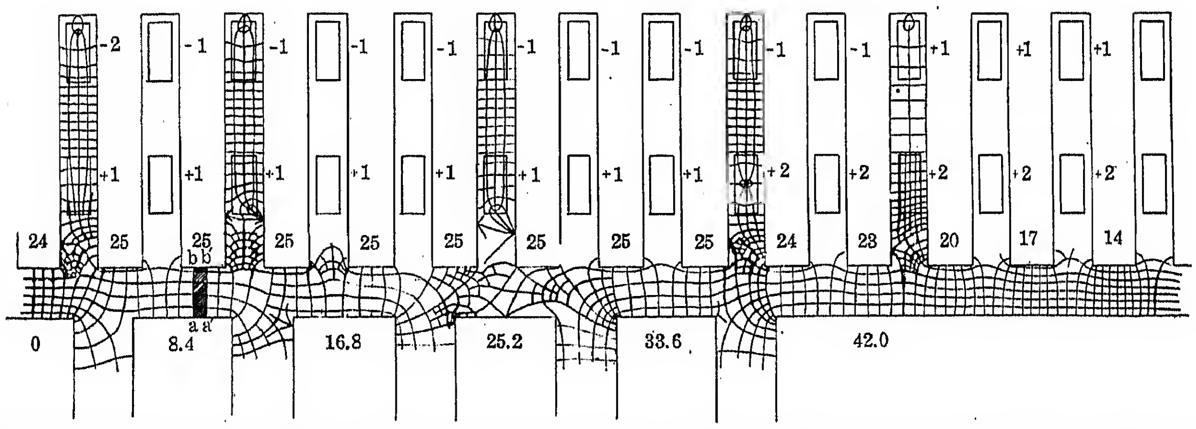

FIG. 18—TOTAL ARMATURE AMPERE-TURNS PER POLE = 13,260 AND ARE TAKEN AS PROPORTIONAL TO 25 IN THESE CALCULATIONS. Total field ampere-turns per pole = 22,277 and are taken as proportional to 42 in these calculations. Per inch perpendicular to the sheet the flux per tube $a - a'$ to $b - b' = 3.19 \times 22{,}277 \times \frac{4}{42} = 6768$ lines

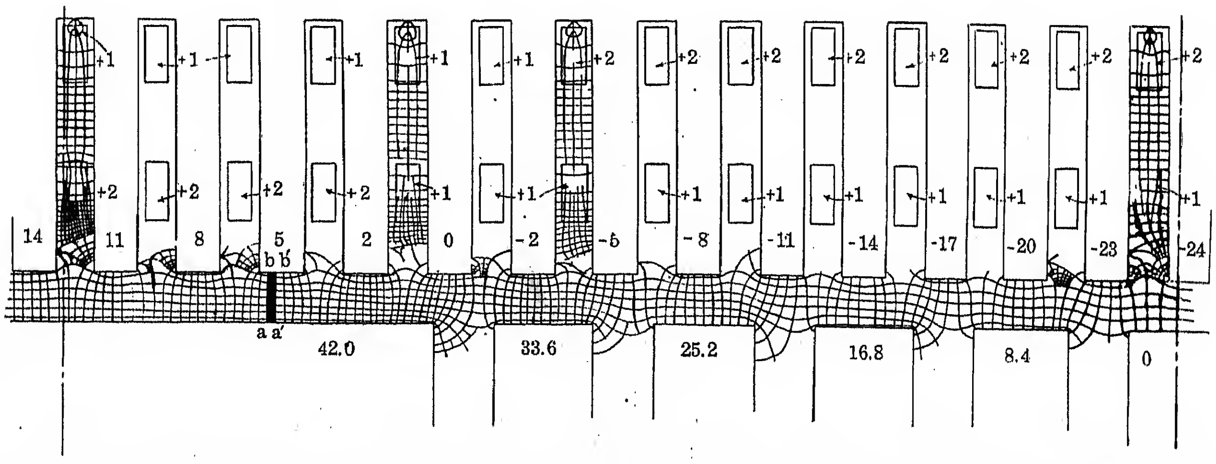

FIG. 19—TOTAL ARMATURE AMPERE-TURNS PER POLE = 13,200 AND ARE TAKEN AS PROPORTIONAL TO 25 IN THESE CALCULATIONS. Total field ampere-turns per pole = 22,277 and are taken as proportional to 42 in these calculations. Per inch perpendicular to the sheet the flux per tube $a - a'$ to $b - b' = 3.19 \times 13{,}260 \times \frac{5}{25} = 8460$ lines

mental and analytical investigations indicate that this method should be satisfactory for determining the necessary data and constants for calculating the losses of electric machines which cannot be calculated or measured directly.

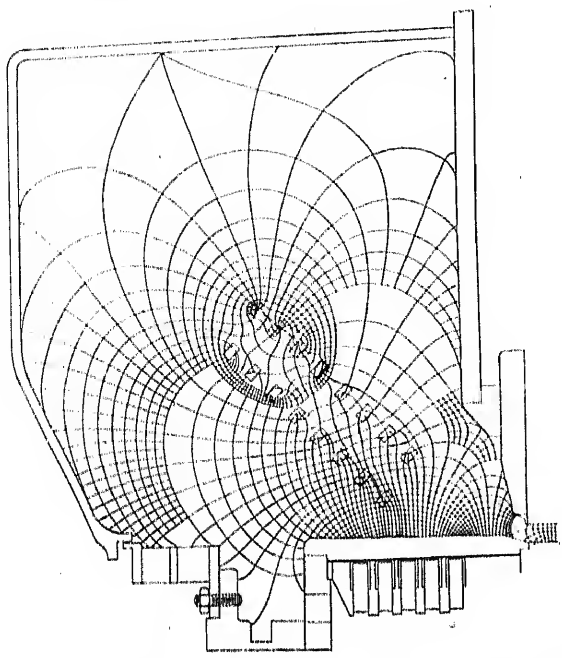

FIG. 20—TURBO GENERATOR END BELL LEAKAGE FLUX

Three-phase diamond coil armature winding section through radial plane of maximum flux densities for full load voltage and zero per cent power factor with armature current of 0.866 maximum value in two phases and zero in the third.

SUMMARY AND CONCLUSIONS

a. The magnitude of the losses of high speed synchronous machines can be determined with a satisfactory degree of accuracy for any load condition, by measuring the volume and temperature rise of the cooling medium which passes through the machine.

b. The temperature rise of the cooling medium can be determined by measuring the difference in e. m. fs. induced in thermocouple junctions, or the difference in potential drops across resistance elements located at the inlet and outlet duct sections of the generator. The velocities of the cooling medium must be practically uniform at both inlet and outlet sections and readings should be taken at a relatively large number of incremental sections to obtain an accurate value of the mean temperature rise.

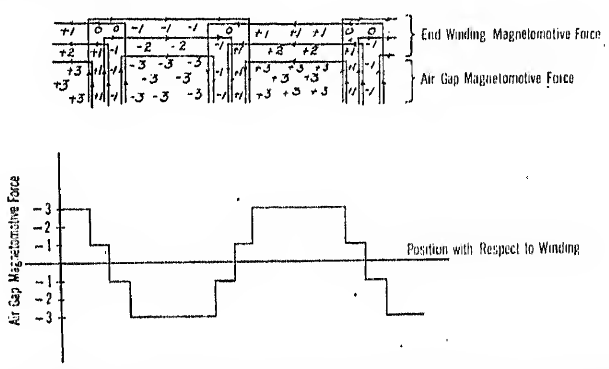

FIG. 22—FULL PITCH CONCENTRIC WINDING. CURRENTS OF EQUAL MAGNITUDE IN BOTH WINDINGS AND WITH DIRECTIONS INDICATED BY ARROWS

Numbers and signs indicate the relative magnitude and directions of magnetomotive forces perpendicular to the surface through all the windings, on the assumption that the flux passes perpendicularly through that surface

c. The volume of the cooling medium passing through the machine can be determined: (a) by introducing a known amount of heat energy into the cooling medium and then measuring its temperature rise; or (b) by measuring the velocity heads at a relatively large number

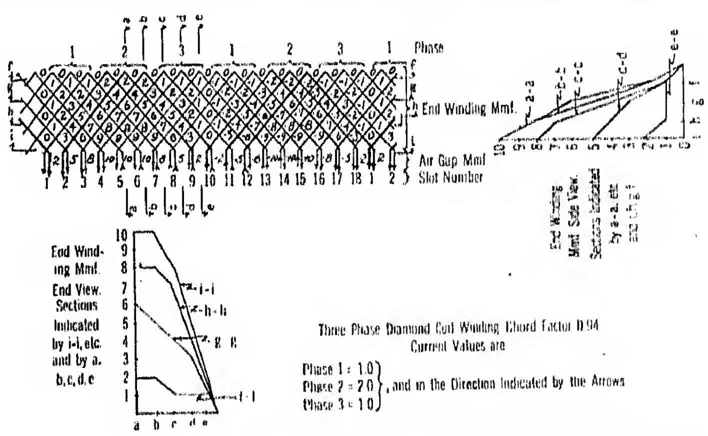

FIG. 23—THE NUMBERS AND SIGNS INDICATE THE RELATIVE MAGNITUDE AND DIRECTION OF THE MAGNETOMOTIVE FORCES PERPENDICULAR TO THE SURFACE THROUGH ALL THE WINDINGS ON THE ASSUMPTION THAT THE FLUX PASSES PERPENDICULARLY THROUGH THAT SURFACE

of incremental sections at the stack outlet. Both methods will give reliable results for high speed turbine generators provided the elements are properly designed and sufficient care is exercised in making the measurements.

d. In the case of the five 3600-rev. per. min. turbine generators which were tested at full kv-a. and zero per cent power factor, the additional loss including increase

in core loss, varied from 3 to 22 per cent of the total losses. This corresponds to approximately 0.14 to 1.0 per cent of the generator input, on the assumption of 95.5 per cent generator efficiency. The additional loss at full kv-a. and approximately zero per cent power factor is 5 to 10 per cent greater than the additional loss measured under sustained short-circuit conditions.

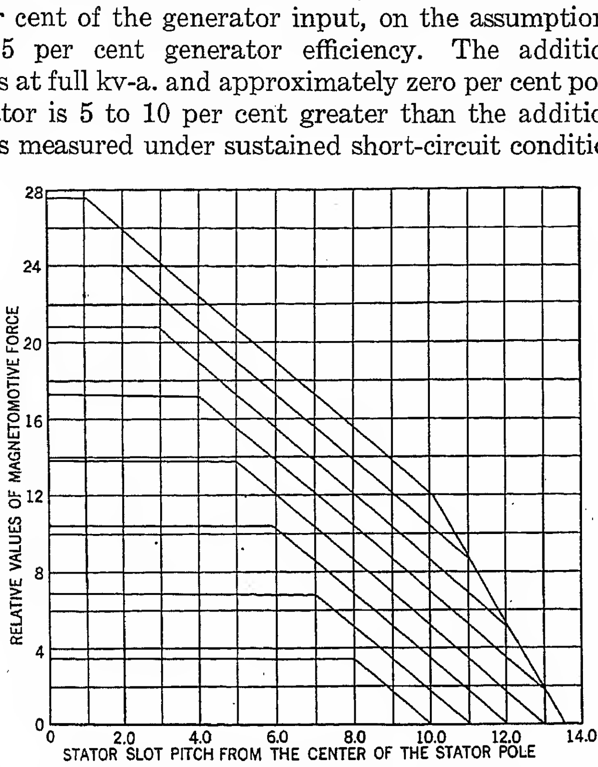

FIG. 24—END WINDING MAGNETOMOTIVE FORCES, END VIEW. THREE-PHASE, 54 SLOTS, PITCH 1-17. EQUAL CURRENTS IN TWO PHASES; ZERO IN THE THIRD

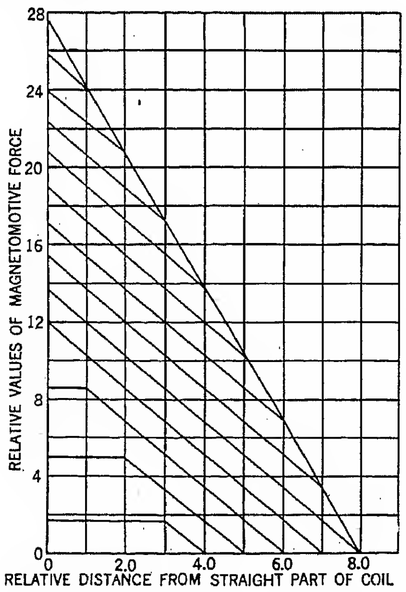

FIG. 25—END WINDING MAGNETOMOTIVE FORCES, SIDE VIEW. THREE-PHASE, 54 SLOTS, PITCH 1-17. EQUAL CURRENTS IN TWO PHASES; ZERO IN THE THIRD

Since the increase in core loss is slightly larger for low per cent power-factor loads, it is probable that the additional losses of these machines, when carrying full kv-a., 80 per cent power-factor load, are approximately the same as for sustained short circuit with full load armature current. Since it is of considerable practical importance to know the relative magnitude of the additional losses of large power generating equipment it is suggested that the manufacturers and users o large turbine generators cooperate in making los measurements on several representative machines unde definite operating conditions.

e. In order to predetermine the magnitude of th additional losses of synchronous machines, it is suggeste that the losses in all of the structural parts be obtaine in terms of magnetizing flux as the variable. The losse in the respective parts can be obtained from temperature time curves of these parts for sudden load changes The magnitude and distribution of the magnetizin flux can be determined graphically for any part of th machine with a sufficient degree of accuracy. Th results which have already been obtained in preliminar investigations indicate that this method of measurin the loss and the analytical method of determining th magnetizing flux can be applied to all parts of th machine so that reliable loss constants can be obtaine in terms of the different variable factors. Additiona studies are being made on this subject and on th problem of calculating the increase in core loss fo different load conditions.

ACKNOWLEDGMENTS

The writers acknowledge the assistance of Messrs A. M. Harrison and P. E. Watson and members o the 1926 Electrical Design School in laying out the flu fields. The tests on generators No. 2 and No. 3 wer made by Mr. J. R. Taylor of the Power Engineerin Department. Valuable assistance was received fron Dr. J. Slepian of the Research Department in connection with the general theory of flux distribution.

Discussion

I. H. Summers: Referring to Fig. 3, in which data are given for a 600-volt winding, one bar per slot, the load loss at 100 per cent kv-a. is slightly more than 20 per cent of the full-load loss. Referring to Fig. 4, in which data are given for a 2300-volt winding, 2-coil sides per slot, the load loss at 100 per cent kv-a. is approximately 3 per cent of the full-load loss.

I should like to ask the authors whether or not, in their opinion, this discrepancy can be materially attributed to either the eddy-current loss in the armature windings or the pole-face loss, or both?

W. F. Dawson: I wish to comment on the method of measuring losses by the calorimetric method. I published an article on this subject in the *General Electric Review*, February 1920. Messrs. Laffoon and Calvert have laid particular stress on the stack method. It is one means of measuring the volume of air discharge, but if one refers to the paper published by Barclay and Smith, (*Journal I. E. E.* London, Vol. 57, April 1919), he will find that they also experimented with the stack method and found that the distribution of air velocity across the section was very uneven, varying from 1050 ft. per minute to 1480 ft. per minute. It was necessary to insert several trays of expanded metal as baffles before even approximate distribution was secured. They selected the anemometer for measuring the velocity.

My experiments were commenced over eight years ago. We divided the discharge area into 100 or more rectangular sections and measured the velocity of each section with a manometer or hook gage. These results (see Fig. 3, *G. E. Review*, article) were very discouraging, as the readings varied from 0.05 in. of water to a maximum of 0.154 in., corresponding to velocities of 15 ft. per second and 26.3 ft. per second. We found also that all sorts of whirls and distortions occurred in the discharge pipes, even to an occasional indication of negative flow. These were corrected by placing a large wooden cross near the inlet end of the pipe, having an axial length of about twice the pipe diameter.

Another great difficulty was in averaging the temperatures of the inlet and outlet air. The temperatures of the inlet air were often influenced by the presence of adjacent steam pipes and turbine parts, and at times the variation of temperature across the inlet was greater than the difference between the average inlet and outlet temperatures. Special electrical resistance thermometers were used to average the temperatures of inlet and outlet air, the resistance wires being wound on wooden crossarms, so distributed and spaced as to give a true average of the air temperature. An improvement over the method of attempting to measure at the ordinary generator outlet was to place thereon a long straight pipe of suitable section, on the end of which was a specially shaped, calibrated orifice, similar to that described by Mr. Laffoon. This reduced the area of the outlet sufficiently to bring the discharge velocity up to about 4000 or 5000 ft. per min., corresponding to an air pressure of from 1 to 1.5 in. of water. Properly arranged, these orifices give, by a single reading, observed at the center, the actual accurate air velocity to within 1 per cent.

By using electric resistance thermometers giving true average temperatures, and by inserting electric heaters, and a third resistance thermometer beyond the electric heater, very satisfactory results were obtained, but the hook-gage readings were found unsatisfactory. When this method is used, it is not necessary to make allowance for the varying barometric pressure of the air. It is particularly adaptable to turbine alternators; usually there are two inlets and one discharge and the air stream is confined and guided in such a way that all the air that goes into the machine can be measured.

I show in the accompanying Fig. 1, a generator frame having two inlets and one discharge. The original suggestion for this arrangement is due to Mr. H. M. Hobart.

T_1 = Average temperature (deg. cent.) of inlet air

T_2 = Average temperature (deg. cent.) of outlet air

H = Watts energy supplied to electric heater

T_3 = Average temperature (deg. cent.) of air after leaving heater

$$\text{Watts Loss} = H\,\frac{T_2 - T_1}{T_3 - T_2}$$

$$\text{Cu. ft. air per min.*} = \frac{\text{Watts loss}}{0.585\,(T_2 - T_1)} = \frac{H}{0.585\,(T_3 - T_2)}$$

Caution. From three to four hours are usually necessary for all parts to attain steady temperature. Only about 30 min. are necessary to produce steady temperatures in the electric heater. If readings are recorded three or four times per hour, it will be observed that T_2 increases rapidly when current is applied to the heater. This is due to radiant energy and demands certain precautions and corrections. The heater should be placed 4 to 5 ft. from T_2 and exactly midway between T_2 and T_3. In writing the expression $T_2 - T_1$, use the last reading before heater is

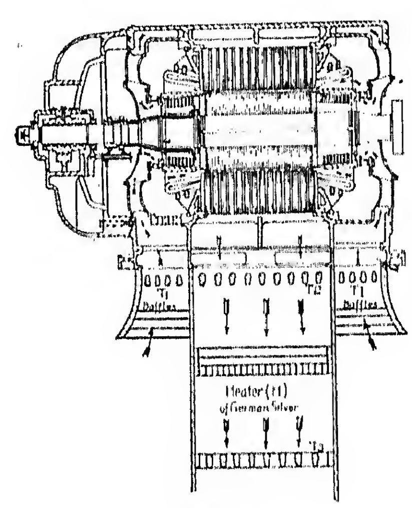

Fig. 1

energized. In writing $T_3 - T_2$, use the last reading with heater applied. Measurable convection losses should be allowed for.

If the loss of the machine be calculated by these equations, we are rid of all such disputes as correct barometric pressure, specific heat and effect of moisture. My experience with two-pole machines of note more than 6000-kw. rating is that the radiation or convection losses amount to probably 3 or 4 per cent of the total losses, which for machines of 1500 to 2000-kw. rating, never exceed 5 per cent of the rating of the machine, nor 4 per cent for machines of 5000-kw. rating.

Mr. Laffoon's paper has made a comparison between the losses, particularly the additional losses observed when a machine is being operated on short circuit and those observed when it is being operated over-excited at zero power factor. It seems, after all, that while that comparison is interesting, it doesn't tell us what we want to know. What the manufacturer wishes to know and what his customers wish to know is what is the ratio of the load losses measured on short circuit to those measured while the machine is operating at normal voltage and power factor in accordance with its rating? The few data that I have gathered indicate that at times at least the losses under normal operating conditions are less than they are on short circuit. I have not, however, confirmed that sufficiently to lay it down as a rule.

E. E. Johnson: Refer to Fig. 20 of the paper by Messrs.

*Standard air at 29.92 in. Hg., 15.5 deg. cent. (60 deg. fahr.)

Laffoon and Calvert. The distribution of the end-bell leakage flux is three-dimensional, and I raise the question as to whether a field plot made on the basis of a two-dimensional distribution, as was done in Fig. 20, holds strictly. It may be that the results obtained from this field plot made on the basis of a two-dimensional distribution are sufficiently accurate for the particular case in question, although, in general, this is not necessarily true. It will be noted that all the areas in the plot of Fig. 20 are curvilinear squares; whereas, on the outer boundaries, they should perhaps not be so, considering that the actual flux distribution there is three-dimensional.

P. L. Alger: The two conclusions that I draw from the paper are: (1) That the method of measuring the total losses by means of the rise of air through the machine is not yet developed to the point where it can be called convenient; and (2) that the extra losses due to the armature leakage flux are not large in machines of the type described. This latter conclusion is not general, as it is evident that very markedly different losses will be obtained with different types of end construction. For example, if a chain-type armature winding had been used, the end losses would have been very much greater.

The most interesting thing about the paper to me is the temperature-rise method used by the authors to determine the separate losses in different parts of the machine. It seems to be quite feasible to determine the initial rate of temperature rise of each part separately, and, from this and the known heat capacity of that part, to determine the segregated losses. We have made some experiments along this line, and have found one of the principal difficulties to be the variation in the rate of heat generation in different parts of the same element of the machine. For instance, the losses in the clamping fingers are localized near the end, and the rate of rise of the tip of the finger is, therefore, much greater than that of the back. It requires considerable care to decide on what is the average rate of rise of each part from a relatively small number of temperature readings.

I should like to ask the authors whether they consider that the average rate of temperature rise of one tooth in the end packet of laminations, for example, can be determined with reasonable accuracy by using only two thermocouples.

E. H. Freiburghouse: The authors of the paper have favored the stack method for determining the stray-load losses of the generator. It has also been our practise at Schenectady to use that method in measuring the stray-load losses of large turbo generators.

I should like to ask the authors whether they have ever applied a baffle-type mixer in the discharge air to get uniformity of temperatures?

I am somewhat surprised to notice the comparison for generators 2 and 3, as to stray-load losses. Generator No. 2 (see Table I) had stator end plates of magnetic material, whereas in generator No. 3, which I assume is the same generator or one of the same rating at least, they used a non-magnetic ring for clamping the core. By Table II and by the curves in Figs. 4 and 5, I find that the load loss is even higher for the machine which had the non-magnetic end ring. This is somewhat of a surprise to me. We have made many experiments on model generators of the turbine type, in which we applied different materials for the end rings, even using wood to determine what the limit would be in the elimination of the loss. Based on our investigation, I believe that the load loss ought to be less in the case of the generator which has the non-magnetic end ring.

Mr. Alger referred to the influence of the rings on the rotor. We have found by the application of non-magnetic end rings on the rotor that the temperatures of the end structure of the stator were higher with the generator running on open circuit than they were with magnetic end rings, whereas on short circuit and normal load conditions, the losses were higher with the magnetic end ring. The temperatures in the end structure on short circuit were considerably reduced by the use of the non-magnetic rings on the rotor.

Fig. 20 indicates that losses should be obtained in the end plate. We see that the flux passes over into the end plates and is localized most intensely nearest the air-gap. I question whether the application of the magnetic end ring gave less loss than the non-magnetic ring.

W. H. Colburn: The purpose of my discussion is to emphasize the importance, from the standpoint of the user of the machine, of a foreknowledge of stray-load losses in general in all machines. For example, let us consider a particular instance of a synchronous converter used in a substation. Assuming certain values for cost of power and of generating and transmission plant tied up by the losses of the machine, we arrive at the conclusion that a gain of efficiency of 0.1 per cent in that equipment is worth about 45 cents per kw. This means that the user could afford to pay for a converter rated at 3000 kw. something like $1350 additional for the machine that would save that 0.1 per cent.

I will illustrate how apparently neglected items may run up in value. The analysis of a certain equipment which had a blower used with it indicated that the more efficient equipment could be justified on the basis of the capitalized efficiency. We then began to investigate the fan and found that the manufacturer had applied it without consideration of actual air and power requirements, so that the balance was thrown to the other equipment.

The same condition exists in connection with consideration of these stray-load losses. We know that it is a very difficult thing to predict them, as the Institute has recognized in its Standards of many years, where you find it repaetedly stated that no definite value could be placed on them. Recently the Standards Committee has asked that 1 per cent of the rating of the machine be added for these stray-load losses.

It is almost useless in the present state of the art to go into a discussion of the results of calculations of and tests for stray-load losses, because they are fraught with many difficulties, but some of these seem to indicate that 1 per cent may be quite wide of the mark. In some cases it seems that these stray-load losses are in the neighborhood of 0.5 per cent and in other cases they may run up to nearly 2 per cent. If this is the case, it is almost useless for the user to attempt to capitalize guaranteed efficiency.

I think these tests which the authors have made are very fine records to have. They are needed to check our design, but I think that it is even more important that we extend these tests to all conditions in and classes of machinery, and that we draw from our tests some indication of how we can attack these problems in advance of construction in order to predict accurately the values of these stray-load losses. Only then can the user of the machine determine whether he is actually getting what he is paying for.

F. D. Newbury: The fact that we have this paper indicates the desire on the part of manufacturers to know more about them. I am quite sure that that desire has long been present with other manufacturers.

The purpose of the present discussion, I think, is to establish, for the benefit of the Institute Standards Committee, a relation between the actual and measurable stray losses in a-c. machines, and particularly of the turbine type. We can only measure these losses under no-load conditions at short circuit or at full voltage and zero power factor. As Mr. Dawson pointed out, the thing of real interest is the ratio of the measurable losses under these conditions and the actual losses under full voltage and current and high power factor. That is a part of the problem still to be studied, and I am quite sure work that is going on will throw light on that interesting point.

The previous speaker referred to a 1-per cent value of the stray losses. The Standards Committee included that value in the 1925 edition for d-c. machines and not a-c. machines. The

Institute Standards for 14 years, at least, have included the full short-circuit losses as load losses for polyphase a-c. machines. The correctness of that practise has been pretty well established for salient-pole machines but it is still to be established for the cylindrical-rotor, turbine-type machines. I think opinion is tending toward acceptance of the short-circuit loss for cylindrical rotors also.

C. M. Laffoon and J. F. Calvert: In reply to the discussion by Mr. I. H. Summers: When a standard turbine-generator frame of a given rating is wound with a one-conductor-per-slot type of winding so as to obtain unusually low voltages, it is generally found that the additional losses are greater than for the two-conductor-per-slot type of winding. With the one-conductor-per-slot type of winding, the current per slot and the magnitude of the harmonics in the armature magnetomotive force are larger than for the more favorable two-conductor-per-slot winding. It is our opinion that these factors are responsible for the relatively larger eddy-current losses in the rotor pole face and other iron parts which are within the range of the pulsating fields. Both calculated values of the eddy-current losses and the measured temperature of the armature copper indicate that only a small part of the increase in additional loss occurs in the armature winding.

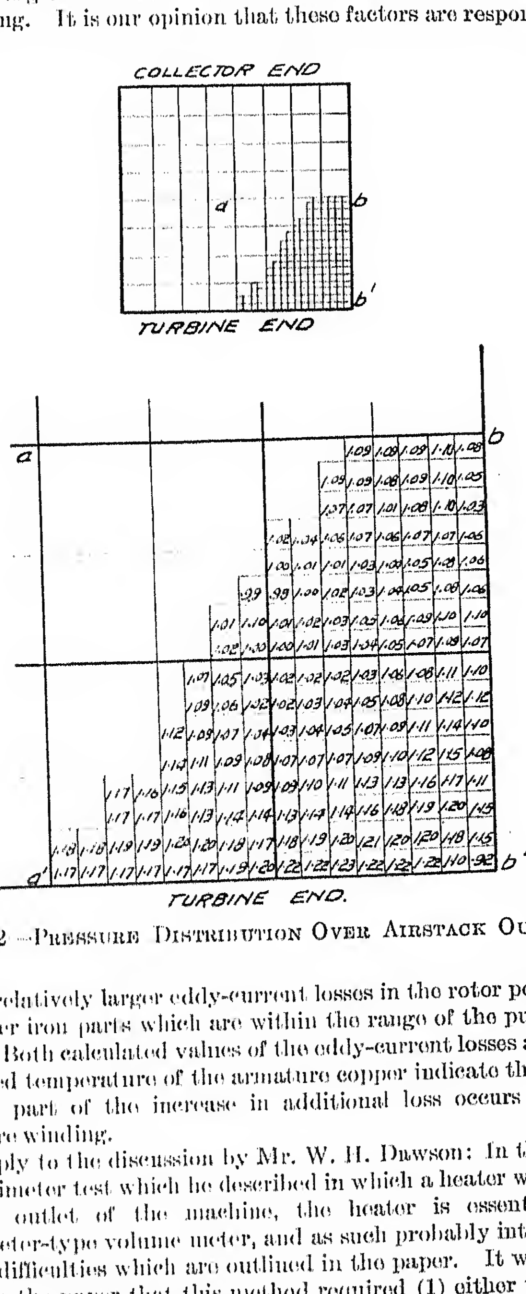

FIG. 2—PRESSURE DISTRIBUTION OVER AIRSTACK OUTLET

In reply to the discussion by Mr. W. H. Dawson: In the type of calorimeter test which he described in which a heater was used on the outlet of the machine, the heater is essentially a calorimeter-type volume meter, and as such probably introduces all the difficulties which are outlined in the paper. It was indicated in the paper that this method required (1) either uniform velocities for at least three sections in the air stream, or (2) a very complicated system for obtaining the mean temperatures of the intake and discharge sections of the heat sources (both the machine and the volume meter); while the use of the stack with the calorimeter test requires uniform air velocities at one less section in the air stream than does the heater or calorimeter-type volume meter. On the basis of results from a large number of tests, it is our conclusion that uniform velocities at several sections in the air stream are inherent requirements in calorimeter tests of this sort, and that the stack, rather than increasing the difficulty, simplifies it. Reference to Fig. 2 herewith will show that sufficiently uniform velocities were established over the outlet of the stack. The maximum variation in velocity pressure head from the average value is 12 per cent; hence the maximum variation in velocity from the mean value is approximately 6 per cent, (neglecting the one low point in the corner).

In the tests described in the paper, care was taken to avoid the convection of heat to the inlet air from transformers, steam pipes, leads, and other sources, so that practically uniform intake air temperatures were maintained. The possible errors due to the existing variations in temperatures and velocities in the intakes were checked on generator No. 5, and found to be a small fraction of one per cent.

The measurements of barometric pressures is a comparatively simple matter, and introduces no serious difficulty in the use of the stack volume meter. Since the variations in the specific heat of air with changes in temperature, pressure, and moisture content are known, corrections can be made if desired; but it did not appear that this difference was of sufficient importance to consider.

The fact that the calorimeter tests and electrical input readings were in agreement for a number of "no-load" 100 per cent power-factor tests at different voltages, is a satisfactory confirmation of both the volume-meter and air-rise measurements, because both these latter two readings could not be in error by just the right amount in each case, and because the electrical readings of input at 100 per cent power factor can be taken as quite reliable.

In reply to the discussion by Mr. E. E. Johnsen: The determination of the end-bell flux field on the basis of a two-dimensional distribution as shown in Fig. 20 of the paper, does not hold strictly, but to consider it as a three-dimensional field, tremendously complicates the already difficult problem of field mapping. Fig. 20 checked the filing photograph very closely in the parts of the field where the flux density is greatest, but deviated somewhat where the density was small. Since the density decreased very rapidly toward the outer edge of the end winding, the errors introduced in either loss or reactance calculations on the basis of the two-dimensional field must be small with this type of winding and end bell.

In reply to the discussion by Mr. P. L. Alger: While the additional losses are not a large percentage of the total losses in many machines, yet in large machines they represent a direct loss to the customer and a limitation to the manufacturer of very considerable importance. Unfortunately, sufficient data were not obtained to tell how many temperature detectors would be necessary to determine the losses from time-temperature curves for the various parts of the machine. It appears, however, that flux mapping can be used to indicate the best location for these detectors, and the safest method would be to locate a rather large number on various radial lines throughout the machine. Then, if it could be shown during the first tests that some couples need not be read, they could be abandoned for later readings.

In reply to discussion by Mr. E. H. Freiburghouse: Before the air discharge stack was built, a model stack was tested under conditions which were intended to give distributions of both temperature and pressure with wider variations than those which would be found at the outlet from the machine. In the tests with models, two types of baffles, as well as a screen, were used in the air stream just preceding the entrance to the stack. The baffles, or air mixers, did not give sufficient improvement to warrant their application. The screen gave considerable improvement in extreme cases, but was not used, because of the undesirable loss of head, and consequent change in air volume from that existing under normal operating conditions. Had the

tests on the actual machine shown the desirability of better distributions, undoubtedly, it would have been necessary to introduce a screen, and perhaps some form of baffle in the air stream at the entrance to the stack.

The tests on generators Nos. 2 and 3 were made to determine the effect of stator end-plate material on the magnitude of the additional losses. The same machine was used in both cases; magnetic plates were used on No. 2 and non-magnetic plates were used on generator No. 3. The total values of the additional losses of these two generators were very small and it appears evident from the end-plate temperatures that only a very small portion of the additional losses actually occurred in the end plates. Hence, it is impossible to draw any definite conclusions from the tests on these two machines in regard to the influence of magnetic and non-magnetic stator end plates on the additional losses of the machines.

Reduction of Armature Copper Losses

The Inverted Turn Transposition for the Reduction of Losses Due to Non-uniform Current Distribution in the Armature Conductors of Large A-C. Machines

BY IVAN H. SUMMERS*

Associate, A. I. E. E.

Synopsis. *A new method of reduction of armature copper losses is described, which consists in the inversion of the conductors of a multi-turn barrel type coil at one or more places in the end portions of the coil. Previous writers have described methods of transposing the conductors in the slot and of carrying insulated strands through successive positions in successive coils, but the new method now described presents distinct points of difference in theory and in construction from any of these earlier methods. The theory of the new form of transposition is briefly described, complete formulas are presented for the most useful cases, and illustrations of its use are given.*

* * * * *

IT is the aim of this paper to present a method for the reduction of extra losses and heating in armature conductors of large a-c. machines due to non-uniform current distribution. The scope of the paper is limited to finitely laminated conductors with the laminations insulated throughout all the turns in a coil. It is further limited to coils wound either with no special twist or inversion at any point, or with one or more of the turns or half-turns inverted as illustrated in the various accompanying diagrams. With the aid of the formulas and tables the calculation of the extra copper losses becomes a simple matter for simple untransposed coils, and the gain to be derived from transposition can be determined by selecting the proper factor from the tables. It is found that in most cases it is a simple matter to select a transposed winding for a large machine so that the extra losses will be reduced to a negligible value and the transposition may be accomplished at very slight additional expense.

A considerable literature on the subject of reduction of eddy-current losses in the armature copper has accumulated, as is evident from an inspection of the bibliography. Nevertheless, the type of transposition here described, which consists in inverting the conductors of a multi-turn coil at one or more points in the end connections during the process of winding, is believed to be entirely new. European writers have chiefly described means of transposing the strands of a bar winding within the slot, thus enabling both ends of the bar to be solidly connected to adjacent bars. American writers have described the reduction of losses secured by the inversions occurring at both ends of the standard barrel type coil, as shown in Fig. 1, and have also described the further means of reducing the losses, which consists in carrying the strands through the several coils of a phase belt by special insulated connections. The earlier papers by Mr. W. V. Lyon and by Mr. H. W. Taylor (see Bibliography) have been of great assistance in furnishing foundations for the present paper.

The new method now described has some distinct advantages in construction over other methods, as it enables solidly connected machine wound coils of identical character to be made practically free from circulating current losses, whatever the number of turns per coil. By making the transpositions in the ends of the coil, space for them is obtained without sacrifice of slot room, and by properly locating them with reference to the already present inversions at the ends of the coils, almost complete avoidance of residual voltages can be secured. Diagrammatic illustrations of the various types of transpositions in the ends here considered are shown in Figs. 2 to 7 inclusive, and a reproduction of an actual coil similar to Fig. 6 is shown in Fig. 9.

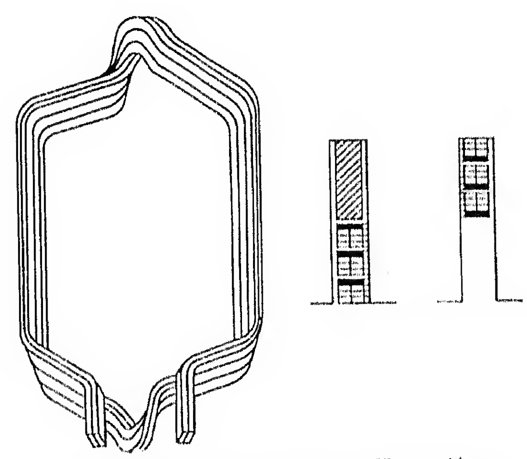

FIG. 1—STANDARD BARREL TYPE COIL

Showing successive positions in slot of a single strand—Type I, Table I

Consider a solid rectangular conductor placed in a rectangular slot in an iron body. It is clear that the reactance of a path at the bottom of the conductor is more than that of any other path in the conductor because the bottom path is enclosed by more flux. Furthermore, a path at the extreme top of the conductor

is reactanceless with regard to the rest of the conductor, and in this respect has resistance only. Thus a larger current will flow at the top than at the bottom. Additional losses will ensue and the temperature will be higher than if uniform current distribution were maintained. This non-uniform current can be thought of as a uniform current with an eddy current superimposed on it so as to increase the total current at the top and decrease it at the bottom. When the term eddy current is used hereafter in this paper, it means this hypothetical superimposed current. The formulas for extra loss factor give the ratio between the loss caused by this eddy current and the loss caused by the uniform current.

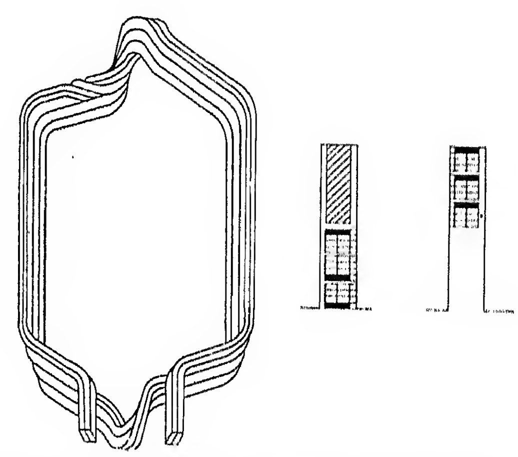

FIG. 7—BARREL TYPE COIL WITH FIRST HALF TURN ONLY INVERTED AT END OPPOSITE CONNECTIONS—TYPE V, TABLE I

If the conductor be laminated, conditions will be improved because the paths will be longer and the eddy currents reduced. Thus an elementary method of reducing the extra losses is simply to laminate the conductor. In addition, this makes the coil more flexible and easier to handle. For this reason most coils in large machines are laminated. Mere lamination, however, is not sufficient to keep the extra losses down to a negligible amount and for this reason various other schemes have been proposed.

The new method now proposed is to invert the laminations at various points in the coil by making a 180-deg. twist in the conductor. This can be arranged usually so that the voltage induced in the whole length of the strands by the leakage flux is more nearly uniform than it would be if there were no inversion. Some of the convenient ways of employing the inversion are illustrated in the accompanying diagrams. They are discussed later and formulas are given to calculate the extra losses which the coils will have.

In order to investigate mathematically the problem of inversion of the turns, certain simplifying assumptions are convenient as in all engineering problems. These are briefly indicated below:

1. Only the horizontal components of flux and magnetizing force are considered. Actually there are additional losses due to the vertical components but these have been found to be small in most practical cases. Horizontal is taken here to mean parallel to the bottom of the slot.

2. The vertical component of current is neglected. The current is always considered to flow straight into or out of the plane of the paper, except, of course, at the soldered joints at the ends of the coils.

3. The iron sides and the bottom of the slot are considered to have infinite permeability and no losses, as far as this problem is concerned.

4. The resistivity of the conductors is supposed to be constant and invariable over the depth of the slot.

5. The voltage induced by the leakage flux in the end connections is the same for each strand.

These assumptions are the same as the ones made by most writers on the subject. From the fundamental laws of electromagnetic theory and these assumptions, the differential equations of the problem can be derived. From these differential equations and their solutions, a general rule for finding the loss in any conductor or combination of conductors can be derived.

CIRCULATING CURRENT LOSS

For a neat statement of the problem and a derivation of rules for finding the loss in infinitely laminated coils (hereafter called circulating current loss) see the paper by W. V. Lyon in the May 1921 issue of the JOURNAL. The rule derived therein may be briefly restated as follows:

Form a quantity I_0 for each conductor which is right side up in the slot by taking

$$I_0 = I_b,$$

where I_b is the vectorial summation of all the currents in the slot below the conductor in question. For each conductor which is the other side up, take

$$I_0 = -(I_b + I_1),$$

where I_1 is the current in the conductor considered. It makes no difference which side up is called right side up. The I_0 used is the average for all the conductors which are in series, and which have strands continuously insulated throughout. Let I_2 be all the current in the bottom coil side of another coil which may be in the slot below the conductors in question and substitute the known value of I_2 in terms of I_1 and solve for $|I_0/I_1|$ and $\cos\alpha$, where $|I_0/I_1|$ is the numerical value of the ratio and α is the angle between I_0 and I_1. Substitute these values in the relation

$$L = \left|\frac{I_0}{I_1}\right|^2 + \left|\frac{I_0}{I_1}\right|\cos\alpha. \tag{1}$$

Then the heat loss in the coil will be determined from the relation

$$K = M + L\,N, \tag{2}$$

where M and N are certain complex hyperbolic quantities[1] and K is the ratio of the total heat loss in the coil to the loss that would exist if the uniform component of the current existed alone.

These quantities are discussed in Appendix B where it is shown that if the current has a distribution which is not widely different from uniform, the extra loss factor due to the eddy currents may be approximated by

$$k = (4 + 15\,L)\,D, \tag{3}$$

where D is a quantity depending on the dimensions of the slot and the coil. It is

$$D = 0.075\left[\frac{f}{60/\text{sec}}\right]^2\left[\frac{r\,b\,n^2\,(d/\text{in})^2}{m^2}\right]^2 \tag{4}$$

for a two-coil side per slot winding. Also

$$D = 1.19\left[\frac{f}{60/\text{sec}}\right]^2\left[\frac{r\,b\,n^2\,(d/\text{in})^2}{m^2}\right]^2 \tag{5}$$

for a one-coil side per slot winding, and

$$D = 1.19\left[\frac{f}{60/\text{sec}}\right]^2[\,r\,(d/\text{in})^2\,]^2 \tag{6}$$

for strand loss calculation.

In these formulas f means frequency of the alternating current; r means the ratio of the width of the copper in the slot to the slot width times the ratio of the depth of conductor plus strand insulation to the net conductor depth; b means the ratio of the length of the slot to the length of a half-turn; d means the depth of a strand; n means the number of layers of strands in the depth of the slot; and m means the number of turns per

1. See Appendix B.

coil[2]. The copper conductors have been assumed to be at 75 deg. cent. and the resistivity for this temperature has been used. The extra loss factors are inversely proportional to the square of the resistivity so that any other temperature may be evaluated if desired.

The quantity L which depends on the type of winding is calculated in Appendix A and is tabulated in Table I. The general method of calculating L for any type of winding is illustrated in Appendix A so that any reader who wishes to investigate types of windings outside the scope of this paper may do so.

Type	Description of Winding.	See Fig.	Value of L
I	Multiturn coil, two coil sides per slot with an involute at each end. (Standard coil with which others are compared.)	1	$L = \frac{m^2-1}{4}$
II.	All turns inverted on the end opposite the connections.	2	$L = \frac{3}{4} - \sin^2 \frac{1}{2}\theta$ (m being odd)
		3	$L = -\frac{1}{4}$ (m being even)
III	All turns inverted on connection end	4 and 5	$L = 0$
IV	Top turn only inverted on connection end.	6	$L = \frac{(m-1)(m-2)}{m}\left[\frac{m^2-5m+2}{4m} + 2\sin^2 \frac{1}{2}\theta\right]$
V	First half turn only inverted on end opposite connections.	7	$L = \left[\frac{m^4-4m^3+m^2+4m+1}{4m^2} + \frac{m-2}{m}\sin^2 \frac{1}{2}\theta\right]$
VI	Bar ... bottom coil side only.		$L = \frac{m^2-1}{3}$
VII	Bar ... Top coil side only.		$L = \frac{7m^2-1}{3} - 2m^2 \sin^2 \frac{1}{2}\theta$
VIII	Bar ... Both coil sides.		$L = \frac{4m^2-1}{3} - m^2 \sin^2 \frac{1}{2}\theta$

Note: Top always refers to open end of slot.

TABLE I—CIRCULATING LOSSES

It is shown in Appendix C that the extra loss factor in a laminated conductor of Type I may be calculated by the simple formula

$$k = 0.28 \left[\frac{f}{60/\text{sec}} \right]^2 \left[\frac{r\, b\, n^2\, (d/\text{in})^2}{m} \right]^2 \qquad (7)$$

for the first order of eddy currents with copper at 7 deg. cent[3].

2. The formulas are dimensionally correct and the quantities may be measured in any consistent system of units. They are so arranged that if f is measured in units of 60 cycles per second, and d is measured in inches, the calculation will be simplified. Thus d/in means the ratio between d and one inch. For example, if d were seven cm., the ratio would be

$$\frac{7 \text{ cm.}}{\text{one in.}} \equiv 7 \times \frac{\text{one cm.}}{\text{one in.}} \equiv 7 \times 0.394 \equiv 2.76$$

As another example suppose that f is 60 cycles per second: then

$$\frac{f}{60/\text{sec}} \equiv \frac{60/\text{sec}}{60/\text{sec}} \equiv 1$$

but if f is 3000 cycles per minute

$$\frac{3000/\text{min}}{60/\text{sec}} \equiv 50 \times \frac{\text{one sec.}}{\text{one min.}} \equiv 50 \times \frac{1}{60} \equiv \frac{5}{6}$$

This system of dimensional formulas has been discussed by V. Petrovsky (see Bibliography). He shows that it is unnecessary to have several formulas, one for each system of units.

3. First order of eddy currents means the eddy currents induced by the uniform current. They are expressed by the first term of an infinite series as shown in Appendix B.

The loss factors in any other type of transposed winding considered may be calculated by using the formulas for L given in Table I or by referring to the ratios given in Table II. Each formula in Table I and each ratio in Table II is given for a single coil, or group of coils, having a definite value of θ, which is the angular phase difference between the top and bottom coil side currents. Thus it is necessary to know from the pitch of the coils how they are distributed. Two factors must then be calculated and the weighted average taken to apply to the whole machine.

Extra loss factors obtained by the methods described are based on the assumption that the extra losses are not too large. Formula 7 may be used without sensible error provided the extra loss factor which it indicates does not exceed approximately 100 per cent. At this point the result is less than six per cent too large, but the error increases beyond this point. Even if the result is larger than 100 per cent it may still be used in combination with Table II provided the result for the type of winding under consideration is not too large. Thus it is clear that the approximate formulas are quite sufficient for any windings that would be allowed in practise.

It may be remarked in passing that the losses in bar windings may be calculated by formulas for coils of Type VI, VII and VIII given in Table I, and if the extra loss factor is large, the complete expression for M and N given in Appendix B should be used together with Equation (2) to obtain the total loss factor. Bar windings have been discussed fully elsewhere[4] and therefore are not treated in this paper.

TABLE II—RATIO OF EXTRA LOSS IN VARIOUS TYPES OF WINDINGS TO THAT IN TYPE I

STRAND LOSS

Up to this point the losses are supposed to be those which may be called circulating current losses and which would occur if the conductor were laminated by infinitely thin laminations. As intimated previously, there are additional losses which are due to the non-uniform distribution of current over the finite depth of the strands themselves. These losses may be approxi-

4. See Bibliography.

mated by considering first that the current is uniform over the depth of the slot, and then calculating the eddy-current loss which would occur in the strands. This may be done by considering each strand to be a bar of a series-connected bar winding and applying formulas for coils of Type VI, VII, and VIII. It is shown in Appendix C that the strand loss may be approximated by

$$k_s = 6.0\, b\, \psi \left[\frac{f}{60/\text{sec}}\right]^2 [r\, n\, (d/\text{in})^2]^2 \qquad (8)$$

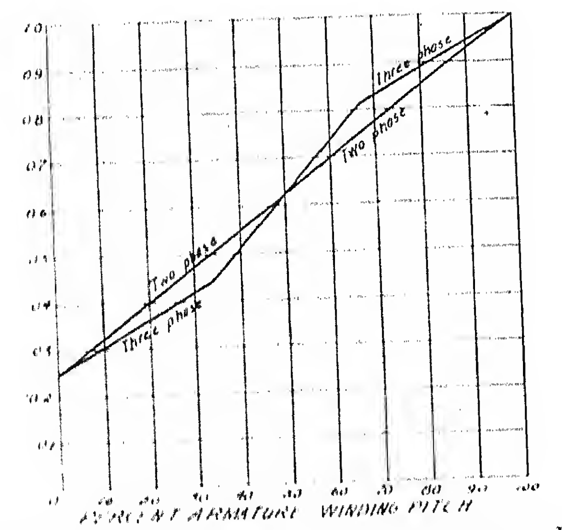

FIG. 8—THE FACTOR ψ_{av} USED IN CALCULATING STRAND LOSS FACTOR

This value is different for each coil that has a different θ, and in general there are two groups of coils in a machine each having a different value of θ. It becomes convenient to average ψ over a whole machine so that the strand loss may be calculated easily. This has been done and ψ_{av} is plotted against per cent pitch in Fig. 8.

The strand loss factor is small in a well-designed machine and may often be neglected when considering the effect of transposition. It is always present no matter what the transposition is and must be added to the circulating current loss factor to get the total extra loss factor for the first order of eddy currents. The strand loss may always be reduced by using finer laminations in the conductor.

To summarize the method of calculation of eddy-current losses it may be noted that an extremely simple slide rule calculation using Formula (7) will obtain the extra loss factor for a coil of Type I. The effect of transposition may be obtained from Table II by selecting a factor to apply to the extra loss factor for Type I. Finally the strand loss factor may be obtained by Formula (8) and added to the circulating current loss factor. The result is the total extra loss factor for the first order of eddy currents. This, multiplied by the normal copper loss of the winding, calculated for uniform current distribution, gives the extra loss due to eddy currents and is accurate, provided it be not so large that the first term of the infinite series discussed in Appendix B fails to properly describe it. If it should be as large as this, however, it would be too large to be considered permissible in a modern winding. A method of transposition would be selected to reduce it to a much smaller value.

An example will help to make these rules understandable. Suppose we are considering an hypothetical three-phase winding having coils of Type V, Fig. 7, with three turns, 17/24 pitch, and two coil sides per slot. Suppose the slot is 0.675 in. wide and each turn is composed of 30 strands, each 0.14 in. wide, 0.075 in. over the strand insulation, and 0.07 in. net depth, and arranged 3 wide and 10 deep. Suppose that the ratio of the length of the core to the length of a half-turn is 0.50, and the frequency is 60 cycles per second.

Then

$$\frac{f}{60/\text{sec}} = 1$$

$$\begin{aligned} r &= 0.667 \\ b &= 0.50 \\ n &= 60 \\ d/\text{in} &= 0.07 \\ m &= 3 \end{aligned}$$

and

$$k = 0.28\,[1]^2 \left[\frac{0.667 \times 0.50 \times (60)^2 \times (0.07)^2}{3}\right]^2 \equiv 1.07$$

A three-phase winding of 17/24 pitch has 87.5 per cent of the coils with an angle θ of 60 deg. and the rest with an angle θ of zero. Thus from Table II the proper factor is

$$0.875 \times 0.093 + 0.125 \times 0.056 \equiv 0.0884$$

Therefore, the extra loss factor for the whole winding is

$$0.0884 \times 1.07 \equiv 0.095$$

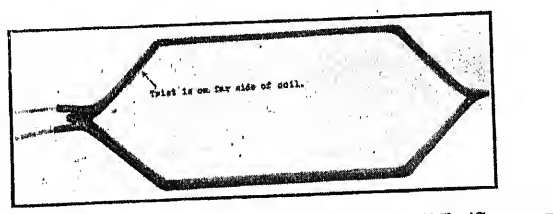

FIG. 9—COMPLETED FIVE-TURN COIL OF TYPE IV (SIMILAR TO FIG. 6)

or the extra loss due to circulating current is about 9.5 per cent of the ordinary copper loss, calculated for the square of the current and the ohmic resistance. Without the transposition, the formulas indicate an extra loss of about 107 per cent. The reduction from 107 per cent to 9.5 per cent by simply inverting the first half-turn when winding the coil is quite a remarkable gain when the simplicity of the transposition is considered.

The strand loss factor to be added to the above in either case is

$k_s = 6.0 \times 0.50 \times 0.822\ [1]^2\ [0.667 \times 60 \times 0.0049]^2 \equiv 0.094$

and the total eddy current loss is about 19 per cent of the normal copper loss. This is a fairly high value for strand loss factor but it can be reduced by using smaller strands.

In all practical cases where there is more than one turn per coil, the extra loss may be kept down to a small fraction of the normal loss by using the proper inverted turn transposition. Where there is only one turn per coil the Roebel or 360-deg. transposition may be used. The discussion of this type of bar is outside the scope of the present argument and it suffices to say that it reduces the circulating current loss in a conductor to practically zero.

In conclusion the author wishes to express his appreciation of the invaluable suggestions of Mr. P. L. Alger and his enthusiastic support. He also wishes to thank Mr. M. C. Holmes for assistance with the numerical work in connection with the tables and for helpful criticism.

Appendix A

In order to illustrate the method of deriving the formulas shown in Table I, two of the cases are derived below. The others may be obtained in a similar manner and will not be proved here. Some of them have been derived previously by other writers but they were all checked in the preparation of this paper.

Consider Type III with an even number of turns. See Fig. 5.

Applying the rule given in the body of the paper

$$I_0 = \sum_1^{\frac{m}{2}}{}^s\, (p-1)\, I_1,$$

where p = 2 s − 1 for all the odd half-turns in the lower[5] coil side,

$$I_0 = \sum_1^{\frac{m}{2}}{}^s\, [(p-1) I_1 + I_2],$$

where $p = 2\,s - 1$ for all the odd half-turns in the upper coil side,

$$I_0 = -\sum_1^{\frac{m}{2}}{}^s\, [(p-1)\, I_1 + I_1],$$

where $p = 2\,s$ for all the even half-turns in the lower coil side, and

$$I_0 = -\sum_1^{\frac{m}{2}}{}^s\, [(p-1)\, I_1 + I_1 + I_2],$$

5. That part of the slot nearest the closed end is referred to throughout this paper as the bottom and that part nearest the open end, as the top.

where p = 2 s for all the rest.

Averaging these over the $2\,m$ half-turns, the result is

$$2\,m\,I_0 = \sum_1^{\frac{m}{2}}{}^s\, [(2\,s-2)\, I_1] + \sum_1^{\frac{m}{2}}{}^s\, [(2\,s-2)\, I_1 + I_2]$$

$$- \sum_1^{\frac{m}{2}}{}^s\, [2\,s\, I_1] - \sum_1^{\frac{m}{2}}{}^v\, [2\,s\, I_1 + I_2].$$

This gives

$$I_0 = -\, I_1$$

Hence

$$\left| \frac{I_0}{I_1} \right| = 1,$$

$$\operatorname{Cos}\alpha = -1$$

and finally

$$L = 0.$$

Now consider Type IV. See Fig. 6.

In a manner similar to the first example

$$2\,m\,I_0 = -\sum_2^{m}{}^p\, [(p-1)\, I_1 + I_1] + \sum_1^{m-1}{}^p\, [(p-1)\, I_1 + I_2]$$

$$- [I_2 + (m-1)\, I_1 + I_1].$$

This reduces to

$$I_0 = \frac{(2 - 3\,m)\, I_1 + (m-2)\, I_2}{2\,m}.$$

Since all the conductors are in series

$$I_2 = m\, I_1 \angle\ \theta.$$

This is substituted and the vectorial summation effected so that

$$\left| \frac{I_0}{I_1} \right| = \frac{\sqrt{(2-3\,m)^2 + (m^2-2\,m)^2 + 2\,(2-3\,m)\,(m^2-2\,m)\cos\theta}}{2\,m}$$

and

$$\operatorname{Cos}\alpha = \frac{(2-3\,m) + (m^2-2\,m)\cos\theta}{2\,m \left| \dfrac{I_0}{I_1} \right|}$$

and finally

$$L = \frac{(m-1)\,(m-2)}{m} \left[\frac{m^2 - 5\,m + 2}{4\,m} + 2 \sin^2 \frac{\theta}{2} \right].$$

Any combination of half-turns may be calculated in a manner similar to the above and the reader may verify the rest of the formulas given in Table I or he may make new formulas for other combinations.

Appendix B

Non-uniform current distribution in armature conductors introduces changes in the effective reactance of the windings as well as in the resistance. The question of the reactance is not considered here. It is possible to set up equations containing complex numbers which express both the resistance and reactance factors, but since only the resistance is considered here M and N are taken[6] as

$$M = \text{real part of } q\,h \coth q\,h$$

$$N = \text{real part of } 2\,q\,h \tanh \frac{q\,h}{2}$$

where

$$q = \sqrt{\frac{8\,\pi^2\,j\,r\,f}{\rho}}$$

and h is the depth of the conductor.

It is always possible by means of the proper transposition to reduce the eddy current loss to a negligible fraction of the normal copper loss and it is therefore unnecessary to use the full expressions for M and N. They may be expanded into infinite series and all unnecessary terms dropped. Thus

$$M = 1 - \frac{4}{45}\,q^4\,h^4$$

$$N = -\frac{1}{12}\,q^4\,h^4$$

Let

$$q = (1 + j)\,g$$

so that

$$g = \sqrt{\frac{4\,\pi^2\,f\,r}{\rho}}$$

and

$$M = 1 + \frac{4}{45}\,g^4\,h^4$$

$$N = \frac{1}{3}\,g^4\,h^4\,.$$

M appears in every expression for the circulating current loss factor. The constant part of it represents the normal copper loss while the variable part represents the extra loss. Thus the extra loss factor is

$$k = \frac{4}{45}\,g^4\,h^4 + \frac{L}{3}\,g^4\,h^4$$

or

$$k = [4 + 15\,L]\,D$$

where

$$D = \frac{g^4\,h^4}{45}\,.$$

6. See the paper by W. V. Lyon, Bibliography, 1.

The quantity h is the depth of one turn, while d is taken as the depth of one strand, m is the number of turns per coil, and n is the number of layers of strands in the slot, so that for a two-coil side per slot winding

$$h = \frac{n\,d}{2\,m};$$

for a one-coil side per slot winding

$$h = \frac{n\,d}{m},$$

and for strand loss calculation

$$h = d\ .$$

In a laminated winding the current is forced to flow over the whole length of a half-turn by the voltages induced in the core portion only. The resistivity ρ is taken as $1/b$ times the actual resistivity for this reason where b is the ratio of the length of the core to the length of a half-turn. Copper at 75 deg. cent. is assumed. Substituting the value of ρ and g, the value of D for a two-coil side per slot winding becomes

$$D = 0.075\left[\frac{f}{60/\text{sec}}\right]^2\left[\frac{r\,b\,n^2\,(d/\text{in})^2}{m^2}\right]^2$$

and for a one-coil side per slot winding, it becomes

$$D = 1.19\left[\frac{f}{60/\text{sec}}\right]^2\left[\frac{r\,b\,n^2\,(d/\text{in})^2}{m^2}\right]^2$$

and for strand loss calculation

$$D = 1.19\left[\frac{f}{60/\text{sec}}\right]^2[r\,(d/\text{in})^2]^2.$$

Appendix C

Circulating Current Loss

The formula for a coil of Type I is taken from Table I and substituted in Equation (3), resulting in

$$k = \left[4 + \frac{15}{4}\,(m^2 - 1)\right]D,$$

or

$$k = \left[\frac{15}{4}\,m^2 + \frac{1}{4}\right]D\,.$$

The constant term in this expression may be dropped without fear of sensible error and the result is

$$k = \frac{15}{4}\,m^2\,D\,.$$

Substituting the proper value of D

$$k = 0.28\left[\frac{f}{60/\text{sec}}\right]^2\left[\frac{r\,b\,n^2\,(d/\text{in})^2}{m}\right]^2.$$

Circulating current loss factors for any other type of winding may be calculated by selecting the proper factor

from Table II and applying it to the result just obtained. That is, the effect of the transposition on a coil of Type I is to reduce the extra loss in the ratio given in Table II. This table has been made up with the use of Table I and Formula (3.)

Strand Loss

The strand loss in a one-coil side per slot winding is obtained by substituting

$$L = \frac{m^2 - 1}{3}$$

in Formula (3.) The result is

$$k_s = \left[4 + \frac{15}{3}(m^2 - 1) \right] D$$

and this is practically equal to

$$k_s = 5\, m^2 D \ .$$

When the proper value of D is substituted

$$k_s = 6.0\, b \left[\frac{f}{60/\text{sec}} \right]^2 [r\, n\, (d/\text{in})^2]^2 \ .$$

The factor b is introduced because the extra losses occur in the slot portion only.

In a two-coil side per slot winding

$$L = \frac{4\, m^2 - 1}{3} - m^2 \sin^2 \frac{\theta}{2}$$

and therefore

$$k_s = \left[4 + \frac{15}{3}(4\, m^2 - 1) - 15\, m^2 \sin^2 \frac{\theta}{2} \right] D \ .$$

Practically this is

$$k_s = 20\, m^2 D\, \psi$$

where

$$\psi = 1 - \frac{3}{4} \sin^2 \frac{\theta}{2} \ .$$

The correct value of D is now substituted and b is introduced with the result that

$$k_s = 6.0\, b\, \psi \left[\frac{f}{60/\text{sec}} \right]^2 [r\, n\, (d/\text{in})^2]^2$$

This is the same result that was obtained for the strand loss in a one-coil side per slot winding where θ is zero, and is therefore general. Various coils in a machine may have different values of θ and it becomes convenient to have an average value of ψ to apply to a whole machine. This has been done and ψ_{av} is given in Fig. 8. For a three-phase machine ψ_{av} varies linearly from 1.0 at 100 per cent pitch to 13/16 for 66⅔ per cent pitch and from there linearly to 7/16 at 33⅓ per cent pitch and from there linearly to 0.25 at zero pitch. For a two-phase machine ψ_{av} varies linearly from 1.0 at 100 per cent pitch to 5/8 at 50 per cent pitch and from there linearly to 0.25 at zero pitch.

Table of Symbols

- I_0 A quantity used in the formation of equations for extra loss. The rule for obtaining I_0 is given in the body of the paper.
- I_b The vectorial summation of all the current in the slot below the conductor in question.
- I_1 The current in the conductor in question.
- $\left| \frac{I_0}{I_1} \right|$ The numerical value of the ratio indicated.
- α The angle between I_0 and I_1.
- L A quantity which depends on the type of coil and its transposition. It is defined by Equation (1).
- K The ratio of the total heat loss in the coil to that due to uniform current distribution.
- k The ratio of the extra heat loss in the coil due to eddy currents to that due to uniform current distribution. Also called extra loss factor due to circulating currents.
- D A quantity depending on the dimensions of the slot and coil, the frequency, the number of turns per coil, and the number of coil sides per slot. It is defined in Equations (4), (5) and (6).
- f The frequency of the alternating current.
- r The ratio of the width times the over-all height of the copper conductor in the slot to the slot width, times the net conductor height.
- b The ratio of the length of the slot to the length of a half-turn.
- d The depth of a strand.
- n The total number of layers of strands depthwise in the slot including both coil sides.
- m The number of turns per coil.
- k_s The ratio of the extra loss due to strand loss to that due to uniform distribution of current. Also called strand loss factor.
- p The order of the conductor under consideration. The one nearest the bottom of the slot in the coil side under consideration is $p = 1$. The effect of eddy currents is calculated by averaging I_0 over all conductors and is accomplished by finding I_0 for the general conductor p and summing up all such values.
- s Any integer. The summations in Appendix A are effected with respect to s between the limits indicated.
- h The depth of a conductor, or turn.
- q A quantity depending on frequency, resistivity of the conductor, width of conductor, width of slot, length of slot, and length of a half-turn. It is a complex quantity.
- j The square root of minus one.
- g The quantity q divided by $(1 + j)$. It is real.
- ψ A quantity used in strand loss calculation. It is $\psi = 1 - (3/4) \sin^2 (\theta/2)$.

ψ_{av} The quantity ψ, averaged over all the coils in a machine.

ρ The resistivity of the conductor.

θ Angular phase difference between the currents in the top and bottom coil sides in one slot.

Discussion

G. H. Rockwood, jr.: In order to compute the losses in these transpositions which Mr. Summers has described, it is necessary to determine the percentage of slots in the winding having a given value of the angle θ between current in the top and bottom coil sides. Necessity for visualizing the winding may be done away with and the computation simplified by the following procedure:

In a three-phase winding of full pitch, the angle between the currents in the top and bottom coil sides of all slots is zero; for a two-thirds pitch winding, it is 60 deg.; for a one-third pitch winding, 120 deg., and for a zero pitch winding, 180 deg. Between these limiting values, the percentage of coils having a given value of the angle θ will vary linearly with pitch. We may, therefore, plot the data of Table II of the paper, as is done in the accompanying Fig. 1, and obtain a family of curves for each transposition. Such a plot will enable us to omit the rather laborious computation in the paper, and to read the reduction factor for circulating current directly as a function of the coil pitch.

P. L. Alger: Mr. Summers' idea of making an inversion in one or more turns at the ends of an armature winding seems to me to be a very simple and satisfactory method of avoiding eddy currents. In Schenectady, in building a considerable number of large machines, we have used it with very good success. The advantage of the method is that it enables a standard machine-wound coil to be made without the extra expense of special insulated clips, the connecting of adjacent coils, or any other complications. All other schemes that have been proposed before have involved some inconvenient departure from the simple standard manufacturing processes, and so their use has not seemed to be warranted unless the circulating-current loss without transposition was more than about 25 per cent. With the new method, we have found it desirable to transpose the winding whenever the circulating-current loss should exceed approximately 10 per cent without it.

It is true that the inverted-turn idea is very similar indeed to those which have been suggested by H. W. Taylor in England and by others; but so far as I know, no one has proposed exactly the same scheme, nor has anyone worked out, completely, the eddy-current loss formulas for this case. I feel, therefore, that Mr. Summers has made a very distinct contribution to the art of electrical machine design.

J. R. Dunbar: I desire to point out that the method of transposition advocated by Mr. Summers was used by H. B. Dwight on experimental coils for machines that were being manufactured by the Canadian Westinghouse Company. At that time, it was decided that the reduction in eddy-current losses was insufficient to justify the added complication in the winding of the coils for the machines then being considered. I should like to ask Mr. Summers if it is proposed to use in machines now under construction any of the transpositions he describes?

F. D. Newbury: It may be of interest to point out a few of the more general considerations affecting transposition. There have been three methods advocated: First, there is transposition secured by means of certain connections between coils. That method has been applied for 10 or 12 years in large machines

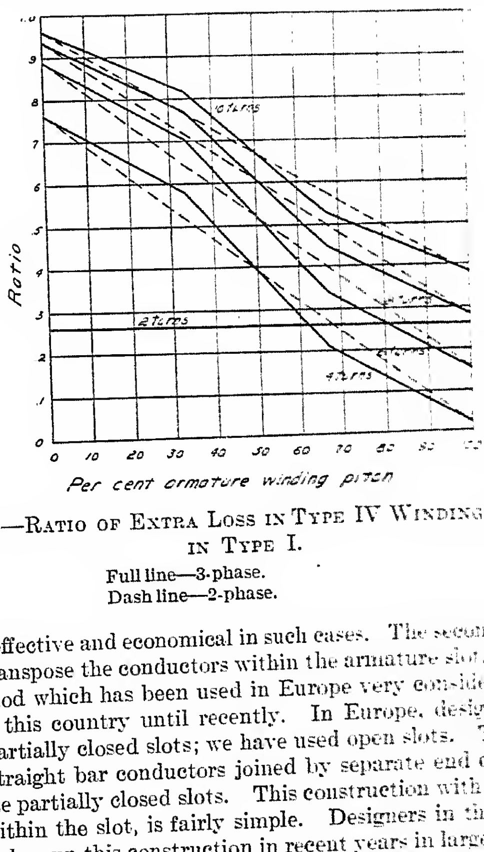

FIG. 1—RATIO OF EXTRA LOSS IN TYPE IV WINDING TO THAT IN TYPE I.

Full line—3-phase.
Dash line—2-phase.

and is effective and economical in such cases. The second method is to transpose the conductors within the armature slot. That is a method which has been used in Europe very considerably but not in this country until recently. In Europe, designers have used partially closed slots; we have used open slots. They have used straight bar conductors joined by separate end connectors in these partially closed slots. This construction with transposition within the slot, is fairly simple. Designers in this country have taken up this construction in recent years in large machines because coils became so long that it was desirable to deal with half coils instead of complete coils, and it is only possible to deal successfully with half coils when it is possible to connect both ends of the conductor solidly in forming the complete winding. So in American practise, in our largest machines the transposition within the slot is coming into use.

It seems to me that this third method advocated and described by Mr. Summers is a very desirable construction for the moderate-sized machine where it is still desirable to use complete coils, machine-wound, and to secure transposition economically.

In looking over the bibliography at the end of this paper[2] there is another thought that occurs to me. It illustrates the greatly accelerated progress in the mathematical and theoretical bases of

1. *Heat Loss in Stranded Armature Conductors*, W. V. Lyon, TRANS. A. I. E. E., 1922, p. 199.

our design work. From this bibliography you will note that the earliest American paper was one by A. B. Field, presented in 1905. There was no other important contribution, at least, not in America, until Gilman's paper in 1920,—a period of fifteen years. In the six or seven years since that, we have had the important papers by Prof. Lyon, and now another one by Mr. Summers, which indicates the very healthy condition of progress in this branch of design.

C. M. Laffoon: I wholly subscribe to the views given in the paper; in fact, I used the method a few years ago.

W. V. Lyon: I agree with Mr. Summers that in the computation of the extra-loss factor for any winding that is properly designed, it is sufficiently accurate to use the first terms in the expansion of the hyperbolic functions. This is also the expressed opinion of H. W. Taylor. For anyone who might wish to compare the approximate with the exact values of these hyperbolic functions, I am appending a table of such values.

I should like to call attention to one minor correction. It is in regard to the use of the ratio r when calculating the strand loss. This ratio takes into account the effect of the insulation between the strands. The magnetic field that exists in the space between adjacent strands plays its part in affecting the distribution of current among the strands and thus is a factor in determining the circulating-current loss. On the other hand, this magnetic field does not influence the strand loss. The expression for the strand loss can be corrected by using either a different value for the ratio b or the ratio r. The effect of this correction will be to multiply the strand loss by the ratio of (the net depth of strand)^2 to (the gross depth of strand)^2. Making this correction in Mr. Summers' numerical example reduces the strand loss factor from 0.094 to 0.082.

I believe that there are still one or two points in the theory of these extra losses that are not fully appreciated. The extra circulating-current loss is zero when the current is equally divided among the strands. The extra strand loss is not a minimum for this condition, however, but for the condition when the current is more concentrated toward the top of the slot. As a simple illustration of this, consider two equal strands placed one above the other. The total loss in these strands is a minimum when the current in the lower strand is one-half of the total multiplied by the fraction $\left(1 - \frac{N}{M}\right)$ and the current in the upper strand is one-half of the total current multiplied by $\left(1 + \frac{N}{M}\right)$. As further evidence of this fact, consider the expressions for strand loss that were derived in my 1922 paper.[1] In case 5 of that paper, the circulating-current loss is much smaller than in case 6, but the strand loss is smaller in case 6 in about the ratio of 13 to 16 for full-pitch slots and in about the ratio of 10 to 13 for three-phase fractional-pitch slots. It is readily shown that in the windings which have a small circulating-loss factor, it is very nearly correct to compute the strand loss on the assumption that the current is equally divided among the strands, as Mr. Summers has done. The exact expression for the strand loss is readily deduced by following the method outlined in my 1922 paper. It is:

$$\left\{ \frac{1}{2\,n} \left(\sum_{\mathrm{D}} \left| I_b \right|^2 + \sum_{\mathrm{R}} \left| I + I_b \right|^2 \right) - \left| I_o \right|^2 \right\} T_r'$$

The notation is the same as in my paper. The value of n is the number of turns in the coil. The first term is the sum of the squares of the currents in the slot *below* the successive half-turns of the coil in which the strands are numbered in the direct order. The second term is the sum of the squares of the conductor current plus the current in the slot below the successive half-turns of the coil in which the strands are numbered in the reverse order. The last term is the square of the current I_o. Mr. Summers describes the method of computing I_o.

For a given depth of copper in the slot, the strand loss can be reduced to a reasonable value by increasing the number of strands. For a given number of strands it is nearly independent of the strand arrangement. The circulating-current loss, on the other hand, depends in a marked degree upon the strand arrangement. The problem then seems to be to reduce this latter loss to its smallest possible value.

With full-pitch slots, Mr. Summers' quantity, L, has its smallest value when $\frac{I_o}{I} = -\frac{1}{2}$, for which condition $L = -\frac{1}{4}$.

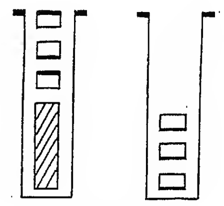

FIG. 2

This then gives the condition for minimum circulating loss. This value of $\frac{I_o}{I}$ can always be obtained, if the coil has an even number of turns, by inverting the end connections as shown in his Fig. 3. It can also be obtained if the coil has an odd number of turns provided the current in the lower coil side is in phase with that in the upper coil side. Figs. 2 and 3 herewith show how it may be accomplished when the coil has three turns and when it has five turns. Mr. Summers does not show this type of inversion. It will be found, however, in H. W. Taylor's paper. With these same inversions, the losses will be somewhat greater for fractional-pitch slots. There is another type of inversion, however, that will give more nearly the theoretical minimum loss for the case of an odd number of turns and fractional-pitch slots. In the case of three-phase, fractional-pitch slots, the minimum value of L is $-\frac{1}{18}$ if the coil has three turns. The arrangement is the same as shown in my Fig. 2, except that the lower conductor of the lower coil side is inverted. For three-phase, fractional pitch slots, arranged as shown in Fig. 2, L is zero. If the conductors have a value of $q\,h$ equal to 2.0, which is not excessive, the inversion of this bottom conductor reduces the circulating-current extra-loss factor from 0.309 to 0.245 for these fractional-pitch slots. Although fractional pitch has certain distinct advantages from the standpoint of flux distribution and wave-form of generated e. m. f., it prevents the attainment of the minimum copper-loss factor except in the single case of a winding having an even number of turns arranged as in Mr. Summers' Fig. 3.

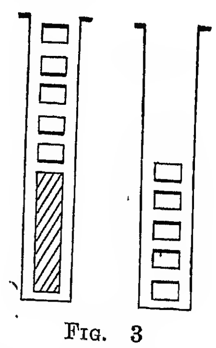

FIG. 3

There is one more case that is perhaps worth while mentioning. A certain large 25-cycle generator has a calculated extra-loss factor of 9.9 per cent. If it had been mechanically possible to invert the end connections, as in Mr. Summers' Fig. 3, the extra-loss factor would have been 0.6 per cent, a reduction of 8.5 per cent in the armature copper loss. For the same armature heating loss the rating of this generator might have been increased nearly 2000 kv-a. There might possibly have to be a slight modification of the field winding to compensate for the increased armature reaction.

TABLE OF APPROXIMATE AND EXACT HYPERBOLIC FUNCTIONS

$q\,h$	M Exact	$1 - \frac{(q\,h)^4}{45}$ Approximate	N Exact	$-\frac{(q\,h)^4}{12}$ Approximate
0.4	1.001	1.00058	0.002	0.00213
0.8	1.008	1.0091	0.034	0.0342
1.2	1.044	1.0461	0.169	0.173
1.6	1.137	1.146	0.512	0.546
2.0	1.309	1.356	1.147	1.333
2.4	1.566	1.738	2.074	2.766
2.8	1.874	2.368	3.17	5.12

H. W. Taylor (communicated after adjournment): When a coil consists of two or more turns, methods of reversing the order of laminations of the conductor in different parts of the coil have been previously known whereby the circulating-current loss may be reduced to a minimum, which minimum loss corresponds to that of a conductor at the bottom of the slot, consisting of half the laminations of the conductor actually used in the coil.

Sometimes it is found inconvenient, however, to arrange all the coil ends so as to change the order of the lamination in the top and bottom conductors as frequently as is required to provide a minimum loss. The author of this paper is to be congratulated upon having disclosed in Fig. 6 a method of winding multi-turn coils which provides a compromise between facility in winding the coil on the one hand and reduction of the circulating eddy-current losses on the other.

In order to consider the merits of the various forms of coil windings with laminated conductors, the writer has found it convenient to consider the circulating loss only and as if the conductor were infinitely limited. The term in the formula for extra loss in an infinitely laminated conductor which involves the position of the conductor in the slot is

$$\frac{4}{45} - \frac{(p^2 - p)}{3}$$

where p is the position of the conductor counting from the bottom of the slot.

In the following table, particulars have been tabulated for two- up to six-turn coils for the ordinary method of winding, for the most perfect method, and for Summers' method as described in the paper. In the table, parallel columns give equivalent values of p, the value of $(p^2 - p)$ and the value of the above expression (leaving out the denominator of 180 in all cases), as a figure of merit.

No. of turns in coil	Ordinary Method			Most Perfect Method			Compromise Method		
	p	(p^2-p)	Fig. of merit	p	(p^2-p)	Fig. of merit	p	(p^2-p)	Fig. of merit
2	1 ½	¾	61				0	0	4
3	2	2	136				1/3 or 2/3	−2/9	3
4	2 ½	15/4	241	½	− ¼	1	¼ or ¾	−3/16	5
5	3	6	376				1 1/5	6/25	59
6	3 ½	35/4	691				1 1/3	10/9	83

It will be seen that the author's method is particularly applicable to two-, three-, and four-turn coils. It provides considerable improvement in five- and six-turn coils, but owing to the fact that in coils with this larger number of turns, the total depth of conductor would be relatively shallow, the loss in such coils would in practise, be small in any case.

I. H. Summers: Mr. Rockwood has presented a very interesting and valuable discussion. His curves should materially simplify the computation of extra-loss factors. They will be especially valuable in design work where it is highly desirable to have a quick and convenient method for checking the efficacy of proposed windings.

Mr. Dunbar has stated that H. B. Dwight experimented with transpositions similar to those I have described but gave up the idea because of the belief that the reduction in loss was insufficient to justify their use. Mr. Alger has answered this statement by pointing out that a considerable number of large machines has already been built using these transpositions with good success and that it is found economical in Schenectady to use the transposition whenever the extra circulating eddy-current loss would exceed about 10 per cent without it. It will be noted that some of the types of transpositions described are more effective than others. Naturally, in any given winding, that method will be selected which combines a sufficient reduction of eddy-current loss with economy in making the winding.

With regard to Mr. Newbury's points about the applicability of various types of transpositions to particular classes of windings, I may say that there is no gain to be expected from the inverted-turn transposition when it is applied to a one-turn coil. For machines using a one-turn coil, an effective form of transposition is already in extensive use, which completely eliminates the circulating eddy-current loss. The transposition in this case is accomplished within the slot, and a bar winding, consisting of half coils, is used.

H. W. Taylor's discussion is very interesting. His tabulation shows that type IV, Fig. 6, is particularly applicable for two-, three-, and four-turn coils, when the winding is full-pitch. I wish to remark that type V, Fig. 7, is quite applicable also for two- and three-turn coils; in fact it gives a lower loss than type IV if the coils are wound with fractional pitch. For coils of four or more turns, type IV is preferable in any case.

I am very much indebted to Prof. Lyon for calling attention to an error in the use of the ratio r. The correction for the strand insulation was not a part of the original manuscript but was sent in as an after-thought. Obviously, it should have been applied to the circulating-current loss but not to the strand loss. Perhaps the best way to take care of this is to define r simply as the ratio between the total width of copper in the slot and the slot width. Then, a new factor c should be introduced into the formula for circulating-current loss wherever it occurs, where c is the square of the ratio between (strand height including strand insulation) to (net strand height).

Prof. Lyon's remarks concerning the problem of strand loss are pertinent and it is interesting to note that his exact results lead him to the conclusion that my formulas are sufficiently accurate for practical windings. Perhaps it is in place to point out that the first duty of the engineer who sets out to provide a solution to a problem is to solve it in the most general and exact manner that he can devise. Prof. Lyon has done this in a neat and logical way. In so doing, he has provided a firm foundation for anyone who later wishes to apply his results. It is often possible in such cases to reduce the general solution to a more practical form which will be the simplest possible, consistent with the accuracy required. Thus, it may be simplified so that practical men will find great use for it. This is what I have attempted to show in my paper.

Graphical Determination of Magnetic Fields
Theoretical Considerations

BY A. R. STEVENSON, Jr.[1] and R. H. PARK[1]
Associate, A. I. E. E. Non-member

Synopsis.—*Three papers on the general subject, "Graphical Determination of Magnetic Fields," are being presented simultaneously to cover three phases of the subject: 1. Theoretical Considerations, 2. Comparison of Calculations and Tests, by E. E. Johnson and C. H. Green, 3. Practical Applications to Salient-Pole Synchronous Machine Design, by R. W. Wieseman. In the following paper, which is the first of this series, the authors have reviewed the history of the subject, have briefly stated the ordinary rules for plotting magnetic flux in air and in current-carrying copper, have developed additional rules for checking the accuracy of field plots, and have given theoretical methods for mathematically calculating the distribution of field in certain cases commonly encountered in practise.*

The authors have called attention to the great value of the mathematical work by the German engineer, Rogowski, and the graphical methods by the French engineer, Lehmann. These German and French articles contain the only extensive practical applications of the plotting of magnetic fields in current-carrying regions with which the present authors are familiar. Since it is much more difficult to plot fields in current-carrying regions, and since the majority of readers are less familiar with this phase of the subject, the greater part of the first paper, "Theoretical Considerations," is devoted to a study of such fields. As special examples, the mathematical solutions for the magnetic field between the poles of a salient-pole alternator and the magnetic field in a circular conductor in a circular slot are given in Parts I and III, respectively, of this first paper.

Part II of the first paper contains a set of theorems which deal with various questions which have arisen while studying this subject—such as the proof that there is no refraction of the lines of force at a copper-air boundary, but a change of curvature when a line of force crosses such a boundary; and a general law for checking any field plot by the relation of the magnetic intensity and its rate of change to the current density and the radius of curvature of the magnetic field. The first two appendixes contain practical rules for the free-hand plotting of flux distribution in both air and copper; Appendix C contains an interesting discussion of the conception of vector potential, showing how easily it can be applied to the solution of practical problems.

The three papers in this group should be considered as one complete whole and the reader will find very interesting a comparison between the mathematical plots given in this paper on "Theoretical Considerations" and the experimentally determined plots in the second paper on "Comparison of Calculations and Tests," and the practical uses for these methods in the design of machinery given in "Practical Applications to Salient-Pole Synchronous Machine Design."

In the early days of the design of electrical machinery, magnetic distributions were largely a matter of guesswork, but in these days of more severe competition and closer refinement of design, an accurate knowledge of the magnetic distribution is a necessary fundamental of the greatest importance in determining the best designs.

* * * * *

Historical Introduction

In the design of electrical apparatus, the accurate calculation of the characteristics of a proposed design depends on the distribution of magnetic flux in the machine.

A few shapes lend themselves to rigorous mathematical analysis. One of the most famous examples of this is the calculation of the fringing coefficient due to the slots along the periphery of an induction motor air-gap, by F. W. Carter[2], who used the theory of functions of a complex variable to obtain a solution of Laplace's equation.

The mathematical complications encountered in analyzing the magnetic fields surrounding many of the irregularly shaped iron boundaries commonly found in electrical machinery, however, have led many authors to advocate and describe graphical and experimental methods. One of the best bibliographies on this subject is given by J. F. H. Douglas in an article[3] in which he reviews the many methods suggested by other authors, but especially emphasizes the use of high-resistance templets for experimentally plotting a field.

2. See bibliography, 1.
3. See bibliography, 5.

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

There are many articles[4] that describe the graphical method of plotting magnetic fields in air, but almost none of them give any suggestion of a method for plotting fields within current-carrying conductors. One of the best articles on the subject is "The Free-Hand Graphic Method of Determining Stream Lines and Equipotentials," by L. F. Richardson[5]. This author makes the statement that in a region occupied by current, the difference of successive chequer ratios in a direction perpendicular to the lines of force, divided by the mean chequer area, is equal to a constant times the current density in the region[6]. But he goes on to say:

"To draw chequers free-hand, so as to satisfy a difference relation of this sort between chequer ratios, is likely to be toilsome, and we will here consider only the case where $\Delta^2 v = 0$."

The remainder of Richardson's paper is given up to the sketching of various fields, in none of which does he take into account the effect of current-carrying conductors in the space occupied by the flux.

The most complete treatise on the free-hand plotting of fields of magnetic flux will be found in a series of French articles by Lehmann[7]. The 1909 article con-

4. See bibliography, 8 and 10.
5. See bibliography, 2.
6. See Appendix B for a proof of this statement.
7. See bibliography, 4, 7 and 9.

tains many valuable suggestions for plotting fields in air, and the 1923 articles give an elaborate set of rules for plotting magnetic fields in regions where the curl of the field is not zero —*i. e.*, in space occupied by current-carrying conductors.

It has always been said that there are no lines of magnetic equipotential in current-carrying space. This is true, but Lehmann pointed out that a system of lines orthogonal to the lines of force can be drawn. He called these lines gradients, and called attention to the fact that they all converge to one or more points in the copper which he called points of indifference.

Consider the field in and around a cylindrical conductor. The lines of force are circles. The gradients, or lines of no work, as the authors prefer to call them, are radial lines; and the point of indifference, or kernel, is the center of the wire. It is also seen that the lines of no work on leaving the copper become lines of equipotential.

This conception of lines of no work radiating from one or more kernels greatly facilitates plotting fields in copper. In Appendix B, a very brief set of rules for plotting the flux in the current-carrying regions is given by one of our associates, Mr. Lloyd P. Shildneck, using as an illustration the distribution of flux between the field poles of an alternator.

In June, 1918, Messrs. Doherty and Shirley published a paper[8] which made practical use of many sketches of magnetic fields in air. Since that time, the company with which the authors are associated has made considerable use of free-hand sketching in the predetermination of the air-gap fields of salient-pole machinery. Except in a few special cases, however, our attempts to sketch magnetic fields in regions occupied by current-carrying conductors were rather unsatisfactory.

In the fall of 1924, not yet having noticed Lehmann's 1923 article, we started to investigate this problem seriously. The task of sketching is greatly simplified when one knows in advance the approximate shape which the sketch should have. Not yet having gained the conception of a kernel from which lines of no work radiate, we had only vague and incorrect ideas as to the detail distribution of flux within the copper coils surrounding alternator field poles, which was the problem we set ourselves to solve.

After many attempts to make a reasonable looking sketch, we decided that it would be worth while to attempt a mathematical analysis of this field, in the hope of obtaining a picture which would at least suggest the general arrangement of the lines of force in the copper. The purpose of this article is to describe this mathematical method, the route by which it was derived, and the additional suggestions for free-hand sketching which resulted from this work.

Professor V. Karapetoff called our attention to a most valuable article by Rogowski[9] which we immediately adopted as a basis for our work. Unfortunately, this is out of print in German and had never been translated into English until recently, when a partial translation was given in an article by one of the present authors[10], which it will be necessary to read in order to understand Part I of this paper. Rogowski mathematically plotted the leakage field in and around transformer coils. The pictures shown in Rogowski's article called our attention to the kernels or points of indifference.

The two fundamental ideas which we obtained from Rogowski's work were:

1. The simultaneous solution of four relatively simple differential equations set up to satisfy the conditions in four adjacent regions into which the field was divided. This simplified the problem greatly because each region, taken by itself, could be analyzed easily; whereas, the alternative course, a consideration of all four regions at once, would have been a very difficult task.

2. This division into regions made it possible to represent the current distribution by a Fourier's series of only one of the space coordinates.

The contribution of the present article consists in the extension of Rogowski's method to more complicated magnetic shapes. We followed Rogowski by dividing the field of a salient-pole alternator into several regions which could be solved simultaneously. The current-carrying region was represented by an infinite series of reflected and re-reflected images, while the mathematical expression for the boundary region between the pole tips was obtained from a free-hand sketch. This combination of a strictly mathematical method with the theory of images and with free-hand sketching in the parts which can easily be sketched free-hand, into one consistent system of equations which gives mathematical expressions for the lines of force in the part of the field which cannot be easily sketched, is, we believe, a valuable engineering tool which can be applied to many other problems. Illustrations are given of its application to a problem with rectangular boundaries and also to a problem with circular boundaries. The method can probably be extended to an even wider range of problems by expressing the equations of Poisson and Laplace in more complicated systems of coordinates.

It has been our experience that, in certain cases, so much sketching and resketching is required before the kernel can be found by the free-hand method that this mathematical method could actually be worked out, by the use of comptometers, more quickly than the field could be sketched.

This theoretical work also led to additional rules for guiding the construction and checking the accuracy of free-hand sketches.

8. See bibliography, 6.

9. See bibliography, 3.

10. See bibliography, 11.

The body of the paper is arranged in three parts:

PART I. Calculation of the flux leakage between poles in an alternator with approximately parallel pole sides.

PART II. Point conditions in coplanar magnetic fields. (New rules for constructing and checking of free-hand sketches.)

PART III. Application of the method to polar coordinate systems.

Five appendixes have been included, the first two

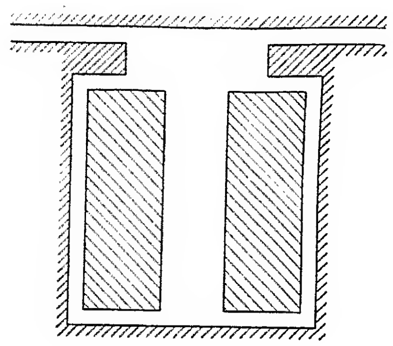

FIG. 1

merely in the interest of completeness; but the last three contain valuable original material.

APPENDIX A. Rules for plotting flux in air.

APPENDIX B. Method of plotting two-dimensional magnetic fields in space occupied by current-carrying conductors.

APPENDIX C. Vector potential in coplanar magnetic fields.

APPENDIX D. The relation of the scalar potential

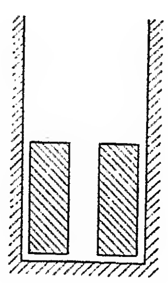

FIG. 2

function to the vector potential function in coplanar magnetic fields.

APPENDIX E. Calculation of inductance from a knowledge of vector potential.

I. CALCULATION OF THE FLUX LEAKAGE BETWEEN POLES IN AN ALTERNATOR WITH APPROXIMATELY PARALLEL POLE SIDES

It is desired to calculate the flux distribution in the two-dimensional magnetic circuit of Fig. 1, which is supposed to represent a cross-section of an actual pair of field poles. The shaded area is intended to represent current-carrying copper. It is assumed that the current density is constant over the cross-section of the conductors and that the iron is of infinite permeability.

One step in the solution of the problem in which the actual magnetic circuit was replaced by an infinitely deep slot, as in Fig. 2, was suggested by one of our associates, Mr. C. J. Koch. Under this assumption, the complete magnetic circuit may be replaced by a double row of images extending to infinity, as shown in Fig. 2A. It was found that the solution used by Rogowski[11] for the flux in a transformer with pancake coils could be applied to this case, by using a Fourier's series for the infinite string of images.

The problem may be reduced, in fact, to a consideration of an infinite series of rectangular conductors parallel to an infinite plane of iron, as in Fig. 2B, and the solution is the same as Rogowski's for the case $\mu = \infty$ except that, since all the currents are of the

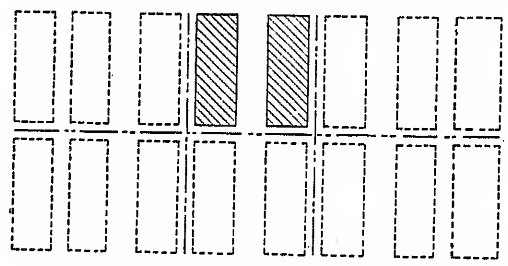

FIG. 2-A

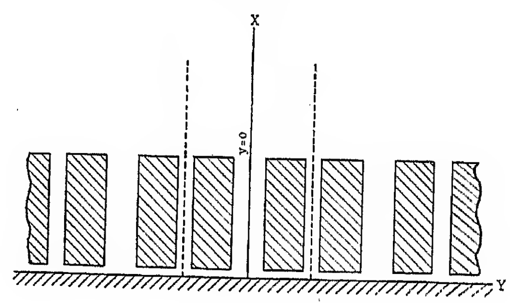

FIG. 2-B

same sign, there will be a constant term, α_0, in the Fourier's series for the current density, which requires an additional term, $2\,\pi\,\alpha_0\,x^2$, in the equation for R in current-carrying space, and it will also be found that the constant terms and coefficients of x will not drop out as they did in the transformer problem.

The solution for dimensions of coils and slots given in Fig. 3, is as follows:

Region I:

$$R = \sum_{1}^{\infty} \frac{2\,\pi\,\alpha_n}{(k\,n)^2}[1 - \epsilon^{-kn(b-a)}]\,[\epsilon^{-kn(a-x)} + \epsilon^{-kn(a+x)}]\cos n\,\theta$$

Region II:

$$R = 2\,\pi\,\alpha_0\,(x-a)^2 + \sum_{1}^{\infty} \frac{2\,\pi\,\alpha_n}{(k\,n)^2}\,[2 - \epsilon^{-kn(b-x)}$$

11. For translation, see bibliography, 11.

$$- \epsilon^{-kn(x-a)} (1 - \epsilon^{-2kna} + \epsilon^{-kn(b+a)})] \cos n\, \theta$$

Region III:

$$R = 2\, \pi\, \alpha_0\, (b - a)\, [2\, x - (b + a)\,]$$

$$+ \sum_{1}^{\infty} \frac{2\, \pi\, \alpha_n}{(k\, n)^2} [1 - \epsilon^{-kn(b-a)} - \epsilon^{-2knb}$$

$$+ \epsilon^{-kn(b+a)}]\, \epsilon^{-kn(x-b)} \cos n\, \theta$$

wherein, for convenience, the y coordinate has been

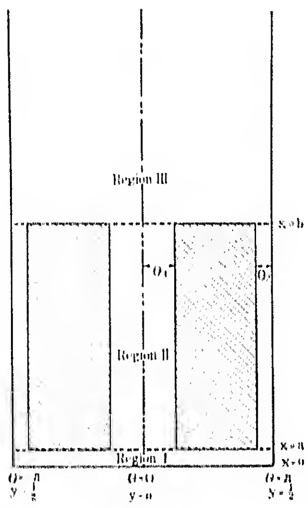

Fig. 3

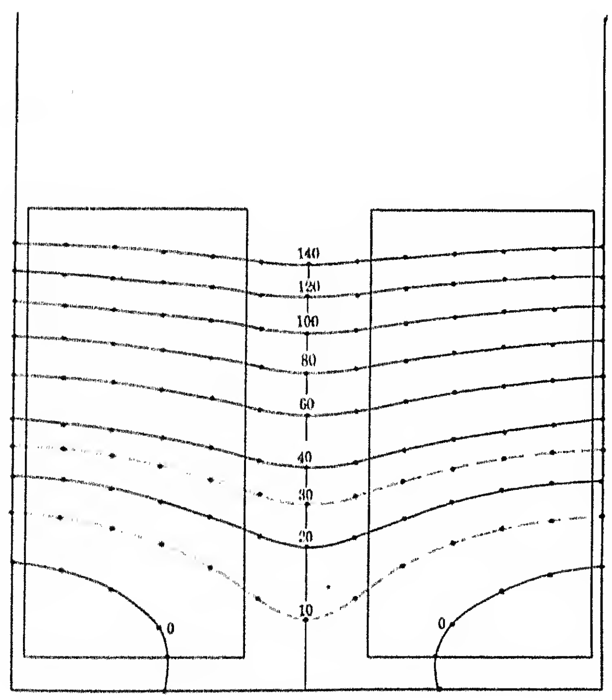

Fig. 3-A

replaced by θ which varies from $-\pi$ to π across the total width of the slot. Also,

$$k = \frac{2\, \pi}{l} \text{ where } l \text{ is the width of the slot.}$$

$$\alpha_0 = \frac{\pi - (\theta_1 + \theta_2)}{\pi}\, i$$

$$\alpha_n = \frac{2\, i}{n\, \pi} [\sin (n\, \theta_1) + (-1)^n \sin (n\, \theta_2)\,]$$

where i is the current density in the copper and θ_1 and θ_2 are indicated in Fig. 3. The field distribution for this case is given in Fig. 3A.

In order to extend the solution to include the effect of the pole tips and the finite depth of slot, it was suggested that the field be calculated by replacing the actual magnetic circuit with a closed rectangular

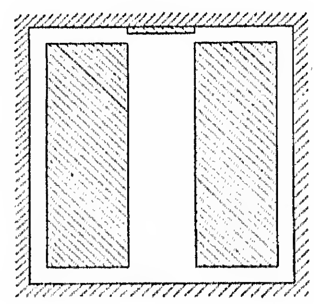

Fig. 4

magnetic circuit of the same dimensions as though the pole faces came together, leaving no air-gap. The effect of the air-gap was to be simulated by a narrow strip of copper along the surface of the iron, assumed to carry a total current equal to the sum of the currents in the two field coil sides (see Fig. 4.).

A better method of solution is provided by first estimating one component of the field in the air-gap

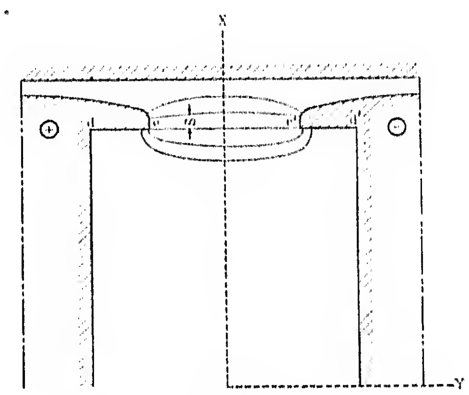

Fig. 5

between the pole faces and using this estimated field component as a boundary condition.

The procedure is as follows:

The field at the air-gap is first calculated or plotted free-hand on the basis of a definite potential between the field poles.

The Y component of the field along the line $d\, d'$ (Fig. 5) is zero from d to e. It is approximately

inversely proportional to the vertical distance s between two lines of force in the neighborhood of the line $d\,d'$ from e to e' and is again zero from e' to d'. The arrangement is symmetrical with respect to the x axis.

The variation of Y is calculated in this way from d to d', or from $\theta = -\pi$ to $\theta = \pi$, and is plotted to any convenient scale. The general character of the curve is shown in Fig. 6.

This curve of Y along the upper boundary of Region III can be expressed as a Fourier's series[12] of the form:

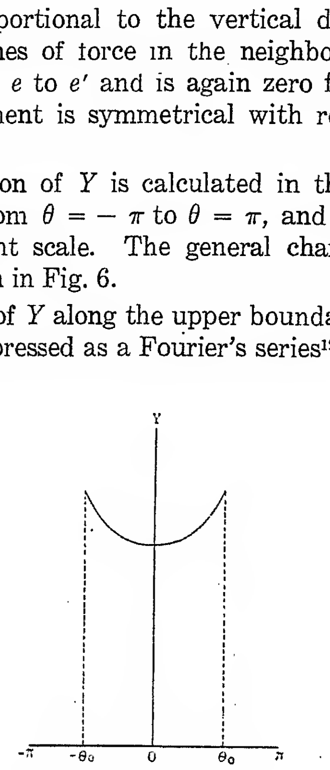

Fig. 6

$$Y = \beta_0 + \sum_1^\infty k\, n\, \beta_n \cos n\,\theta$$

Unfortunately, it seems necessary to use about a dozen harmonics in using this equation as a boundary condition.

The solution for the vector potential R at any point in the three regions is then given by three equations:

Region I:

$$R = \sum_1^\infty [a_n\, \epsilon^{-kn(a-x)} + a_n'\, \epsilon^{-knx}] \cos (n\,\theta)$$

Region II:

$$R = 2\,\pi\,\alpha_0\,(x-a)^2 + \sum_1^\infty [b_n\, \epsilon^{-kn(b-x)} + b_n'\, \epsilon^{-kn(x-a)} + 2\,K_n] \cos (n\,\theta)$$

Region III:

$$R = 2\,\pi\,\alpha_0\,(b-a)\,[2\,x - (b+a)\,] + \sum_1^\infty [c_n\, \epsilon^{-kn(c-x)} + c_n'\, \epsilon^{-kn(x-b)}\,] \cos (n\,\theta)$$

where the six constants of integration determined from the original Fourier's series for current distribution and the six boundary conditions, one of which is another Fourier's series, are as follows:

$$a_n = \frac{\beta_n\, \epsilon^{-kn(c-a)} + K_n\, [1 - \epsilon^{-kn(b-a)} + \epsilon^{-kn[2c(b+a)]} - \epsilon^{-kn2(c-a)}]}{1 - \epsilon^{-2knc}}$$

$$a_n' = a_n\, \epsilon^{-kna}$$

$$b_n = \frac{\beta_n\, \epsilon^{-kn(c-b)} - K_n\, [1 + \epsilon^{-kn[2c-(a+b)]} - \epsilon^{-kn2(c-b)} - \epsilon^{-kn(2c+a-b)}]}{1 - \epsilon^{-2knc}}$$

$$b_n' = \frac{\beta_n\, \epsilon^{-kn(c+a)} - K_n\, [1 - \epsilon^{-2kna} + \epsilon^{-kn(b+a)} - \epsilon^{-kn(2c+a-b)}\,]}{1 - \epsilon^{-2knc}}$$

$$c_n = \frac{\beta_n + K_n\, \epsilon^{-kn(c-b)}\, [1 - \epsilon^{-kn(b-a)} + \epsilon^{-kn(b+a)} - \epsilon^{-2knb}\,]}{1 - \epsilon^{-2knc}}$$

$$c_n' = \frac{\beta_n\, \epsilon^{-kn(c+b)} + K_n\, [1 - \epsilon^{-kn(b-a)} - \epsilon^{-2knb} + \epsilon^{-kn(b+a)}\,]}{1 - \epsilon^{-2knc}}$$

wherein the letters a, b, and c refer to Fig. 7, and

$$K_n = \frac{2\,\pi\,\alpha_n}{(k\,n)^2}$$

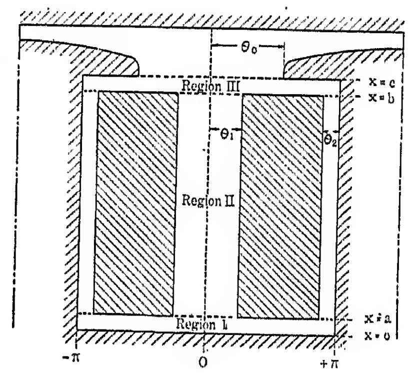

Fig. 7

By assuming that the function of Fig. 6 between $-\theta_0$ and $+\theta_0$ may be represented in the form,

$$Y = f + g\,\theta^2 + h\,\theta^4$$

the values of β_n become

$$\beta_n = \frac{\left[\left[\frac{1+h'\,\theta_0^4}{n} + \left(g' - \frac{12\,h'}{n^2}\right)\left(\frac{\theta_0^2}{n} - \frac{2}{n^3}\right)\right] \sin (n\,\theta_0) + \left[\frac{4\,\theta_0^3\,h'}{n^2} + \left(g' \frac{12\,h'}{n^2}\right)\frac{2\,\theta_0}{n^2}\right] \cos (n\,\theta_0) \right]}{\frac{\theta_0}{2} + \frac{g'\,\theta_0^3}{6} + \frac{h'\,\theta_0^5}{10}} \left[\frac{2\,\pi\,\alpha_0\,(b-a)}{(k\,n)}\right]$$

12. The determination of the Fourier's series will be simplified if the curve (Fig. 6) between $-\theta_0$ and $+\theta_0$ is assumed of the form: $Y = f + g\,\theta^2 + h\,\theta^4$.

where:

$$g' = \frac{y}{f}$$

$$h' = \frac{h}{f}$$

Any inaccuracy in the determination of g' and h' will result in inaccuracy in the field plot only in the immediate vicinity of the pole tips.

In the above equation, θ_0 is the value of θ at the pole face edge, as indicated in Figs. 6 and 7, and k and α_n are the same as in the solution for the infinite slot.

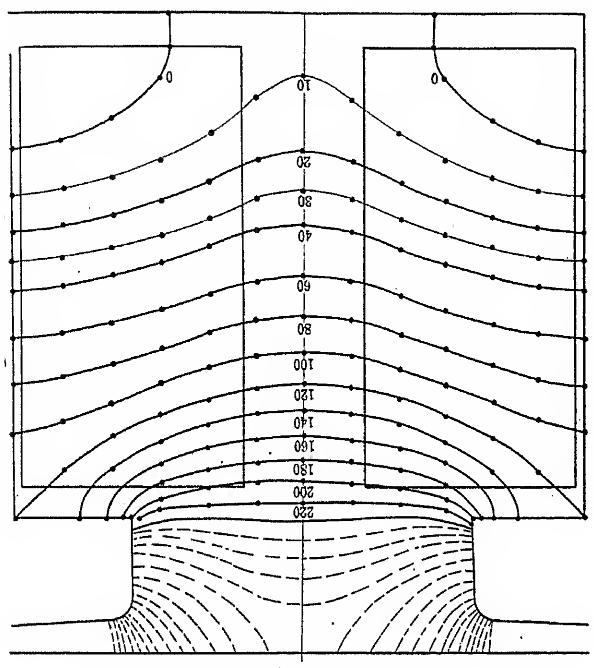

FIG. 8

The solution, assuming the current density such that $\alpha_0 = \frac{1}{2\pi}$, is shown in Fig. 8. The dotted lines in the figure indicate that portion of the flux distribution which was sketched in free-hand.

Although the problem has been worked out for the particular case of the flux distribution between two field poles, it is evident that the same method may be applied to any problem with rectangular boundaries. In case the magnetic circuit or the current distribution is not symmetrical about a central axis, it will be necessary to express R as a series of sines and cosines.

II. Point Conditions in Coplanar Magnetic Fields

The theory used in the preceding calculation can be made to answer various questions which arise in the free-hand sketching of magnetic fields, and also offers various criteria for judging the accuracy of the sketch.

The question is sometimes asked whether there is any refraction of the lines of force at a copper-air boundary. It will be proved that there is no such refraction, or discontinuity in slope, but that the radius of curvature of a line of force may change suddenly when the line crosses the boundary of a current-carrying region. This change in the curvature of the field at the boundary of current-carrying copper is readily detected on a correctly drawn field plot, especially where the lines emerge from the copper perpendicularly and the field intensity is low.

Theorem I. There is no refraction at a copper-air boundary. In studying the possibility of refraction at copper-air boundaries where the permeability is continuous, the classical problem of refraction at a boundary where the permeability is discontinuous will be considered, taking into account a flow of current on one side of the boundary.

Fig. 9 indicates the boundary of two regions, I and II, of permeabilities μ_1 and μ_2. The normal and tangential components of the magnetic field on either side, but immediately adjacent to the boundary, are H_{n1} and H_{n2}, and H_{t1} and H_{t2}, respectively.

In order that the total flux emanating from the space included by the dotted area shall vanish, it is necessary that the integral of the outward component of flux around the area must vanish. If the flux density is everywhere finite, in the limiting case in which the area is made vanishingly thin, the flux emanating from the ends of the area may be neglected. Therefore

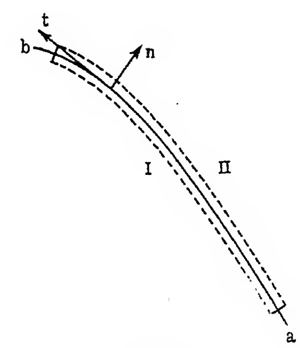

FIG. 9

$$\int_a^b \mu_1 H_{n1}\, d\,t = \int_a^b \mu_2 H_{n2}\, d\,t$$

and

$$\mu_1 H_{n1} = \mu_2 H_{n2} \tag{1}$$

From the application of the condition that the line integral of the field around the dotted area must equal 4π times the current included, and the assumption that the current density is finite, it follows in the limiting case, in which the area is made vanishingly thin, that the current included, and therefore the complete line integral around the boundary, vanishes, that is:

$$\int_a^b H_{t1}\, d\, t + \int_b^a H_{t2}\, d\, t = 0$$

Therefore,

$$H_{t1} = H_{t2} \tag{2}$$

From Equations (1) and (2), it is evident that the well-known rule that, at any point of a magnetic field, the normal component of flux density $\mu\, H_n$ and the tangential component of field intensity H_t are continuous across any boundary, holds even when there is current flowing on one side of the boundary, provided that the current density is not infinite at the point under consideration.

Since the permeability of copper and air are approximately equal, it therefore follows that there can be no discontinuity in the normal and tangential components, or in the direction of the field at the boundary of the copper, even though it be carrying current, provided that the current density at the boundary is not infinite. Q. E. D.

Note: In the analysis of practical electrical problems involving coplanar fields, it is sometimes convenient to idealize to the extent of assuming the exciting currents to be concentrated in a ribbon of negligible thickness—that is, to assume that a finite amount of current flows into the plane of the field through a line drawn in that plane.

In this case, the current density is infinite for points on the line. It will be readily verified that, at a boundary along which a linear distribution of current density exists, Equation (2), Theorem I, becomes:

$$H_{t2} - H_{t1} = 4\,\pi\, i'$$

where i' is the linear current density at the point in question.

In particular, for a linear distribution of current density along an iron surface, we have:

$$H_{t1} = 0$$

and thus:

$$H_{t2} = 4\,\pi\, i'$$

That is, the tangential field intensity along an iron surface

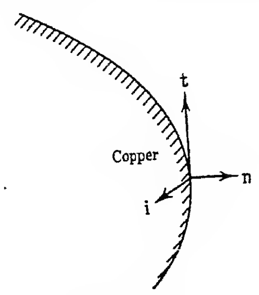

Fig. 10

faced with a distribution of linear current density depends only on the value of the linear density at the point in question. This relation, which is obvious as soon as appreciated, may be seen to necessitate the generally understood rule that equipotential lines shall enter such a surface at points separated so as to mark off sections including equal amounts of current. From the point of view that such equipotential lines when continued into the copper to form lines of no work shall enclose equal amounts of copper, this conclusion might appear to be open to question. A further rather obvious point that, however, is sometimes neglected, is that equipotential lines and lines of force must, in general, enter such linear distributions of current at a slant.

Theorem II. There will be a change in the normal gradient of tangential field intensity at a boundary of current-carrying copper.

At a copper-air boundary the relation, curl $H = 4\,\pi\, i$, may be written in the form,

$$\frac{\partial\, H_t}{\partial\, n} - \frac{\partial\, H_n}{\partial\, t} = 4\,\pi\, i \tag{3}$$

where the vectors n, t, i form a right-handed system of unit vectors, as in Fig. 10, and t and n are respectively

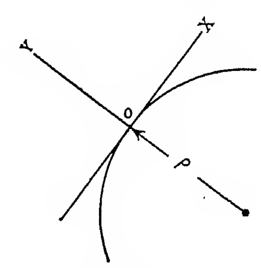

Fig. 11

tangent and normal to the copper-air boundary. Since H_n is continuous across the boundary, it follows that $\partial\, H_n/\partial\, s$ is continuous across the boundary, where the term s refers to distance measured along the boundary. But, at any point on the curve, neglecting infinitesimals of higher order, the arc and the tangent coincide. Therefore, $\partial\, H_n/\partial\, s = \partial\, H_n/\partial\, t$ and $\partial\, H_n/\partial\, t$ is also continuous across the boundary, from which it follows that

$$\Delta\left(\frac{\partial\, H_t}{\partial\, n}\right) = 4\,\pi\,\Delta\,(i) \tag{4}$$

The discontinuity in $\partial\, H_t/\partial\, n$ across the boundary at any point, therefore, is equal to $4\,\pi$ times the discontinuity in current density at that point. Q. E. D.

Theorem III. At any point in the field, the quotient of the magnetic density divided by the radius of curvature of the lines of force, minus the rate of change of the magnetic density along a line normal to the lines of force, equals $4\,\pi$ times the current density in the region under consideration.

Equations (3) and (4) may be used to check the accuracy of a field plot sketch, but a somewhat more convenient relation, and one which involves the curvature of the field directly, is available.

Let the curve in Fig. 11 be a line of force within a field carrying current. It is desired to investigate its curvature at the point 0. Shift the axes of coordinates so that the origin coincides with the point in question, and rotate them until the x axis is tangent to the curve as shown.

Using these axes, the curve can be expressed by an equation,

$$y = f\,(x)$$

The relation between the curl of the field and the current density is

$$\frac{\partial Y}{\partial x} - \frac{\partial X}{\partial y} = 4\,\pi\,i \qquad (5)$$

And since X and Y are the components of the field intensity, the slope of the line of force can be expressed:

$$\frac{d\,y}{d\,x} = f'\,(x) = \frac{Y}{X} \qquad (6)$$

or

$$Y = X\,\frac{d\,y}{d\,x}$$

Differentiate this[13] with respect to x;

$$\frac{\partial Y}{\partial x} = \frac{d\,Y}{d\,x} = \frac{d\,X}{d\,x}\,\frac{d\,y}{d\,x} + X\,\frac{d^2\,y}{d\,x^2}$$

But, since the x axis is tangent to the field at the point in question,

$$X = H \text{ and } \frac{d\,y}{d\,x} = 0$$

Therefore,

$$\frac{\partial Y}{\partial x} = H\,\frac{d^2\,y}{d\,x^2}$$

Substituting in Equation (5),

$$H\,\frac{d^2\,y}{d\,x^2} - \frac{\partial H}{\partial y} = 4\,\pi\,i \qquad (7)$$

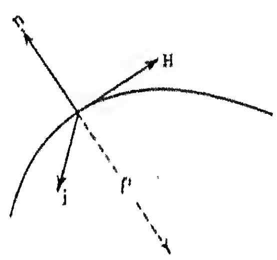

Fig. 12

but the radius of curvature of any curve $y = f\,(x)$ is

$$\rho = \frac{[1 + (d\,y/d\,x)^2]^{3/2}}{d^2\,y/d\,x^2}$$

and, since $d\,y/d\,x = 0$, at the point in question,

$$\frac{d^2\,y}{d\,x^2} = \frac{1}{\rho}$$

Making this substitution, Equation (7) becomes

$$\frac{H}{\rho} - \frac{\partial H}{\partial y} = 4\,\pi\,i$$

Or, since y is the coordinate normal to the curve, a more general form would be

$$\frac{H}{\rho} - \frac{\partial H}{\partial n} = 4\,\pi\,i \qquad (8)$$

where the quantities H, n, i form a right-handed system of vectors, as in Fig. 12, and the radius of curvature ρ is to be measured to the position of the center of curvature on the vector n[14]. It should be noted that, in Equation (8), n is a unit vector normal to the field rather than a unit vector normal to the copper-air intersurface, as in Equations (3) and (4).

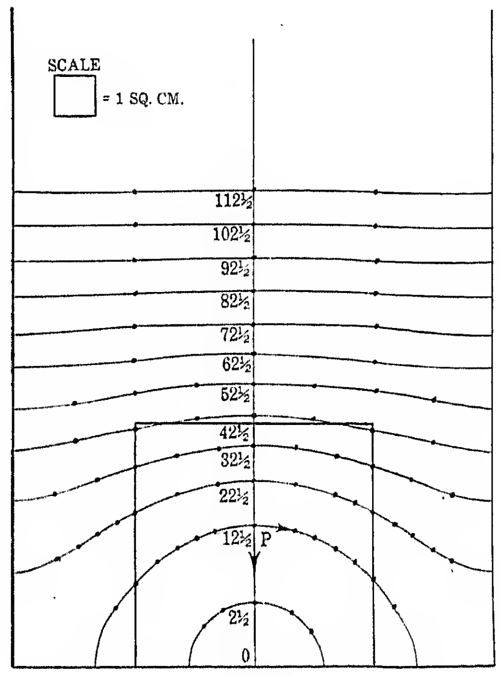

Fig. 13

Equation (8) provides a method of checking up with tolerable accuracy the shape of lines of force which have been sketched in free-hand.

Numerical Application of Theorem III. In order to test its probable accuracy, this method was used to check a field plot at a point inside a square conductor in the bottom of an infinitely deep slot (see Fig. 13). The lines of force had already been plotted from an exact formula for this case. Since the current is flowing downward perpendicular to the paper, the positive directions of H and of the normal are as indicated by the arrow heads.

Assume that the cross-section lines of the figure are spaced a centimeter apart. The tube (22½–12½) has a width of 1.11 cm. and contains 10 lines of force. Therefore, the flux density is 9.0 lines per sq. cm. The tube (12½–2½) has a width of 1.86 cm., and contains 10 lines. Therefore, its flux density is 5.38. The flux density at the point P is assumed to be the average of these two.

Therefore, $H = 7.19$ lines per sq. cm.

The distance between the center lines of tube

13. At the origin, the slope of the line $y = f\,(x)$ is zero and the partial derivative of Y with respect to x becomes equal to the total derivative with respect to x at that point.

14. The value of ρ shown in Fig. 12 is negative because it is measured in the negative direction.

(22½–12½) and tube (12½–2½) is 1.5 cm. Since the difference in density is – 3.62, the rate of change of density with respect to distance measured along the normal is

$$\frac{\partial H}{\partial n} = \frac{-3.62}{1.5} = -2.41$$

The radius of curvature of the 12½ line at the point P determined with a pair of dividers is

$$\rho = +3.95$$

Substituting these in the left portion of Equation (8),

$$\frac{H}{\rho} - \frac{\partial H}{\partial n} = \frac{7.19}{3.95} + 2.41 = 4.23$$

The plot was made with an assumed current density in the coil of $1/\pi$ abamperes per sq. cm.[15]. Therefore,

$$i = \frac{1}{\pi}$$

and

$$4\pi i = 4$$

Substituting these values in Equation (8),

$$4.23 = 4.00$$

This inequality would indicate an error of about 5.75 per cent.

Special Case Where the Field Crosses a Copper-Air Boundary Perpendicularly. In the case that the field crosses a copper-air boundary perpendicularly, as in

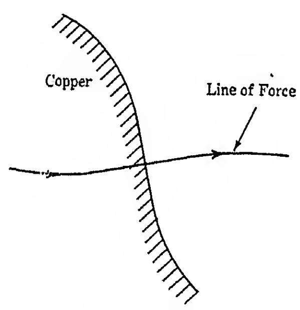

Fig. 14

Fig. 14, the term $\partial H/\partial n$ is identical with the quantity $\partial H/\partial s$, where s refers to distance measured along the copper-air boundary, and $\partial H/\partial n$ is, therefore, continuous across the boundary. The discontinuity in H/ρ across the boundary, therefore, is equal to 4π times the discontinuity in current density across the boundary; that is,

$$\Delta\left(\frac{H}{\rho}\right) = 4\pi\,\Delta i$$

Or, since H is not discontinuous,

$$\Delta\left(\frac{1}{\rho}\right) = \frac{4\pi}{H}\,\Delta i$$

Hence, it follows that near the nucleus, where H is small, a discontinuity in current density at a given point may easily produce a large discontinuity in the curvature of the field at that point.

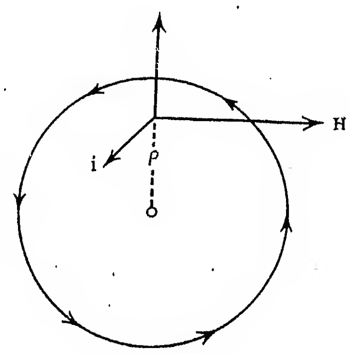

Fig. 15

Special Case Where the Field is Tangent to the Copper-Air Intersurface. If the field is tangent to the copper-air intersurface, this surface coincides with the x axis in Fig. 11. It should be noted that

$$\frac{H}{\rho} = \frac{\partial Y}{\partial x}$$

It is equal, therefore, to the rate of change of the normal component along the surface of the copper which is continuous across the boundary.

Therefore, in this case, any discontinuity in Equation (8) must be written

$$\Delta\,(\partial H/\partial n) = -4\pi\,\Delta i$$

Thus, in the case of an isolated circular wire carrying a longitudinal current, the field inside the wire is given by

$$H = -2\pi i r$$

and differentiating:

$$\frac{\partial H}{\partial n} = \frac{\partial H}{\partial r} = -2\pi i$$

If r_0 is the radius of the wire, the field outside the copper is given by

$$H = \frac{-2(\pi r_0^2)\,i}{r}$$

and differentiating,

15. This value of current density can be checked as follows: The area of the conductor is 36 sq. cm. Therefore, the total current is

$$I = \frac{36}{\pi}$$

$$m.\,m.\,f. = 4\pi I = 144$$

The width of the slot is

$$l = 12 \text{ cm.}$$

$$H = \frac{\text{m. m. f.}}{l} = \frac{144}{12} = 12 \text{ lines per sq. cm.}$$

Therefore, in the region where the lines of force are straight parallel lines, the width of the tubes containing 10 lines should be $10/12 = 0.835$ cm.

$$\frac{\partial H}{\partial n} = \frac{\partial H}{\partial r} = \frac{+ 2 \pi r_0^2 i}{r^2}$$

Therefore, at $r = r_0$,

$$\frac{\partial H}{\partial n} = - 2 \pi i \text{ inside the copper}$$

$$= + 2 \pi i \text{ outside the copper}$$

$$\Delta \frac{\partial H}{\partial n} = 4 \pi i = - 4 \pi \Delta (i)$$

as would be expected since the field at the boundary is tangent to the copper.

In the case of an infinitely deep slot partly filled with

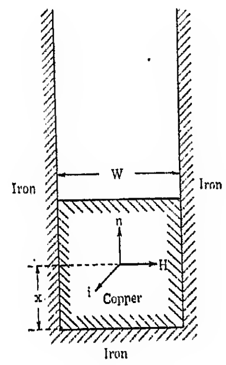

FIG. 16

copper (see Fig. 16), the curvature is zero, and we have

$$H = - 4 \pi i x$$

and differentiating,

$$- \frac{\partial H}{\partial n} = - \frac{d H}{d x} = 4 \pi i$$

while outside the copper the field is constant, so that $\partial H / \partial n$ vanishes. Hence, at this type of copper-air intersurface also,

$$\Delta \frac{\partial H}{\partial n} = - 4 \pi \Delta (i)$$

as would be expected.

III. Application of the Method to Polar Coordinate Systems

One of the authors' associates, Mr. T. R. Rhea, has plotted the flux in and about a round bar[16] in a round slot, as shown in Fig. 17.

The tangential component of field intensity H_θ will be zero around the iron surface $\mu = \infty$ except at the air-gap. Here the value of H_θ will rise abruptly and follow some sort of curve to the other side of the air-gap. If H_θ, obtained from a free-hand sketch, is plotted against θ around the circumference (at $r = r_0$), a curve something of the shape shown in Fig. 18A would be obtained.

The sharp peaks on the curve are caused by the corners where the slot cuts into the circumference. To obtain a boundary condition that would exactly represent the boundary conditions of our problem, the Fourier's series for the above curve should be obtained, after this curve had been determined from an accurate and quantitative field sketch at the air-gap.

It is assumed, however, that these peaks may be neglected and the average value of H_θ across the air-gap used. This will greatly simplify the Fourier's series representing the boundary conditions, and will not greatly affect the calculations farther down in the regions which are to be investigated.

With this assumption, the boundary condition curve for H_θ will be of the form shown in Fig. 18B.

θ_1 is the angular opening of the slot.

The total m. m. f. across the slot is $4 \pi I$, where I is the total current in abamperes. As the medium

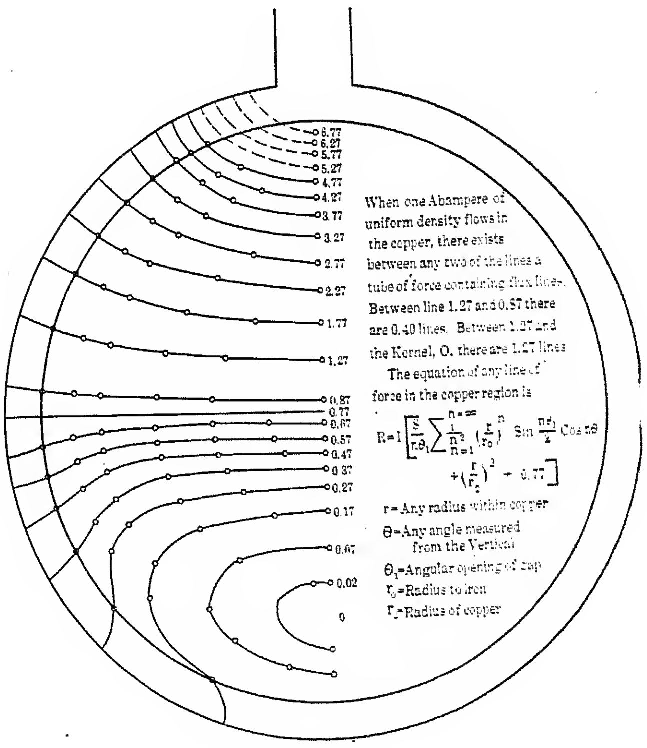

FIG. 17

in the slot is air, the field intensity, assumed uniform across the gap, will be

$$H_{\theta_1} = \frac{4 \pi I}{r_0 \theta_1}$$

The Fourier's series expressing such a curve will be of the form,

$$H_\theta = C_0 + \sum_{n=1}^{n=\infty} C_n \cos n \theta \qquad (9)$$

16. With alternating current flowing in the bar, the current distribution would not be uniform, but the problem of skin effect is outside the scope of this present paper and, for purposes of illustration, it is here assumed that the current density is uniform.

The constant C_0 is the average value of the curve, and has the value

$$C_0 = \frac{\dfrac{4\,\pi\,I}{r_0\,\theta_1} \times \theta_1}{2\,\pi} = \frac{2\,I}{r_0} \tag{10}$$

The value of the general constant C_n may be found from the expression:

$$C_n = \frac{1}{\pi}\int_{-\pi}^{+\pi} H_\theta \cos n\,\theta\, d\,\theta$$

$$= \frac{1}{\pi}\int_{-\theta_1/2}^{+\theta_1/2} \frac{4\,\pi\,I}{r_0\,\theta_1} \cos n\,\theta\, d\,\theta$$

$$= \frac{8\,I}{r_0\,n\,\theta_1} \sin n\,\frac{\theta_1}{2} \tag{11}$$

Having obtained a Fourier's series for the boundary

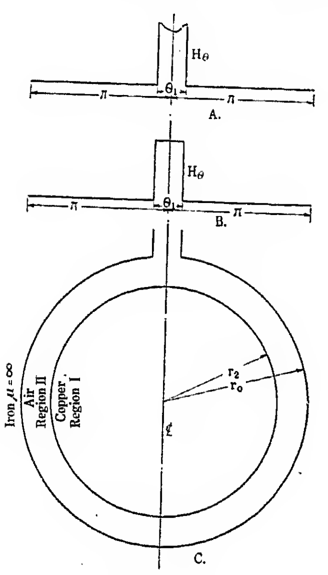

FIG. 18

condition, it is now necessary to set up expressions for the vector potential that will satisfy all the conditions.

The four conditions are:

Condition I: Poisson's equation for the vector potential R in Region I, expressed in polar coordinates[17], is

$$\frac{1}{r}\,\frac{\partial R}{\partial r} + \frac{\partial^2 R}{\partial r^2} + \frac{1}{r^2}\,\frac{\partial^2 R}{\partial \theta^2} = +\,4\,\pi\,i \tag{12}$$

where i is the current density (assumed uniform).

Condition II: At the boundary between Regions I and II, both H_θ and H_r are continuous functions because there is no change in permeability.

Condition III: Laplace's equation for the vector potential in Region II, expressed in polar coordinates, is

$$\frac{1}{r}\,\frac{\partial R}{\partial r} + \frac{\partial^2 R}{\partial r^2} + \frac{1}{r^2}\,\frac{\partial^2 R}{\partial \theta^2} = 0 \tag{13}$$

17. See foot-note 25.

Condition IV: The outer boundary condition at $r = r_0$ has already been given in Equation (9).

A solution which will satisfy these four conditions is provided by the form:

$$R = R_1 + R_2$$

where R_1 is the vector potential of an isolated wire in space and R_2 is a function satisfying Equation (13) and so adjusted that Equation (9) is satisfied. That this solution satisfies the conditions imposed in both regions may easily be verified.

Choosing $R_1 = 0$, at $r = 0$, the function R_1 is, in Regions I and II, respectively,

$$R_1{}^{\mathrm{I}} = +\,I\left(\frac{r}{r_2}\right)^2 \tag{14}$$

$$R_1{}^{\mathrm{II}} = +\,2\,I\left[\log_\epsilon\left(\frac{r}{r_2}\right) + \frac{1}{2}\right] \tag{15}$$

A sufficient form for the function R_2 in both Regions I and II will be found to be:

$$R_2 = b_0 + \sum_{n=1}^{n=\infty}\left(\frac{r}{r_0}\right)^n (b_n \cos n\,\theta + a_n \sin n\,\theta) \tag{16}$$

In Region I, the total vector potential is

$$R^{\mathrm{I}} = R_2 + R_1{}^{\mathrm{I}}$$

where the expression for R_2 and $R_1{}^{\mathrm{I}}$ would be taken from Equations (14) and (16).

In Region II, the total vector potential is

$$R^{\mathrm{II}} = R_2 + R_1{}^{\mathrm{II}}$$

From Equations (15) and (16),

$$R^{\mathrm{II}} = b_0 + \sum_{n=1}^{n=\infty}\left(\frac{r}{r_0}\right)^n (b_n \cos n\,\theta + a_n \sin n\,\theta) + 2\,I\left[\log_\epsilon\left(\frac{r}{r_2}\right) + \frac{1}{2}\right]$$

Maxwell has shown that

$$H_\theta = +\,\frac{\partial R}{\partial r} \tag{17}$$

$$H_r = -\,\frac{1}{r}\,\frac{\partial R}{\partial \theta} \tag{18}$$

Taking the partial derivative of (R^{II}) with respect to (r), we therefore obtain

$$H_\theta = +\,\frac{\partial R^{\mathrm{II}}}{\partial r}$$

$$= +\,\frac{1}{r_0}\left[\sum_{n=1}^{n=\infty} n\left(\frac{r}{r_0}\right)^{n-1} (b_n \cos n\,\theta + a_n \sin n\,\theta)\right] + \frac{2\,I}{r}. \tag{19}$$

This must satisfy the terminal conditions imposed by Equation (9), when $r = r_0$. Hence, Equation

(19) must equal Equation (9) when $r = r_0$. Therefore,

$$+\frac{1}{r_0}\sum_{n=1}^{n=\infty}(b_n \cos n\,\theta + a_n \sin n\,\theta) + \frac{2\,I}{r_0} = C_0 + \sum_{n=1}^{n=\infty} C_n \cos n\,\theta$$

A comparison of these series, term by term, gives

$$a_n = 0$$

$$b_n = +\frac{r_0\,C_n}{n}$$

And from Equation (10), we already know that

$$C_0 = \frac{2\,I}{r_0}$$

All the constants except b_0 are now known, and the equations for vector potential in Regions I and II are

$$R^{\mathrm{I}} = b_0 + \sum_{n=1}^{n=\infty}\frac{8\,I}{n^2\,r_0\,\theta_1}\left(\frac{r}{r_0}\right)^n\left[\sin\frac{n\,\theta_1}{2}\right]\cos n\,\theta + I\left(\frac{r}{r_2}\right)^2 \qquad (20)$$

$$R^{\mathrm{II}} = b_0 + \sum_{n=1}^{n=\infty}\frac{8\,I}{n^2\,r_0\,\theta_1}\left(\frac{r}{r_0}\right)^n\left[\sin\frac{n\,\theta_1}{2}\right]\cos n\,\theta + 2\,I\left[\log_\epsilon\left(\frac{r}{r_2}\right)+\frac{1}{2}\right] \qquad (21)$$

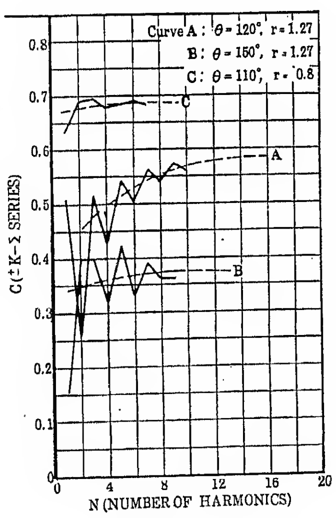

FIG. 19

where

$r_0 = 1.43$ cm.

$I = 1$ abampere $=$ total current in conductor

$\theta_1 = 0.222$ radians

$r_2 = 1.27$ cm.

It is not necessary to know b_0 in order to plot the field. Make the calculation on the assumption that $b_0 = 0$. This will make $R_1 = 0$ when $r = 0$. Later, b_0 will be given the proper value to cause R_1 to be zero at the kernel.

It is well known that curves of constant R are lines of force and that unit difference of R is one maxwell.[18] The field can be plotted, therefore, from the expressions for R^{I} and R^{II} in Equations (20) and (21).

The arithmetical evaluation of R is interesting, and a part of this work is therefore included. A number of terms of the series are calculated for particular

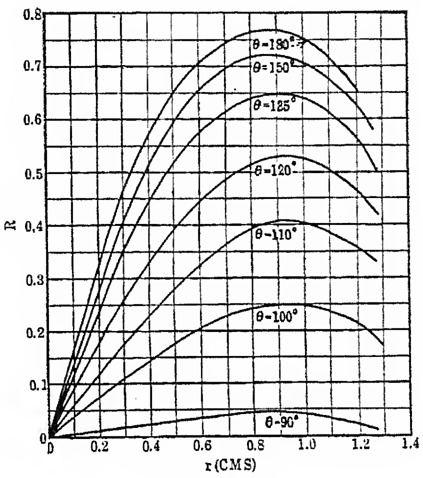

FIG. 20

values of θ and r. Unfortunately, for the larger values of r, the series does not converge rapidly. Plotting the sum of the series against the number of terms n was found to be a convenient method of determining the value to which the series converged. Several of these plots are given in Fig. 19. It is most important that the convergence value of the series be determined accurately, because it is subtracted from the value $(r/r_2)^2$, which, when r approaches r_2, is of the same order of magnitude. Thus it is a case where small differences between the relatively large numbers have to be determined accurately.

After having found the value of R for a sufficient number of points, r and θ, a set of curves was drawn of R against r, with θ as a parameter. Also, a set of curves was drawn of R against θ, with r as a parameter. A sample of these curves is included, Fig. 20.

With the help of these curves and parameters of r and θ, curves for constant values of R could easily be plotted as lines of force in the magnetic field.

Neglect of the constant b_0 made the flux at the center of the figure zero and the flux at the kernel $+ 0.77$. As it was desired to have the flux at the kernel zero, the sign of Equations (20) and (21) was changed and a value of $+ 0.77$ assigned to the constant b_0, in order to make the entire flux plot positive.

The field plot in Fig. 17 is believed to be very accurate within the copper, but due to the slow convergence of the series it is not so accurate outside the copper in Region II.

18. See bibliography, 11, or Appendix C.

Appendix A

Brief Rules for Plotting Flux in Air

Although various authors have given rules for plotting flux in air, it seems well in the interest of completeness to briefly sum up the more important principles.

The method used by Messrs. Doherty and Shirley can best be described by reference to a particular problem, illustrated in Fig. 21, which represents a couple of alternator field poles.

In attacking a problem of this sort, Mr. Doherty and Mr. Shirley made the following assumptions:

1. That the magnetomotive force is due to an infinitely thin coil distributed along the pole[19]. The armature reaction is neglected while plotting the flux due to the field m. m. f.; and later, after another sketch is made of the field due to the m. m. f. of armature reaction, the two are superposed.

2. The magnetic potential of one pole due to the m. m. f. of its own winding was $+F$. The magnetic potential of the other pole due to its own m. m. f. was $-F$.

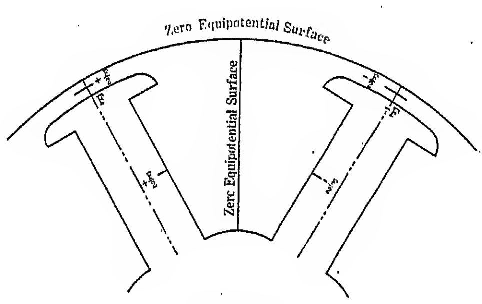

Fig. 21

3. Assuming infinite permeability, the armature and field pole faces are equipotential surfaces.

4. By symmetry, a zero equipotential surface is drawn midway between the two poles.

5. The armature surface is also assumed to be a zero equipotential surface.

6. At the surface of the left-hand pole, the potential is $+F$. As the air-gap is crossed, this drops to 0 at the surface of the armature. In crossing back across the gap from the armature surface to the right-hand pole, the magnetic potential drops to $-F$. Therefore, the total drop from one pole face to the other is $2F$.

7. In any place where the flux lines are known to be straight and parallel, as is approximately true in the air-gap, the potential drop is a linear function of distance. Thus, a line half-way across the gap represents one-half potential.

8. The equipotential planes $+F/2$ and $-F/2$ will curve from the center of the air-gap to the mid-points of their respective poles. The beginning and ends of the one-quarter potential planes can be similarly located. In sketching the traces of these planes through points known to be at the same potential, there must be no discontinuity in the gradual change in shape of adjacent potential lines—*i. e.*, when near the pole they follow its configuration, but those near the zero equipotential line must approach its rectangular shape.

9. After the equipotential lines have been sketched, the lines of force are drawn perpendicular to them. The whole surface is thus divided into chequers. If enough lines are drawn, these chequers become very small rectangles. The sketch is not correct until all the angles are right angles.

10. In space through which no current is flowing, all these rectangles must be similar—*i. e.*, the spacings of lines of force at two different places in the field must be proportional to the spacing of equipotential lines at the same respective points. It is recommended as a matter of convenience that the flux density be represented by such a number of lines as will make these rectangles curvilinear squares.

The above method of plotting magnetic fields is a cut-and-try method. The first few sketches will obviously be wrong, but there are sufficient conditions so that the final picture obtained after several readjustments will be approximately correct.

The actual flux density can be calculated at any point from the picture as follows:

a. The total m. m. f. per pole,

$$F = 4\,\pi\, n\, I \tag{22}$$

where n is the number of turns per pole and I is the field current in abamperes.

b. If there are m equipotential planes drawn between the pole and the zero equipotential surface, the potential gradient between any two of these surfaces is

$$\frac{d\,P}{d\,s} = \frac{4\,\pi\,n\,I}{m\,\delta} \tag{23}$$

where δ is the perpendicular distance measured in centimeters between adjacent equipotential surfaces at the point in question; *i. e.*, $m\,\delta$ = air-gap.

c. Since the permeability of air is unity, the density in lines of force per sq. cm. at every point is exactly equal to the potential gradient.

$$B = \frac{d\,P}{d\,s} = \frac{4\,\pi\,n\,I}{m\,\delta} \tag{24}$$

d. But, if the figure has been drawn so that the small chequers are square, the lines of force will have the same spacing, δ, as the equipotential surfaces. Therefore, the flux included in the tube between consecutive lines of force is

$$\Delta\,\phi = B\,\delta = \frac{4\,\pi\,n\,I}{m} \tag{25}$$

e. At the risk of criticism for repetition, attention

19. This approximation is more accurate than neglecting the distribution of the coil entirely, as has been done by some others, and apparently does not very much affect the accuracy of flux distribution in the air-gap.

is called to the fact that if δ is the spacing of lines of force, the area of a tube δ wide and 1 cm. thick is δ, and the density at any point is

$$B = \frac{\Delta \phi}{\delta} = \frac{4 \pi n I}{m \delta} \qquad (26)$$

Equation (26) is identical, of course, with Equation (24), and merely represents another viewpoint.

In order to check the accuracy of the free-hand method, 23 different men determined the effective air-gap of a motor by making free-hand sketches of the flux. By Carter's equation, the correct value of the effective gap was 0.575. The results of the free-hand sketches were as follows:

Results Between	Number
0.570 0.605	8
0.605 0.640	6
0.640 0.675	4
Rejected for gross inaccuracy	5
Total	23

The above table indicates that the more accurate sketches gave a minimum reluctance. This agrees

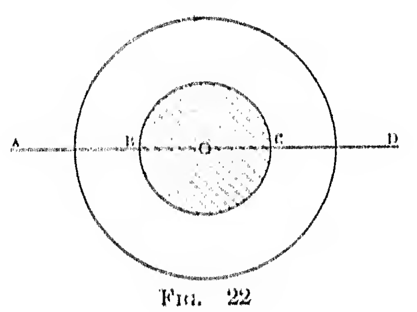

FIG. 22

with Arnold's[20] statement: "The most nearly correct distribution of the flux will be shown by the sketch which makes the permeance of the flux tubes a maximum."

It is probably obvious that the flux will arrange itself in such a manner as to follow the path of least resistance; but it is interesting to note that a comparison of the reluctances determined from several independent flux plots with the mathematically correct permeance confirms this theory so well.

Appendix B

METHOD OF PLOTTING TWO-DIMENSIONAL MAGNETIC FIELDS IN SPACE OCCUPIED BY CURRENT-CARRYING CONDUCTORS

Consider a section of an infinitely long cylindrical conductor, shown in Fig. 22. The work done in making a complete circuit about such a conductor with a unit pole is

$$W = 4 \pi I \qquad (28)$$

20. See bibliography, 12.

The difference of potential between two points is usually defined as the work done against the field in transporting a unit pole from one point to the other by any path whatever.

Let the potential at A be zero. Then the potential at D is

$$P_D = 2 \pi I \qquad (29)$$

But the potential continues to increase as the circle is completed. On returning to A after a complete circuit, the potential is no longer zero, but

$$P_A = 4 \pi I \qquad (30)$$

Every time the unit pole is taken around the conductor, the potential increases by this amount.

It might be asked, "How does the law of conservation of energy apply?" The answer is that in taking the unit pole around the conductor, a voltage has been induced. The product of this induced voltage multiplied by the current in the conductor represents electrical power which, integrated for the elapsed time, gives electrical energy. Thus the mechanical work done in carrying the unit pole about the conductor is converted into electrical energy.

Again referring to Fig. 22, it should be noticed that no work would be done in going from A to D by the path $A\,B\,O\,C\,D$, because this path at all points is perpendicular to the lines of force. Such lines, therefore, can be called lines of no work.

The following are the most important rules to be followed in plotting flux in regions containing current-carrying conductors:

1. The equipotential lines in the air space, when projected as lines of no work into the copper, must divide the copper into equal areas. It is thus seen that each particular part of the ampere conductors may be regarded as responsible for a particular part of the field.

2. The work done in carrying a unit pole along any line of force from one point to another is proportional to the current flowing in the area enclosed by the line of force and the lines of no work passing through the two points.

3. The spacing of lines of force must be inversely proportional to the copper enclosed and proportional to the length of the part of the tube enclosing the copper.[21]

21. As stated in the Introduction, Mr. L. F. Richardson has given a rule for the plotting of fields in current-carrying copper to the effect that in a region occupied by current "the difference of successive chequer ratios in a direction perpendicular to the lines of force, divided by the mean chequer area is equal to a constant times the current density in the region." A proof of this relation is briefly outlined below.

Let n and t represent distance measured along lines of no work and along lines of force, respectively. Let small quantities of the order x be represented by the symbol $o\,(x)$. Then, referring to the adjoining figure (Fig. 23A), if n and t are small enough increments so that the field intensity and current density change

In Fig. 23:

$$H\,l = 4\,\pi\,C$$

If (k) is the number of lines in a tube, the width is

$$a = \frac{k}{H} = \frac{k\,l}{4\,\pi\,C}$$

The spacing between lines of force must be proportional, therefore, to the ratio l/C, where l is the length of the tube under consideration between the lines of no work and C is the total current included by this length of tube and the boundary lines of no work.

4. The line of half potential outside the copper, when extended as a line of no work into the copper, does not necessarily intersect every line of force at a point which would divide into two equal halves the work done in carrying a unit pole around the line. A similar statement can be made, of course, for the other potential lines.

---

only slightly for points included in their variation, the relations exist:

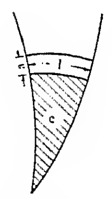

Fig. 23

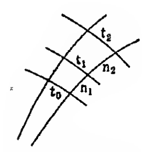

Fig. 23-A

$$H = o\,(0)$$
$$n,\,t = o\,(1)$$
$$H_1\,t_1 - H_0\,t_0 = 4\,\pi\,i\,n_1\,t_1 + o\,(3) \qquad \textbf{(30a)}$$
$$H_2\,t_2 - H_1\,t_1 = 4\,\pi\,i\,n_2\,t_2 + o\,(3) \qquad \textbf{(30b)}$$

where

H_n = field intensity along t_n,

i = current density at any point near n_1, n_2, t_1, t_2.

If n_1 and n_2 are chosen so that the flux between t_2 and t_1 is the same as the flux between t_1 and t_0, then

$$(H_1 + H_0)\,n_1 = (H_2 + H_1)\,n_2 + o\,(3) = 2\phi + o\,(3)$$

where

ϕ = the flux between t_1 and t_0, and between t_2 and t_1.
$= o\,(1)$.

Also,
$$n_2 - n_1 = o\,(2)$$
$$n_2\,t_2 = n_1\,t_1 + o\,(3) = n\,t + o\,(3)$$

Adding (**30a**) and (**30b**), there results:

$$(H_2 + H_1)\,t_2 - H_1\,(t_2 - t_1) - (H_1 + H_0)\,t_1 + H_0\,(t_1 - t_0)$$
$$= 8\,\pi\,i\,n\,t + o\,(3) \qquad \textbf{(30c)}$$

But $H_0\,(t_1 - t_0) - H_1\,(t_2 - t_1) = (H_0 - H_1)\,(t_1 - t_0)$
$- H_1\,(t_2 + t_0 - 2t_1) = o\,(3)$

Therefore, **30c** becomes

$$(H_2 + H_1)\,t_2 - (H_1 + H_0)\,t_1 = 8\,\pi\,i\,n\,t + o\,(3)$$

Substituting (4) in the above, there results

$$\phi\left(\frac{t_2}{n_2} - \frac{t_1}{n_1}\right) = 4\,\pi\,i\,n\,t + o\,(3)$$

$$\frac{t_2}{n_2} - \frac{t_1}{n_1} = \frac{4\,\pi\,i\,n\,t}{\phi} + o\,(2)$$

Thus, omitting second order terms, we obtain a relation involving quantities of the first order on either side:

$$\frac{\dfrac{t_2}{n_2} - \dfrac{t_1}{n_1}}{n\,t} = \frac{4\,\pi}{\phi}\,i$$

which is the rule stated by Richardson.

Brief Rules for Construction of Field Flux Plots Inside the Copper

(BY L. P. SHILDNECK)

The following directions have proved very helpful in making flux plots of the fields of salient-pole machines.

Consider the case of a copper and iron distribution as given by a field pole (Fig. 24), with lines of no work $o\,a$, $o\,b$, $o\,c$, $o\,d$, $o\,e$, etc., drawn so as to divide the current into equal areas. Then the work done in transporting a unit pole from a to b is equal to the work done in transporting a unit pole around the path $a\,b\,o\,a$.

$$\text{Work }(a\,b) = \text{work }(a\,b\,o\,a)$$
$$= \text{work }(b\,c) = \text{work }(b\,c\,o\,b)$$
$$= \text{work }(c\,d) = \text{work }(c\,d\,o\,c),\text{ etc.}$$
$$\text{for work} = (\,a\,o)\text{ work }(b\,o) = \text{work }(c\,o) = 0.$$

That is, the work done in going from one equipotential line such as a to another such as b, is equal to the m. m. f. between these two lines, or $4\,\pi$ times the current enclosed by the lines $a\,b$, $b\,o$, and $o\,a$. Consequently, work $a\,b$ equals work $a'\,b'$; but work $c\,d$ is greater than work $c'\,d'$, for more current is enclosed by $c\,d$. It is well to remember that the m. m. f. between any two points in the copper, such as c' and d', is proportional to the amount of current enclosed by the line of flux $c'\,d'$ and the lines of no work $c'\,o$ and $d'\,o$. Therefore, if a tube of flux is desired along $a'\,b'\,c'\,d'$, so that it may enclose the same flux at all points of the tube, the

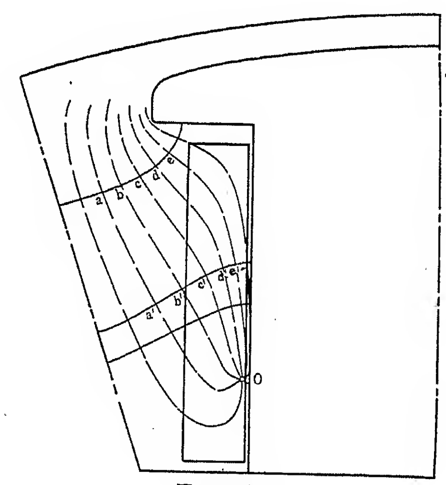

Fig. 24

reluctance must vary in direct proportion to the m. m. f. And since the m. m. f. varies in direct proportion to the amount of current enclosed, the ratio l/a[22] for the curvilinear rectangles must vary in direct proportion to the amount of current enclosed. This relation makes it possible to extend the plot into the copper.

---

22. The reluctance is proportional to the length l of the path and inversely proportional to the area a of the path. Since unit thickness is chosen for the plot, the width of a tube represents its area.

The subsequent rules will aid materially in shortening the time necessary to obtain an accurate field plot. The reasons for following the directions in the order given will be obvious.

1. Draw bisectors of the angles at the points a, b, c, d, e, f, as shown in Fig. 25. These are the directions of the lines of flux at these points. Continue them wherever it is possible to do so with any degree of accuracy, as at a, b, c, d, entering the opposite side at right angles.

2. Divide the current into eight equal regions, as shown in Fig. 25. The reason for the peculiar division is that later the lines of no work will roughly coincide with the construction lines, thereby providing an easy method of sketching the lines of no work so that they will divide the current into equal parts. If it is found later that some of the construction lines are not placed to best advantage, of course others may be drawn.

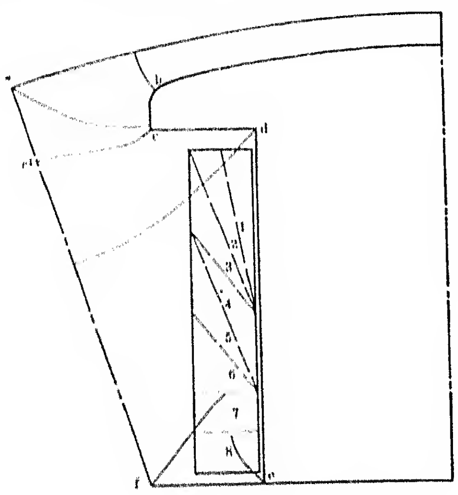

FIG. 25

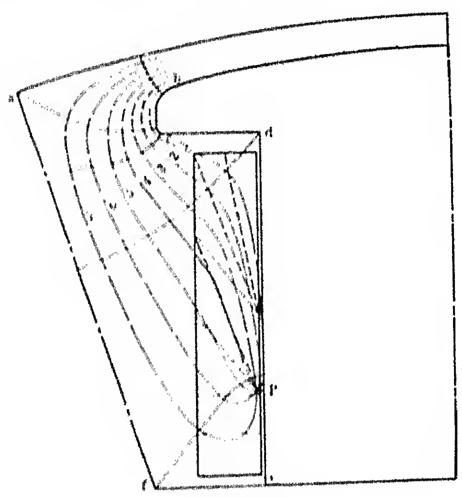

FIG. 26

3. Draw a trial set of seven lines of no work (see Fig. 26), crossing the lines of flux a, b, c, d at right angles, hugging the sharp projections closely, as at b and c, and keeping away from the inverted corners as at a and d. This trial set must divide the current region into eight equal portions. Arbitrarily choose some point P down in the corner closest to the iron, for the kernel. If no iron were present, it would lie in the center of the copper; if iron were touching the copper along one surface, the kernel would be at the copper-iron boundary; if iron were touching the copper along two surfaces, the kernel would be on both copper-iron boundaries, at the corner. Obviously, the kernel, in all practical cases, would lie somewhere between the center of the copper and the lower corner near the iron. Line No. 4 must divide the current into two equal regions. The advantage of the straight construction line between Regions 4 and 5, dividing the current into two equal portions, is evident. The other construction lines are also located so as to be most useful in enabling an accurate division of the current to be made by judging only small differences in area with the eye.

4. Starting from some line of flux $c\,c'$ (Fig. 27), draw lines of flux, making curvilinear squares along the line $a\,c'\,f$ in the region where there is no current.

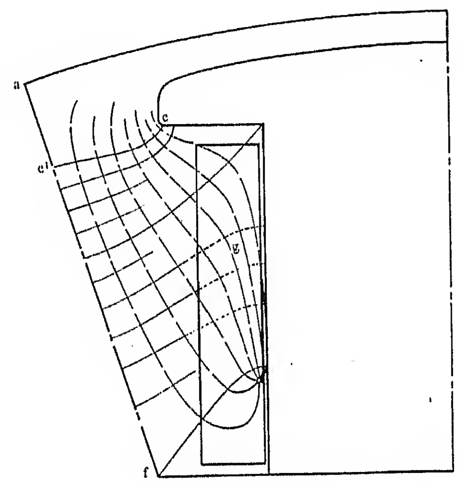

FIG. 27

Then extend the lines of force into the current region orthogonal to the lines of no work.

5. The correctness of the plot may now be tested as follows:

a. Lines of flux must cross lines of no work at right angles.

b. Lines of flux must enter the iron at right angles (assuming infinite permeability).

c. All rectangles outside the current must be curvilinear squares (ratio l/a = unity).

d. Within the current region, the rectangles must have a ratio l/a less than unity and equal to the ratio between the current enclosed and the one-eighth portion of the total current. Thus at a point g (Fig. 27), if the flux line, and the two lines of no work intersected by it, enclose one-half of the eighth portion of current, then the length of the rectangle at this point should be one-half of the width.

6. If the ratios l/a are *not* proportional to the current enclosed, then the plot must be redrawn, either

changing the position of the kernel or else shifting the position of the lines of no work, and making the corresponding necessary changes in the lines of flux.

It is well to use tracing paper, for then each previous trial may be used for a guide.

Fig. 28 is the final plot. Any required accuracy may be obtained by continuing the process indefinitely. By this method, however, a large portion of the cut-and-try is eliminated because as many of the required conditions as possible are fulfilled in the first part of the construction, and after three or four trials a surprisingly accurate sketch can be obtained.

Appendix C

Vector Potential in Coplanar Magnetic Fields

Neither the problems nor the general methods in this appendix are new but it is believed that the application of the little used conception of vector potential to a group of familiar problems will be of interest.

In problems where the flux distribution can be represented by a two-dimensional sketch,[23] the vector

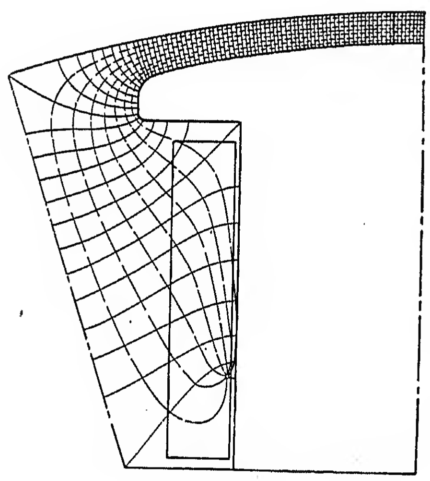

Fig. 28

potentials are all perpendicular to the plane of the paper and consequently can be added and subtracted exactly like scalar quantities. This makes the construction of field plots by lines of equi-vector potential very much easier than by the more usual method which employs the two components of the vector field intensity.

Let X and Y be the x and y components of the field. Then, integration around any small area in the $x\,y$ plane will show that[24]

$$\frac{\partial Y}{\partial x} - \frac{\partial X}{\partial y} = 4\pi i \qquad (27)$$

where i is positive when directed upward out of the plane of the paper.

23. Such fields are said to be coplanar in the plane of the paper.

24. See bibliography, 11.

Let R be a function[25] such that

$$X = -\frac{\partial R}{\partial y} \qquad (28)$$

$$Y = +\frac{\partial R}{\partial x} \qquad (29)$$

Then

$$\frac{\partial^2 R}{\partial x^2} + \frac{\partial^2 R}{\partial y^2} = +4\pi i \qquad (30)$$

The function R is known as the vector potential of the field. In a coplanar magnetic field a line of force is characterized by the equation $R = \theta =$ a constant, because

$$dR = \frac{\partial R}{\partial x}dx + \frac{\partial R}{\partial y}dy = 0 \qquad (31)$$

and solving for the slope of the line $R =$ a constant:

$$\frac{dy}{dx} = -\frac{\partial R/\partial x}{\partial R/\partial y} = \frac{Y}{X} \qquad (32)$$

which shows that this line has the same direction as the magnetic field.

Also, $\Delta\phi = \phi_1 = \phi_2$ is equal to the flux included between the lines of force $R = \phi_1$ and $R = \phi_2$, for

$$\Delta\phi = \int_1^2 dR = \int_1^2 Y\,dx - X\,dy \qquad (33)$$

may be seen to give the flux included between the points 1 and 2 whatever the path of integration employed.

In any problem in which the only sources of m. m. f., are currents within the regions under consideration, the boundary conditions imposed consist in variations of permeability from the region under consideration to the adjoining regions and in general from the adjoining regions to other regions.

This type of boundary condition may be recognized to consist of a sum of terms containing constants and partial derivatives operating on R.

It is then clear that if two solutions R_1 and R_2 satisfy these boundary conditions and the point Equation (30) for current densities i_1 and i_2 separately, their sum must also satisfy these boundary conditions and the point Equation (30) for a current density $i_1 + i_2$.

It is possible, therefore, to superpose solutions for vector potential due to two distributions of current density and the result may be extended to any number

25. In the above, it has been found convenient, in order to make the sign of R positive, to define it by the relations:

$$Y = \frac{\partial R}{\partial x}, \quad X = -\frac{\partial R}{\partial y}$$

instead of

$$Y = -\frac{\partial R}{\partial x}, \quad X = \frac{\partial R}{\partial y}$$

as in Rogowski's work.

of superpositions; and thus from a knowledge of the vector potential of an element we may by integration determine the vector potential of a complicated distribution of current density.

I. The Vector Potential of an Isolated Straight Wire of Circular Section. Let the radius of the wire be a and let the total current through the wire be I.

Then inside the wire the field intensity[26] is

$$H = \frac{2\,I\,r}{a^2} \tag{34}$$

and outside the wire:

$$H = \frac{2\,I}{r} \tag{35}$$

If we choose $R = 0$ at $r = 0$, then inside the wire:

$$R = \int_{r=0}^{r=r} H\,d\,r = \frac{I\,r^2}{a^2} \tag{36}$$

and outside the wire:

$$R = \int_{r=a}^{r=r} H\,d\,r + \frac{I\,a^2}{a^2} = 2\,I\left[\log_\epsilon\left(\frac{r}{a}\right) + \frac{1}{2}\right] \tag{37}$$

II. The Vector Potential of Two Isolated Straight Wires of Circular Section. Let r_1 and r_2 be the radii vector from wires 1 and 2, respectively, and let a_1 and a_2 be the respective radii of the conductors. Then inside conductor 1:

$$R = 2\,I_2\left[\log_\epsilon\left(\frac{r_2}{a_1}\right) + \frac{1}{2}\right] + I_1\frac{r_1^2}{a_1^2} \tag{38}$$

Inside conductor 2:

$$R = 2\,I_1\left[\log_\epsilon\left(\frac{r_1}{a_1}\right) + \frac{1}{2}\right] + I_2\frac{r_2^2}{a_2^2} \tag{39}$$

Outside both conductors:

$$R = 2\,I_1\left[\log_\epsilon\left(\frac{r_1}{a_1}\right) + \frac{1}{2}\right] + 2\,I_2\left[\log_\epsilon\left(\frac{r_2}{a_2}\right) + \frac{1}{2}\right] \tag{40}$$

a. In the *special case* where the currents are in opposite directions, $I_2 = -\,I_1 = I$, and $a_1 = a_2$, the vector potential outside the conductors is

$$R = 2\,I\log_\epsilon\frac{r_1}{r_2} \tag{41}$$

and the equation of a line of force, R = a constant, is

$$\frac{r_1^2}{r_2^2} = \epsilon^{R/I} \tag{42}$$

The well-known fact follows that the lines of force outside the conductors are circles.

In particular, if the centers of the wires are located at $x = -\,b$, and $x = b$, respectively, Equation (42) becomes

$$[x + b\coth(R/2\,I)]^2 + y^2 = \frac{b^2}{\sinh^2(R/2\,I)} \tag{43}$$

b. In the *special case* where the currents are in the same direction, $I_1 = I_2 = I$, and $a_1 = a_2 = a$,

$$R = 2\,I\left[\log_\epsilon\left(\frac{r_1\,r_2}{a^2}\right) + 1\right] \tag{44}$$

The equation of the line of force in this case is of the fourth degree.

III. The Vector Potential of a Straight Wire Near the Corner of two Infinitely Permeable Planes. The wire and images for this case are shown in Fig. 29. Outside the wire

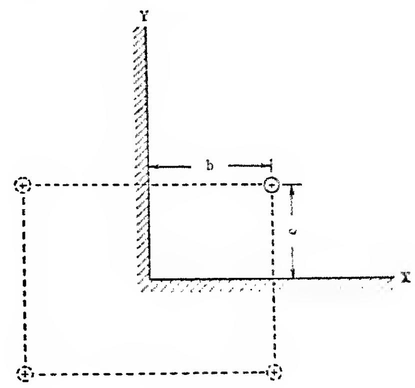

FIG. 29

$$\frac{R}{I} = \log_\epsilon\frac{(x-b)^2 + (y-c)^2}{a^2} + \log_\epsilon\frac{(x-b)^2 + (y+c)^2}{a^2} + \log_\epsilon\frac{(x+b)^2 + (y-c)^2}{a^2} + \log_\epsilon\frac{(x+b)^2 + (y+c)^2}{a^2} + 4 \tag{45}$$

Equations of the type of (45) may be solved by plotting since only the real roots are desired. In the case under consideration, R/I should be plotted as a function of x with y as a parameter. Points on a line of force are then determined by the intersections of the curves along lines of R/I = a constant.

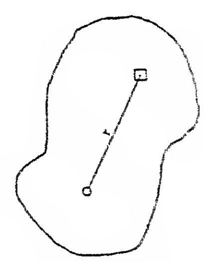

FIG. 30

IV. The Vector Potential of an Isolated Wire of Any Cross-Section in Air. Referring to Fig. 30, the vector potential of an element of the wire is, in general,

$$d\,R = i\,(\log_\epsilon r^2)\,d\,a + \text{a constant} \tag{46}$$

26. $H = \sqrt{X^2 + Y^2}$.

where r is the distance from the point at which R is determined to the element under consideration, i is the current density, and $d\,a$ the area of the element. The value of R for the whole wire is, then,

$$R = \int_S i\,(\log_\epsilon r^2)\,d\,a + \text{a constant} \qquad (47)$$

the integral being taken over the whole surface of the wire. If the current density over the cross-section is constant, we have

$$\frac{R}{i} = \int_S (\log_\epsilon r^2)\,d\,a + \text{a constant}^{27} \qquad (48)$$

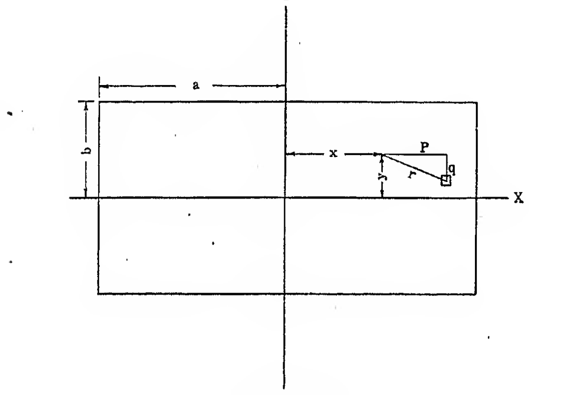

FIG. 31

a. For the *special case* of an isolated wire of rectangular section we have, referring to Fig. 31,

$$\frac{R}{i} = \int_{q=y-b}^{q=y+b} \int_{p=x-a}^{p=x+a} \log_\epsilon (p^2 + q^2)\,d\,p\,d\,q \qquad (49)$$

Integrating and adding the constant terms,

$$-4\,a\,b\log_\epsilon(a^2+b^2)-6\,a\,b-4\,a^2\tan^{-1}\frac{b}{a}-4\,b^2\tan^{-1}\frac{a}{b}$$

In order to make $\frac{R}{i} = 0$ at the origin, Equation (49) can be reduced to the symmetrical form:

$$\frac{R}{i} = (x+a)\,(y+b)\log_\epsilon\left[\frac{(x+a)^2+(y+b)^2}{a^2+b^2}\right]$$

$$-\,(x-a)\,(y+b)\log_\epsilon\left[\frac{(x-a)^2+(y+b)^2}{a^2+b^2}\right]$$

$$-\,(x+a)\,(y-b)\log_\epsilon\left[\frac{(x+a)^2+(y-b)^2}{a^2+b^2}\right]$$

$$+\,(x-a)\,(y-b)\log_\epsilon\left[\frac{(x-a)^2+(y-b)^2}{a^2+b^2}\right]$$

$$+\,(x+a)^2\left[\tan^{-1}\frac{y+b}{x+a}-\tan^{-1}\frac{y-b}{x+a}\right]$$

$$-\,(x-a)^2\left[\tan^{-1}\frac{y+b}{x-a}-\tan^{-1}\frac{y-b}{x-a}\right]$$

$$+\,(y+b)^2\left[\tan^{-1}\frac{x+a}{y+b}-\tan^{-1}\frac{x-a}{y+b}\right]$$

$$-\,(y-b)^2\left[\tan^{-1}\frac{x+a}{y-b}-\tan^{-1}\frac{x-a}{y-b}\right]$$

$$-\,4\,a^2\tan^{-1}\frac{b}{a}-4\,b^2\tan^{-1}\frac{a}{b} \qquad (50)^{28}$$

The field in and around a rectangular conductor of dimensions two units by four units, carrying a current of 80 amperes, *i. e.*, $a = 2$, $b = 1$, $i = 1$, has been plotted from Equation (50) by one of our associates, Mr. R. S. Arthur, and is shown in Figs. 32 and 33. Figs. 34 and 35, showing R as a function of x and y, were used in plotting Figs. 32 and 33.

b. *Special Case.* Infinitely thin ribbon.

For sufficiently small values of b, that is, if the rectangle degenerates into a ribbon, putting $2\,b\,i = i'$ = current per unit length of the ribbon and adding

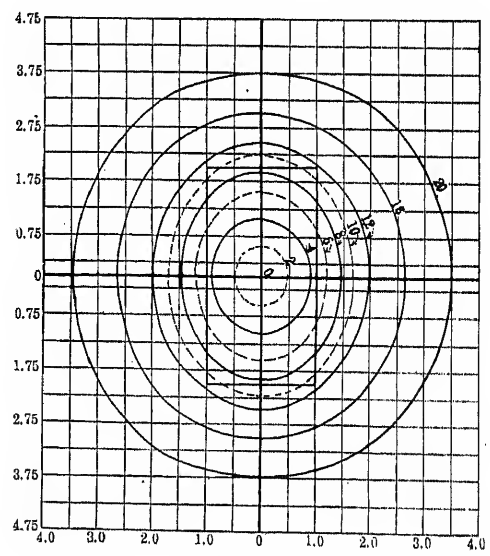

FIG. 32

terms such that $\frac{R}{i'} = 0$ at $x = y = 0$, Equation (50) can be written

$$\frac{R}{i'} = (a+x)\log_\epsilon\frac{(a+x)^2+y^2}{a^2}$$

27. This result may be expressed in the form $\frac{R}{i} = \log D^2$ + a constant, where D equals the geometric mean distance of the point at which R is to be computed from the area of the section of the conductor.

28. The variable terms in (50) and (51) may be checked against those given by Maxwell, "Electricity and Magnetism," paragraph 692, for the mean geometric distance of a point from a rectangle and a straight line, respectively.

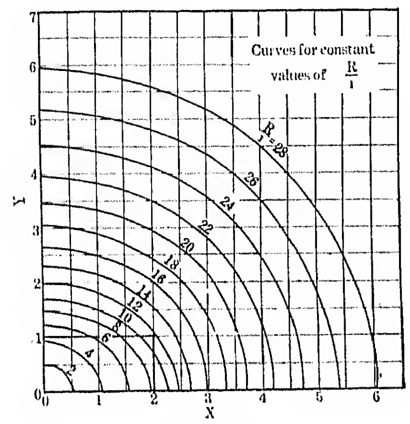

FIG. 33

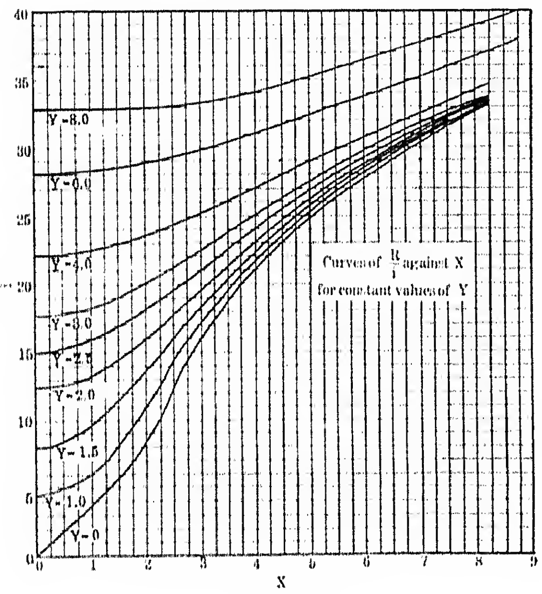

FIG. 34

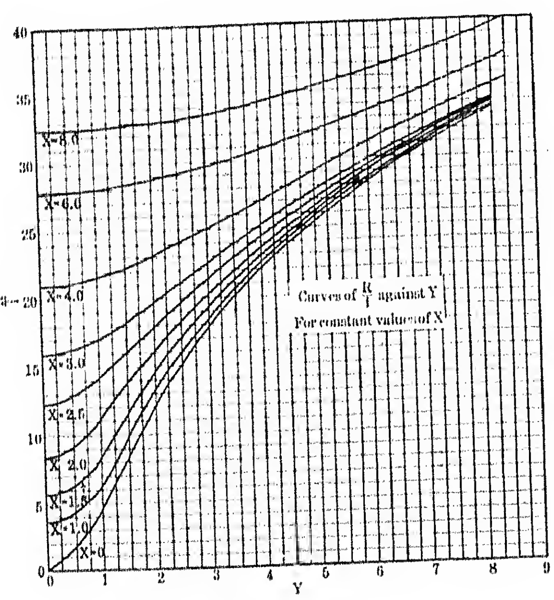

FIG. 35

$$+ (a - x) \log_\epsilon \frac{(a - x)^2 + y^2}{a^2}$$

$$+ 2\, y \left[\tan^{-1} \frac{a + x}{y} + \tan^{-1} \frac{a - x}{y}\right] \qquad (51)^{28}$$

Equation (**51**) corresponds precisely to the case of a vanishingly thin isolated conductor, or to a narrow strip of conductor on an infinite iron surface.

In the case of a ribbon conductor two units long,

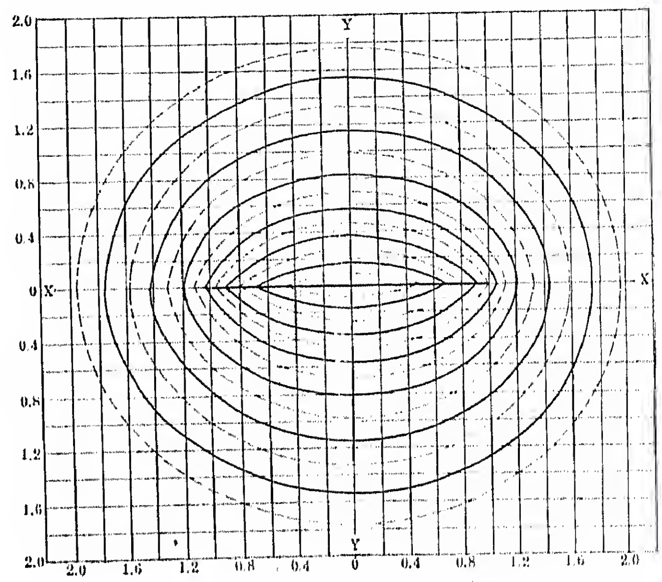

FIG. 36

carrying a current of 20 amperes, the expression for vector potential is

$$R = (1+x) \log_\epsilon [(1+x)^2+y^2]+(1-x) \log_\epsilon [(1-x)^2+y^2]$$

$$+ 2\, y \left[\tan^{-1} \left(\frac{1 + x}{y}\right) + \tan^{-1} \left(\frac{1 - x}{y}\right)\right] \qquad (52)$$

The field for this case as plotted by one of the authors is shown in Fig. 36. The curves of R as a function of x and y which were used in plotting Fig. 36 are shown in Figs. 37 and 38.

Appendix D

THE RELATION OF THE SCALAR POTENTIAL FUNCTION TO THE VECTOR POTENTIAL FUNCTION IN COPLANAR MAGNETIC FIELDS

For points outside of regions in which current density exists, it is legitimate to construct a potential function V having the property:

$$H_n = \frac{\partial}{\partial n} V \qquad (53)$$

where H_n is the field intensity in a direction n and where n is distance measured in any direction from the point at which H_n exists.

Then, in particular,

$$dV = \frac{\partial V}{\partial x}\,dx + \frac{\partial V}{\partial y}\,dy$$
$$= H\;dx + H\;dy$$
$$V_2 - V_1 = \int_1^2 H_x\,dx + H_y\,dy \qquad (54)$$

where x and y form any convenient set of coordinate axes. The path of integration must be arranged so that it does not traverse regions in which current density exists. At the same time, it is necessary to construct arbitrary boundary surfaces, one beginning at some point of each current-carrying region and dividing the field into arbitrary sections such that within any section it is impossible to enclose current by any path of integration outside the zone of current density. Equipotential lines may be carried through these regions by joining lines which differ by an amount $4\,\pi$ times the current enclosed by any circuit which does not cut through any boundaries, and starting at one side of the boundary and ending at the other side at the same point.

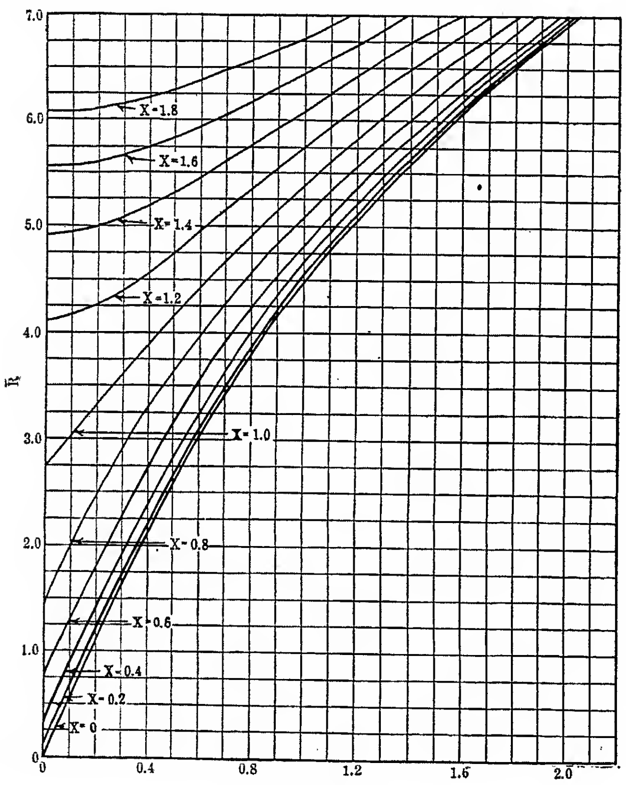

FIG. 37.

If the vector potential of the field is known, we may use Equation (54) in the form:

$$V_2 - V_1 = \int_1^2 \frac{\partial R}{\partial x}\,dy - \frac{\partial R}{\partial y}\,dx \qquad (55)$$

Solutions of scalar potential due to particular distributions of current density will be superposable in the same way and subject to the same limitations a apply to solutions of vector potential.

In the following, the scalar potential functions whic obtain in the various examples of magnetic fields give in other parts of the paper will be worked out briefly

I. Field Pole, or Slot. Referring to Fig. 8, it wi be convenient to divide Region II into a and b parts the a part being between the current-carrying zone and the b part between the current-carrying zones an the iron, and to choose the line $x = a$ from $\theta = \pi - \theta$

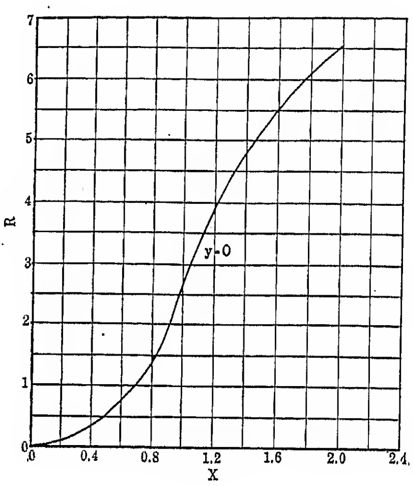

FIG. 38

to $\theta = \pi$, and from $\pi = \theta_2 - \pi$ to $\theta = -\pi$ as the arbitrary boundary surface previously referred to.

Then, choosing $V = 0$ at $x = y = 0$, and remembering $y = \frac{\theta}{k}$,

$$V = \int_0^{0,x} k\,\frac{\partial R}{\partial \theta}\,dx - \frac{1}{k}\,\frac{\partial R}{\partial x}\,d\theta$$
$$= \int_0^{\theta} \frac{1}{k}\,\frac{\partial R}{\partial x}\,d\theta \qquad (56)$$

Thus, for Region I:

$$\frac{\partial R}{\partial x} = \sum_1^{\infty} k\,n\,[a_n\,\epsilon^{-kn(a-x)} - a_n'\,\epsilon^{-knx}]\cos n\,\theta$$

$$V^{\mathrm{I}} = \sum_1^{\infty} [a_n\,\epsilon^{-kn(a-x)} - a_n'\,\epsilon^{-knx}]\sin n\,\theta \qquad (57)$$

For Region II:

$$\frac{\partial R}{\partial x} = 4\,\pi\,\alpha_0\,(x-a) + \sum_1^{\infty} n\,[b_n\,\epsilon^{-kn(b-x)} - b_n'\,\epsilon^{-kn(x-a)}]\cos n\,\theta$$

$$V^{\mathrm{II}a} = 4\,\pi\,\alpha_0\,(x-a)\,y + \sum_1^{\infty} [b_n\,\epsilon^{-kn(b-x)} - b_n'\,\epsilon^{-kn(x-a)}]\sin n\,\theta \qquad (58)$$

In order to obtain the scalar potential for Region IIb, it is convenient to subtract from the known potential at the iron surface, the potential difference from the point in question referred to that surface. Thus:

$$V_{IIb} = 4\,\pi\,\alpha_0\,(b-a)\,\frac{l}{2} - \int_0^{\pi} \frac{1}{k}\,\frac{\partial R}{\partial x}\,d\,\theta$$

$$= 4\,\pi\,\alpha_0 \left[(b-a)\,\frac{l}{2} - (x-a)\left(\frac{l}{2} - y\right)\right]$$

$$+ \sum_1^{\infty} [b_n\,\epsilon^{-kn(b-x)} - b_n'\,\epsilon^{-kn(x-a)}\,]\sin n\,\theta$$

$$= V_{IIa} + 2\,\pi\,\alpha_0\,l\,(b-x) \tag{59}$$

For Region III:

$$\frac{\partial R}{\partial x} = 4\,\pi\,\alpha_0\,(b-a) + \sum_1^{\infty} [c_n\,\epsilon^{-kn(c-x)}$$

$$- c_n'\,\epsilon^{-kn(x-b)}\,]\cos n\,\theta$$

which gives:

$$V_{III} = 4\,\pi\,\alpha_0\,(b-a)\,y + \sum_1^{\infty} [c_n\,\epsilon^{-kn(c-x)}$$

$$- c_n'\,\epsilon^{-kn(x-b)}\,]\sin n\,\theta \tag{60}$$

The solution for an infinitely deep slot may be obtained by inserting $c = \infty$.

II. Circular Slot. In polar coordinates, Equations (54) and (55) become

$$V_2 - V_1 = \int_1^2 H_r\,d\,r + H_\theta\,r\,d\,\theta \tag{61}$$

$$= \int_1^2 -\frac{1}{r}\,\frac{\partial R}{\partial \theta}\,d\,r + \frac{\partial R}{\partial r}\,r\,d\,\theta \tag{62}$$

Taking $V = 0$ at $\theta = 0$, there results:

$$V = \int_0^{\theta} r\,\frac{\partial R}{\partial r}\,d\,\theta \tag{63}$$

For Region II:

$$\frac{\partial R}{\partial r} = \sum_1^{\infty} \frac{n}{r_0}\left(\frac{r}{r_0}\right)^{n-1} [b_n \cos n\,\theta] + \frac{2\,I}{r}$$

which gives:

$$V_{II} = \sum_1^{\infty} \left(\frac{r}{r_0}\right)^n b_n \sin n\,\theta + 2\,I\,\theta \tag{64}$$

III. Scalar Potential of a Wire of Any Section. Evidently, for an isolated circular wire,

$$V = 2\,I\,\theta$$

The solution for several circular wires is obtained by superposition. The solution for a wire of any section is

$$V = \int_S 2\,i\,\theta\,d\,a \tag{65}$$

the integral to be extended over the whole section in which i exists.

It may be found more convenient, however, to obtain V indirectly through (47) and (55).

Appendix E

Calculation of Inductance from a Knowledge of Vector Potential

In general, in order that it shall be permissible to employ the conception of inductance to a conductor of large section, it is necessary that the conductor consist of a bundle of smaller conductors, all of these conductors supposedly connected in series, or in such a way that the same current flows in each[29]. If there is a sufficient number of small conductors, it is permissible as an approximation to calculate the inductance of the system as the average inductance of a continuous distribution of small current filaments, the density of the filaments being in proportion to the density of small conductors. It will further be assumed that the current distribution may be regarded as continuous within the section of the large conductor.[30]

Let ϕ_0 be the total flux outside some particular line of force $R = R_0$ and between that line and the line with respect to which induced voltage is to be computed, where R is the vector potential function of the field.

Then

$$\phi_0 + R_0 - R$$

will be the flux outside any line R.

Let

$$n = \text{the density of small conductors.}$$

The average flux linkages per conductor are

$$\int_S \frac{(\phi_0 + R_0 - R)\,n\,d\,a}{N} = (\phi_0 + R_0) - \int_S \frac{R\,n\,d\,a}{N}$$

where

$$N = \int_S n\,d\,a$$

= the total number of small conductors in the section.

If I is the total current through the section, the component of average inductance due to flux up to the point that ϕ_0 is computed, is

$$L = \left(\frac{\phi_0 + R_0}{I}\right) - \int_S \frac{R\,n\,d\,a}{N\,I}$$

But

$$i = \frac{n}{N}\,I$$

$$I = \int_S i\,d\,a$$

29. From the restricted point of view that stored magnetic energy equals ½ × inductance × current squared, it is permissible to apply the conception of inductance to conductors which are not subdivided.

30. If desired, this approximation may be corrected. A correction of this type is given by Maxwell, "Electricity and Magnetism," par. 693.

or

$$L = \left(\frac{\phi_0 + R_0}{I}\right) - \int_S \frac{R\, i\, d\, a}{I^2} \qquad (66)$$

Equation (66) may be put in the form,

$$L = 4\,\pi\,(P_0 - P) \qquad (67)$$

where P_0 and P are permeance factors;

$$P_0 = \frac{\phi_0 + R_0}{4\,\pi\,I} \qquad (68)$$

$$P = \frac{\int_S R\, i\, d\, a}{4\,\pi\,[\int_S i\, d\, a]^2} \qquad (69)$$

In (68) and (69), the quantity P_0 is the permeance factor that would obtain if the flux $\phi_0 + R_0$ linked all of the conductors, while the factor P takes into account the effect of partial linkages.

It is interesting that in the foregoing equation, the vector potential R need not be computed so that the minimum value of $R = 0$. Thus it is not necessary to calculate the value of R at the kernel. If the kernel is known to exist on some line such that one coordinate x or y, or r or θ, for example, is fixed, the calculation of the value of R at the kernel is comparatively easy. If, as in the field pole problem, however, the value of neither coordinate is known, then on account of the unsatisfactory convergence which usually obtains at the kernel, the calculation of the position and value of R at the kernel is a task of considerable difficulty. It is fortunate, therefore, that this calculation is not required.

Inductance of Two Parallel Cylindrical Conductors. As a simple example of formula (66), consider the case of two straight conductors of circular section carrying currents I and $-I$, respectively. From Formula (38), the vector potential at a point inside one wire is

$$R = I\frac{r_1^2}{a^2} - 2\,I\left[\log\left(\frac{r_2}{a}\right) + 1/2\right]$$

where

a = the radius of the section.

Let

$r_1 = r$

l = distance between centers of the conductors.

The component of inductance due to half the flux will be calculated. Thus ϕ_0 will be chosen equal to 0 for $r_1 = r_2$. But also, from (41), $R = R_0 = 0$ at $r_1 = r_2$. Thus, (66) gives

$$L = -\int_S \frac{R\, i\, d\, a}{I^2}$$

which may be put in the form:

$$L = \frac{1}{\pi\, a^2}\int_0^a\int_0^{2\pi}\left[1 - \frac{r^2}{a^2}\right.$$

$$\left. + \log\left(\frac{l^2 + r^2 - 2\,l\,r\cos\theta}{a^2}\right)\right] r\, d\,\theta\, d\, r \qquad (70)$$

$$= \frac{2}{a^2}\int_0^a\left[1 - \frac{r^2}{a^2} + \log\frac{l^2}{a^2}\right] r\, d\, r$$

$$= 2\log\frac{l}{a} + \frac{1}{2} \qquad (71)$$

which is the usual expression for one-half the inductance of a circuit formed by two parallel Wires.

Application to Field Pole Problem. The use of formula (69) is illustrated below by applying it to the field pole problem. In this case, and considering all the copper as comprising a single coil side, there is

$$P = \frac{2\,i\int_{\theta_1}^{\pi-\theta_2}\int_{x=a}^{x=b} R^{II}\, d\, x\, d\, y}{4\,\pi\,[\alpha_0\,(b-a)\,l]^2} \qquad (72)$$

This integral evaluates to the expression:

$$P = \frac{b-a}{6\,l} - P'$$

where

$$P' = \sum_1^\infty \frac{\alpha_n}{16.\pi^2\,\alpha_0^2.(b-a)^2\,n}\left[(b_n + b_n')\left\{1 - \epsilon^{-kn(b-a)}\right\}\right.$$

$$\left. + 2\,K_n\,k\,n\,(b+a)\right] \qquad (73)$$

Thus, for the field pole shown in Fig. 8,

$$P' = 0.0045$$

For the case of an infinite slot, $c = \infty$, (73) becomes explicitly:

$$P' = \sum_1^\infty \frac{1}{8\,\pi^2}\left(\frac{\alpha_n}{n\,\alpha_0}\right)^2\left(\frac{l}{b-a}\right)\left[1 - \frac{(2 - \epsilon^{-2kna} + \epsilon^{-kn(b+a)})\,(1 - \epsilon^{-kn(b-a)})}{k\,n\,(b-a)}\right] \qquad (74)$$

Thus, for the "infinite" slot shown in Fig. 3A,

$$P' = 0.0037$$

In the case of an infinitely deep slot, it may be verified that the factor P' provides a correction which gives the increase of inductance due to concentration of current above the inductance which would be calculated on the assumption that the lines of force were everywhere perpendicular to the slot sides.

Circular Conductors in a Circular Slot. The expression for P' in the case of a circular conductor is very simple because for b_0 chosen $= 0$, the integral over the area of the copper of the term which involves the effect of the slot is zero and there remains only the term which would exist were the conductor isolated in space.

Thus, with $b_0 = 0$:

$$P' = \frac{i}{4\,\pi}\int_S \frac{R\, i\, d\, a}{(\int_S i\, d\, a)^2} = \frac{1}{4\,\pi^2\,r_2^2}\int_0^{2\pi}\int_0^{r_2}\frac{r^2}{r_2^2}\, r\, d\, r\, d\,\theta \qquad (75)$$

$$= \frac{1}{8\pi} \tag{76}$$

Conductors in Air. The calculation of the inductance of conductors in air permits the development of special formulas involving the conception of geometric mean distance. Thus, for a system of positive currents with return currents within a finite distance, the vector potential calculated from (47) will be zero at any point which is an infinite distance from the system in question, if the constant term is taken equal to zero. Thus, if the voltage due to flux between the system of positive currents and infinity is to be calculated, and if the system of currents fulfills the requirements permitting the calculation of inductance, then:

$$L_1 = -\int_{S_1} \frac{R\, i\, d\, a}{I^2} \tag{77}$$

where S_1 refers to the area of the sections of conductors carrying positive currents and

$$R = \int_{(S_1+S_2)} i \log r^2\, d\, a$$

$$L_1 = \frac{-1}{I^2} \int_{S_1} \left[\int_{S_1+S_2} i \log r^2\, d\, a \right] i\, d\, a \tag{78}$$

The voltage due to flux from infinity to the return is

$$L_2 = \frac{-1}{I^2} \int_{S_2} \left[\int_{S_1+S_2} i \log r^2\, d\, a \right] i\, d\, a \tag{79}$$

The total inductance of the circuit is

$$L = L_1 + L_2 = \frac{-1}{I^2} \int_{S_1+S_2} \int_{S_1+S_2} i \log r^2\, d\, a\, i\, d\, a \tag{80}$$

which may be put in the symmetrical form[31]:

$$L = +2 \frac{\int_{S_1+S_2} \int_{S_1+S_2} i \log r\, d\, a\, i\, d\, a}{\left[\int_{S_1} i\, d\, a\right]\left[\int_{S_2} i\, d\, a\right]} \tag{81}$$

For uniform current density, remembering that the current density is negative over the section of the return conductors, (81) becomes:

$$L = -2 \frac{-\int_{S_1} \left\{ \left[\int_{S_1} - \int_{S_2} \right] \log r\, d\, a \right\} d\, a}{A_1 A_2} \tag{82}$$

31. It is understood that, subject to the conditions imposed,

$$\int_{S_1} {}_1 i\, d\, a = -\int_{S_2} i\, d\, a$$

$$= -2 \frac{\left[\int_{S_2} \int_{S_1} \log r\, d\, a\, d\, a - 2 \int_{S_2} \int_{S_2} \log r\, d\, a\, d\, a + \int_{S_2} \int_{S_2} \log r\, d\, a\, d\, a \right]}{A_1 A_2}$$

$$= 2 \log \frac{R_{12}{}^2}{R_{11} R_{22}} \tag{83}$$

where

R_{11} = geometrical mean distance of section 1 from itself.

R_{22} = geometrical mean distance of section 2 from itself.

R_{12} = geometrical mean distance of section 1 from section 2.[32]

A_1 = area of section 1.

A_2 = area of section 2.

Graphical Determination of Magnetic Fields

Comparison of Calculations and Tests

BY E. E. JOHNSON[1] and C. H. GREEN[2]

Associate, A. I. E. E. Non-Member

Synopsis.—This paper, which deals with the experimental determination of magnetic fields, is presented as a verification of some of the results described by Messrs. A. R. Stevenson, Jr., and R. H. Park in a companion paper, "Graphical Determination of Magnetic Fields—Theoretical Considerations," and to introduce new and convenient methods of determining the flux distributions in ai spaces and in regions occupied by current carrying media. Th particular case dealt with is the determination of the leakage flu about the field poles of an alternator at no load, both in the copper an in the surrounding air spaces.

Test Methods and Results

SINCE this investigation involves a large number of determinations of direction and intensity of magnetic flux in fields of intensity varying from, say, 50 to 40,000 lines per sq. in., it was essential to have a simple, reasonably accurate, and reliable device for the explorations. In deciding upon the methods to be employed in measuring magnetic fields, due consideration was given to those which have been used by various investigators.[3] Finally two devices were chosen for use. One, due to Professor Dellenbaugh,[4] and developed by C. H. Green, measures the intensity by means of a revolving search coil equipped with a collecting device or commutator, and operating at a high and constant speed. The direction of the field is determine by that position of the brush axis which gives eithe maximum or zero reading of the instrument. Thi device is shown in Fig. 1 and described in Appendix A The other device used in this investigation measures th intensity of the magnetic field by the angular deflectio of a small current carrying coil, the direction bein determined by noting the position of the coil axis fc zero deflection of the coil.[5] This device is shown i Fig. 2.

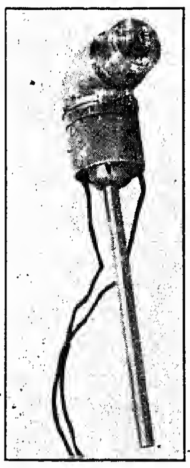

FIG. 1—FLUX MEASURING APPARATUS

This instrument consists of a small coil rotating at high speed which is inserted in the magnetic field to be measured. Connections are made from the coil to a commutator whose brushes are connected to an indicating meter. The revolving parts are enclosed in a non-magnetic casing. The entire instrument is about 6 in. long. The winding consists of two coils 2¼ in. long, of 175 turns each. The rotating parts are driven through a flexible shaft by a 3600-rev. per min. synchronous motor. See Appendix A for further details

In order to get an experimental check of the plot c field flux determined mathematically by Messrs. Steve son and Park, a special pole structure having the require dimensions was constructed of laminated iron. This shown in Fig. 3.

FIG. 2—COMPASS FLUXMETER

This device consists of a current-carrying coil which is inserted in tl magnetic field to be plotted. The movement of the coil is opposed by spring and flux direction is determined by the position of the coil axis f zero deflection. The coil and its shaft are enclosed in a non-magnetic cas The dimensions are as follows:

Length of hollow shaft, 6 in.; diameter of hollow shaft (outside), ¼ i diameter of hollow shaft (inside), 3/16 in., length of armature coil (inside tl shaft), ¼ in.; diameter of armature coil, 5/32 in.; number of turns armature coil, 20

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

5. A similar device employing a bar magnet in place of tl coil was first used. It indicated the direction exactly as does compass, the field strength being determined by offsetting tl needle from its position of rest in the field and counting tl oscillations resulting. The instrument had the objection th the bar magnet became saturated at high field intensities, th changing its strength.

The following description of the experimental methods employed and the results obtained is divided into two parts: first, the Flux Distribution in Air Spaces; and second, the Flux Distribution in Current Carrying Regions.

I. Flux Distribution in Air Spaces

The flux fields in the air spaces between the poles and between the poles and armature were explored by both types of measuring instruments and checked by the

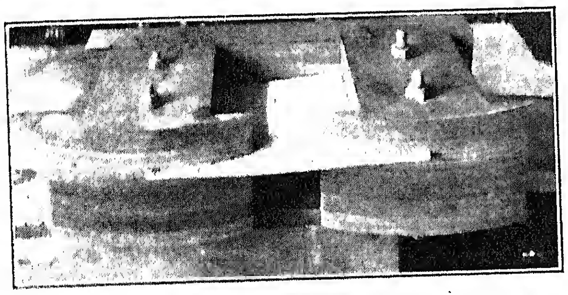

Fig. 3—Experimental Set-up of Alternator Field Poles

iron filing method. Fig. 4 is a reproduction of an actual photograph of the iron filing plot. The plot obtained by use of the instruments is shown and discussed in Part II.

The leakage flux at the end of the field poles of a generator is shown in Fig. 5A and B. The lines in Fig. 5B indicate the direction taken by iron filings and the arrows show the directions as indicated by the measuring instruments. Lines of constant magnetic intensity[6] of the end leakage flux are shown in Fig. 6.

Fig. 4—Flux Field in the Interpolar Space of the Set-up Shown in Fig. 3, as Determined by the Iron Filing Method

II. Flux Distribution in Current Carrying Regions

Although a knowledge of the flux distribution within the current carrying regions of a field pole was made available by the mathematical method described in in the paper by Messrs. Stevenson and Park, no experimental determination had been made, as far as is known, until the present one.

It was thought that the practical difficulty of exploring the field within the copper might be overcome by the substitution of a liquid conductor such as mercury, in the place of the copper, thus, of course, reducing the winding to one turn. The idea worked out successfully, the method of doing it in the case of the field poles being perhaps best explained by reference to Fig. 7.

As indicated in Fig. 7, the field winding consists of one turn per pole. That part of the winding about pole S, which is labeled A, is a non-magnetic tank containing mercury. At the top of this tank is a copper plate perforated with ¼-in. holes, the plate being in electrical contact with the mercury. The holes in the copper plate are for the purpose of giving access to the inside of

6. These lines are lines along which the magnetic intensity is constant. They were useful in studying the effects of the rotating stray fields on the end structure of machines.

the conductor. The armature structure has been purposely omitted from this figure in order to afford a view of the set-up. With the current flowing through the one turn field coils, the conditions as existing in an alternator at no load are practically duplicated, except that due to the high losses in the mercury it is impossible

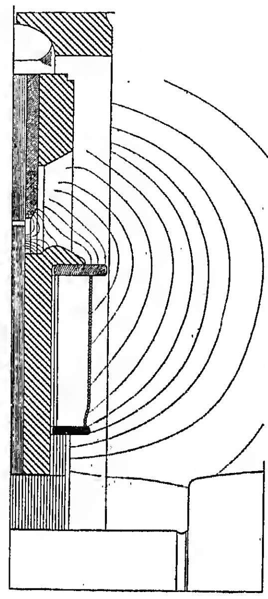

FIG. 6—LINES OF CONSTANT INTENSITY OF THE MAGNETIC FIELD SHOWN IN FIG. 5

to obtain conveniently the flux densities which exist in an alternator.[7]

The insertion of the measuring device displaces some of the mercury and hence some of the current. This involves an error the magnitude of which varies over the field but which, for the present investigation, is negligible except in places where the flux to be measured is of low intensity. In any event, the error is readily calculated and the necessary corrections made. A discussion of this point is given in Appendix A.

The exploring coil element of the measuring instru-

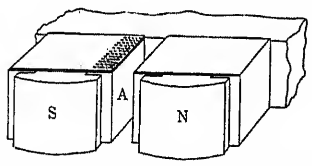

FIG. 7—EXPERIMENTAL SET-UP FOR DETERMINING THE FLUX DISTRIBUTION WITHIN THE FIELD WINDING OF AN ALTERNATOR

ment must necessarily carry a current, the effect of which is to distort the field. This field distortion is practically negligible in most magnetic fields about electrical machinery. This point is discussed in Appendix B.

7. The actual current employed in the single turn was 1000 amperes, thus producing an m. m. f. of 1000 ampere-turns per pole, which is considerably less than that which exists in an actual alternator.

The plot obtained by the free hand method is shown in Fig. 8A, the plot obtained by the mathematical method outlined in the paper by Stevenson and Park is shown in Fig. 8B, and the experimental plot is shown in Fig. 8C. It may be of considerable interest to know that the free hand plot was done first, the mathematical plot second, and the experimental plot third, each

Appendix A

Description of the Flux-Measuring Device Shown in Fig. 1

Complete investigation of both the useful and leakage flux distributions in the air spaces about an alternator requires the measurement of direction and densities in fields varying from, say, 50 to 40,000 lines per sq. in. The idea of using for this purpose a revolving search coil equipped with collecting device for commutator, is due to Mr. F. S. Dellenbaugh (Bibliography, 6).

The instrument developed by C. H. Green is designed to be simple and reasonably accurate, as well as portable and sturdy, for shop use. Fig. 1 shows the device, which is about 6 in. long overall, and therefore easily manipulated with one hand. The miniature armature runs within a protective stationary sleeve and is operated through a pair of small beveled gears driven in turn by detachable flexible drive shafts, from a 1/8th-h. p., 3600-r. p. m. synchronous motor. A dial graduated in degrees may be slipped over the knurled sleeve at the head end.

To obtain a maximum reading on an output meter, the brush position on the miniature commutator is varied by turning this friction sleeve between the fingers so that the direction of the flux being cut may be read off the dial.

The complete device is made of non-magnetic metal, with the exception of Bakelite where required for insulation. Brass is used for the casing, while aluminum monel, a stainless non-magnetic alloy of extremely high resistance, is used for the miniature armature spindle and commutator segments.

The spindle is four inches long, supported by a bearing at its outer end, and is 0.094 inch diameter. The winding consists of two coils each 2½ inches long, confined to the outer end of the spindle. Each coil is wound of 175 turns 0.002 inch enameled copper wire separated from each other and retained to the spindle with silk floss.

The completed armature is impregnated in lacquer to resist oil that might issue from bearings. Connections are made to the four-segment commutator, 3/8 inch diameter. The radio clearance of the armature within the 1/4 inch outside diameter sleeve is 0.015 inch.

The miniature armature is calibrated in a magnetic field of predetermined intensity, so that a factor between milli voltage output and flux density may be applied to subsequent meter readings when the instrument is used in the shop.

Appendix B

Investigation of the Error Involved due to the Displacement of Current Carrying Mercury by the Measuring Instruments

It seems that in order to explore the magnetic field inside of a liquid conductor, such as mercury, it is necessary to displace some of the mercury. If the measuring instruments were infinitesimally small, there would be no appreciable displacement of the mercury and hence no error due to that source would be involved in the field plot so obtained. The instruments used in this investigation, however, have a diameter of 1/4 inch and an error of some magnitude is to be expected.

The effect of the displacement of current carrying mercury is to remove a portion of the current. The removal of this current is equivalent to superposing upon the preexisting current in that portion a current of opposite direction and of the same density in that portion.[8] The magnetic field which results from the effect of the normal current distribution and of the superposed current is the same as that produced by the removal of the portion of current carrying mercury in the actual case.[9]

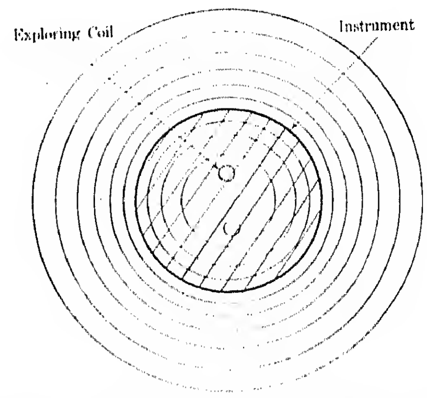

Fig. 9—Flux Distribution which Would Exist if the Space Occupied by the Measuring Instrument Shown was Filled with a Current Flowing in a Direction Perpendicular to the Plane of the Paper, and not Near any Other Electric or Magnetic Circuits

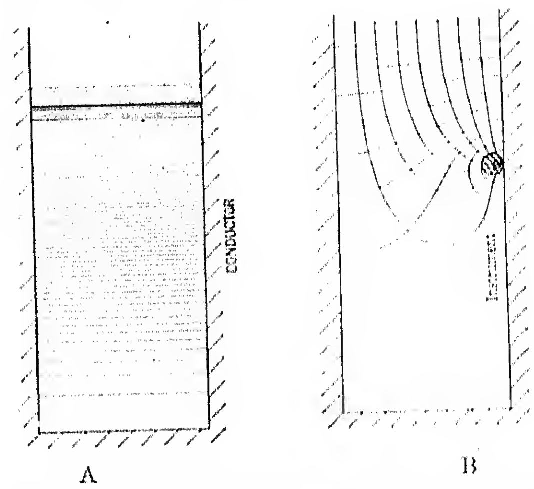

Fig. 10—Flux Distribution Which Exists in an Infinitely Deep Iron Slot Having a Liquid Conductor in its Bottom

A. Without the measuring instrument

B. Due to a reverse current in the space occupied by the measuring instrument after insertion

8. The instrument is properly insulated with varnish to prevent a flow of current through it.

9. Neglecting saturation, of course.

The problem, then, is to determine what effect the current in a cylindrical conductor has on an exploring coil placed in the magnetic field within that conductor for various configurations of the surrounding magnetic circuit.

If the lines of force in the conductor due to its own current are concentric with that conductor, there is no effect on the exploring coil, as may be seen by reference to Fig. 9. If, however, the lines of force are not concentric with the conductor, as when the conductor is brought very near an iron surface, there will be an an effect upon the exploring coil.

As an extreme example of the above, consider the case, shown in Fig. 10, of an infinitely deep slot extending infinitely in the direction perpendicular to the paper, the bottom of which is filled with a liquid

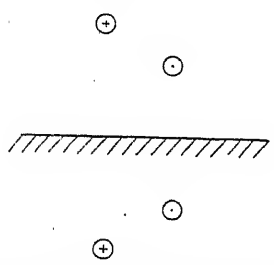

FIG. 11—IMAGE OF THE CURRENTS IN THE MEASURING INSTRUMENTS WHEN NEAR A PLANE IRON SURFACE

conductor, as indicated. A measuring instrument of the sort used in this investigation is inserted in the conductor and in contact with the iron.

The field around the exploring coil is the equivalent of the superposition of the two fields shown in Fig. 10, the first (Fig. 10A) being due to normal current distribution before the instrument was inserted, the second (Fig. 10B) being due to a reverse current in the space occupied by the measuring instrument after insertion.

The error in the magnitude and direction of the magnetic field in the space occupied by the measuring instrument is less than one per cent for the case shown in Fig. 10. The error will be the greatest where the field to be measured is the weakest, which, in the case shown in Fig. 10, is at the bottom of the slot. The error there is about 30 per cent, but this error does not render the method useless because it can always be calculated so that the field plot obtained experimentally may be corrected.

Appendix C

ERROR DUE TO THE MAGNETIC REACTION OF THE MEASURING INSTRUMENTS UPON THE MAGNETIC FIELD TO BE MEASURED

The error due to this cause may be determined readily by making a plot of the magnetic field, which is caused by the current in the instruments and finding the magnitude and direction of the flux at the place occupied by the measuring instrument. If the instrument is near a particular plane iron surface, the magnetic field due to current in the instrument may be determined by the method of images; that is, the iron surface may be considered to be removed and another set of currents similar to those in the instrument placed at an equal distance from the iron surface and in the same direction, as shown in Fig. 11.

The error due to the cause encountered in this investigation is less than one per cent, except very near the kernel where the flux density of the field to be measured is zero.

Graphical Determination of Magnetic Fields

Practical Applications to Salient-Pole Synchronous Machine Design

BY ROBERT W. WIESEMAN[1]

Member, A. I. E. E.

Synopsis.—There are three methods of obtaining the flux distribution in a magnetic field.

First: By test. Templets or models can be made of the field to be explored and the flux distribution can be obtained by test as described in a companion paper "Graphical Determination of Magnetic Fields—Comparison of Calculations and Tests" by Messrs. E. E. Johnson and C. H. Green.

Second: By mathematical analysis. This method is accurate and consistent results can be obtained. If the problem is very complicated, however, the mathematical solution is very laborious and sometimes impossible.

Third: By the graphical method. This method is quite accurate and it can be used for design calculations. It is comparatively easy and it is the quickest method of the three. The graphical method of plotting magnetic fields used in this paper is described in a companion paper, "Graphical Determination of Magnetic Fields—Theoretical Considerations" by Messrs. A. R. Stevenson, Jr. and R. H. Park.

This paper shows how the graphical flux plots can be used very successfully in design calculations. In fact, the performance characteristic of a salient-pole synchronous machine can not be predetermined accurately without the use of flux distribution coefficients.

* * * * *

Introduction

THE distribution of magnetic flux is a very important factor in the design of electrical apparatus. In order to predetermine the characteristics of an electrical device, it is necessary in many cases to plot the flux distribution around the several parts. This is especially so with salient-pole synchronous machines.

Carter, Rogowski, Lehmann, and others have plotted magnetic fields graphically by drawing the potential and flux lines at right angles and by arranging the tubes of flux so that they form approximate squares with the potential lines. This is naturally a cut-and-try method, but usually the symmetry of the figure and the known conditions enable one to arrive at a correct or balanced plot with only a few trials.

As a rule, it is not difficult to determine if the plot is correct because, with a little practise, the eye can be trained to detect any irregularity in the squares formed by the flux and potential lines. The results obtained by some of the graphical flux plots were found to be in very close agreement with similar results obtained mathematically. Furthermore, the flux distribution data given in this paper have been used very successfully in the design calculations of synchronous machinery by a large manufacturing company for nearly ten years.

I. Magnetic Flux Distribution in a Slot

The first practical application of magnetic flux plotting to dynamo design was done by F. W. Carter in 1901[2]. Carter determined the value of the air-gap coefficient by introducing a fringing coefficient which assumes that all of the fringing flux is confined to a limited area instead of to the entire region over the slot. Carter found this fringing coefficient mainly by the use of the theory of functions of a complex variable to obtain a solution of La Place's equation. In this solution, Carter assumed that the depth of the slot and the width of the tooth were infinite[3].

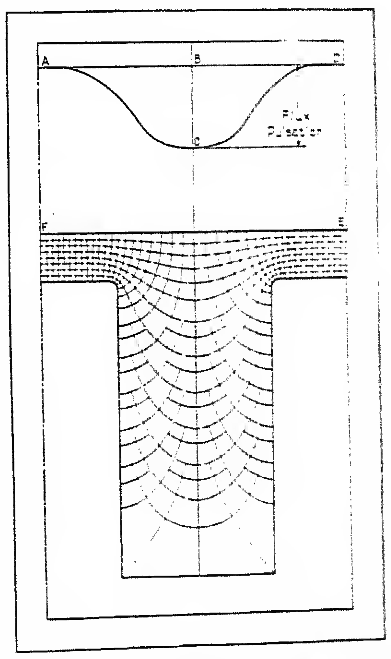

Fig. 1—Flux Distribution in a Slot

$$\frac{\text{Slot width}}{\text{Slot pitch}} = 0.5 \qquad \frac{\text{Slot width}}{\text{Air gap}} = 3.33$$

$$\text{Gap Co-efficient} = \frac{\text{Area } A\ B\ D\ E\ F}{\text{Area } A\ C\ D\ E\ F} = 1.26$$

$$\text{Flux pulsation} = \frac{BC}{AF} = 0.493$$

Calculation of Air-Gap Coefficients from Graphic Flux Plots. Fig. 1 shows the flux distribution in the

2. It is claimed that A. Potier in 1889 derived the permeance between a slotted and a plain surface in his study of the electrometer. It can be found in Vol. 2, page 563, of Potier's translation of Maxwell's treatise.

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February, 7-11, 1927.

3. A mathematical solution for the finite depth of tooth by Hadamard can be found in the *Annales de Chimie et de Physique*, 1909, Vol. 16, Second Series, page 403.

air-gap over one slot pitch. The line $A\,C\,D$ shows how the flux density varies in the air-gap at the surface of a pole. It is evident that the area $A\,B\,D\,C$ represents the amount of flux which is lost due to the slot. In other words, the effective air-gap is increased by the introduction of a slot and thus the air-gap coefficient (Fig. 1) is equal to the area $A\,B\,D\,E\,F$ divided by the area $A\,C\,D\,E\,F$.

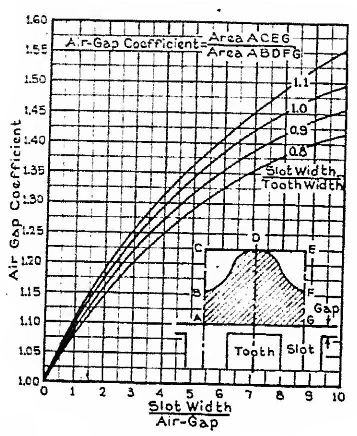

Fig. 2—Air-Gap Coefficient Obtained by Plotting Graphically the Flux Distribution Around a Tooth With Finite Width and Depth as Used in Present Day Machines

Forty graphical plots were made similar to Fig. 1 with various ratios of slot width to air-gap, slot width to tooth width, and with a ratio of slot depth to slot width equal to four. The air-gap coefficients obtained by these plots are shown in Fig. 2. These curves check Carter's work very closely and thus there is practically no difference between the finite and the infinite tooth width and slot depth for open slots which are used in present-day synchronous machines.

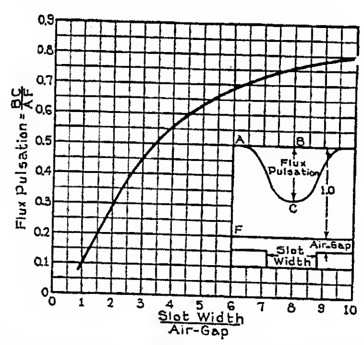

Fig. 3—Magnitude of Flux Pulsation Obtained by Plotting Graphically the Flux Distribution in a Slot With a Finite Width and Depth as Used in Present Day Machines

Flux Pulsation Due to Armature Slots. The variation in the flux density or the flux pulsation $\left(\frac{B\,C}{A\,F}, \text{ Fig. } 1\right)$ was obtained from the flux plots where the tooth width equaled the slot width and the results are shown in Fig. 3. This curve also checks Carter's work for the case of the infinite tooth width and slot depth. The flux pulsation caused by the armature slots produces a loss in the pole face. This loss is part of the open circuit core loss, and it can be calculated when the magnitude of the flux pulsation is known.

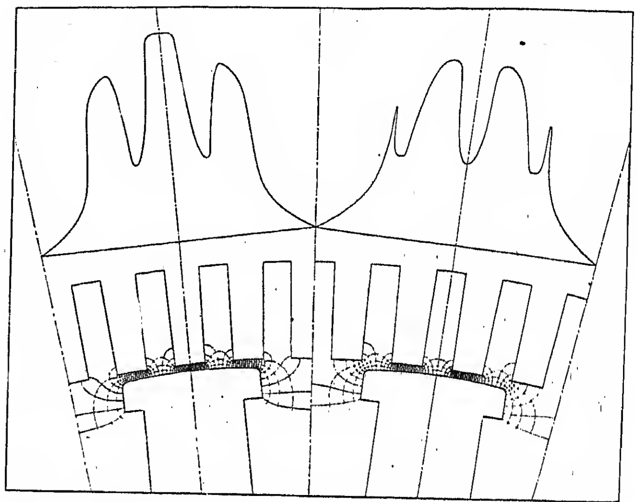

Fig. 4—Flux Distribution at No Load in the Air-Gap of a Salient Pole Synchronous Machine for the Maximum and Minimum Permeance Positions. 10 Per Cent Flux Pulsation

If the number of teeth spanned by a pole varies when the pole moves through a tooth pitch, the pole flux will pulsate if the pole has no low impedance damper winding, etc. Fig. 4 shows a 10 per cent flux pulsation from the maximum to the minimum permeance positions in a machine which has a small number of wide stator slots and a small air-gap. This flux pulsation,

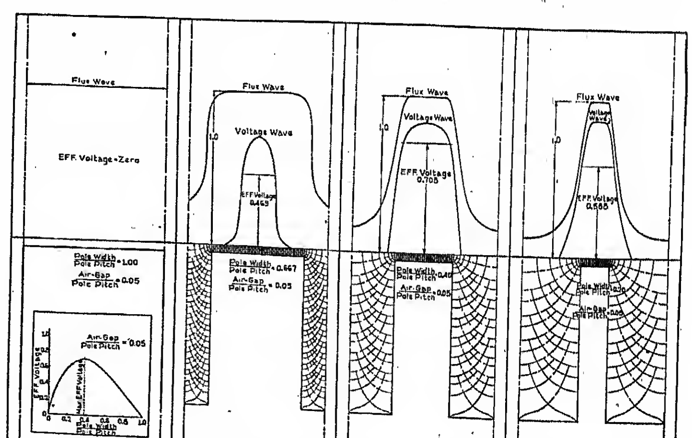

Fig. 5—Magnetic Flux Distribution in Air-Gap of Inductor Alternator Pole Width for Maximum Effective Voltage at No-Load

if excessive, will increase the open circuit core loss and it may produce a magnetic noise. If the teeth are not spiralled, therefore, it is always desirable to have the number of teeth over the pole a constant, especially if a small number of teeth per pole is used.

Inductor Alternator Pole Width Which Gives the Maximum Effective Voltage. There seems to be an increasing demand for high frequency generators for supplying power to induction furnaces, and high-speed tools, for testing, and for experimental work. Usually if the frequency is above 2500 cycles per second, the inductor type alternator is used.

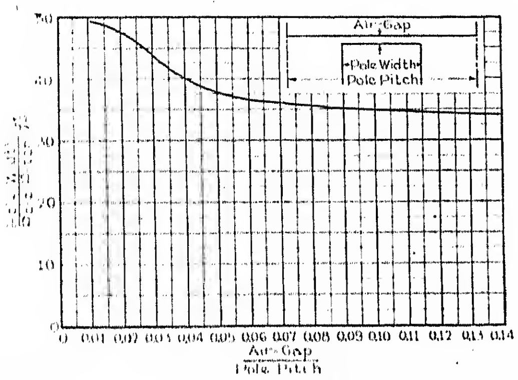

FIG. 6—INDUCTOR ALTERNATOR POLE WIDTH FOR MAXIMUM EFFECTIVE VOLTAGE AT NO LOAD

The voltage induced in an armature coil of an inductor alternator depends upon the flux pulsation, as shown in Fig. 5. If the pole width is 100 per cent of the pole pitch, and if the air-gap is uniform, the flux wave will be a rectangle, and, obviously, the flux pulsation and the induced voltage will be zero. As the pole width is decreased, Fig. 5, the flux pulsation increases. The effective value of the induced voltage, however, increases until it reaches a maximum, and as the pole width is further decreased, the effective voltage decreases. Thus it is very desirable to shape the pole of an inductor alternator so that the voltage induced in the armature coil is a maximum. The insert in Fig. 5 shows how the effective voltage varies with the pole width when the air-gap is five per cent of the pole pitch. In this case the maximum effective voltage at no load occurs when the pole width is 38 per cent of the pole pitch. A number of these flux plots were made for various ratios of air-gap to pole pitch and the corresponding maximum effective voltages were obtained and plotted in Fig. 6. It can be seen that a pole width equal to half of the pole pitch should be used only when the air-gap is infinitely small. For a 10 per cent air-gap, the pole width should be 0.35 of the pole pitch to give the maximum effective voltage at no load. Under load the maximum effective voltage should occur when the pole pitch is a little less than given by the curve in Fig. 6.

II. MAGNETIC FLUX DISTRIBUTION IN THE AIR-GAP OF A SALIENT-POLE SYNCHRONOUS MACHINE AT NO LOAD WHEN EXCITED ONLY BY THE FIELD COILS

Fig. 7 shows the flux distribution around the pole at no load when a salient-pole synchronous machine is excited by its field coil. The full line flux wave was calculated from the flux plot at the surface of the armature and the dotted flux wave was obtained by test with an exploring conductor placed on the surface of the armature. The flux wave fundamental is 1.11 times the maximum value of the flux wave and the flux wave third harmonic is 0.085 times the maximum value of the fundamental.

Fundamental and Third Harmonic in the Air-Gap Flux Wave at No Load. Seventy-five hypothetical flux plots at no load were made of poles used in present-day machines whose pole faces were arcs of circles. The pole shapes used are included in the limits of the following three variables:

$$\frac{\text{Minimum Gap}}{\text{Pole Pitch}} \quad \text{from 0.01 to 0.05}$$

$$\frac{\text{Pole Arc}}{\text{Pole Pitch}} \quad \text{from 0.50 to 0.75}$$

$$\frac{\text{Maximum Gap}}{\text{Minimum Gap}} \quad \text{from 1 to 3}$$

The flux waves were analyzed for their fundamentals and third harmonics, the values of which are shown in Figs. 8 and 9. In Fig. 8, the fundamental A_1 of the flux wave is expressed as a decimal fraction of the maximum value of the flux wave which is taken as unity. In Fig. 9, the third harmonic A_3 of the flux wave is expressed as a decimal fraction of the fundamental which is taken as unity. The polarity of the third harmonic is also given and it is considered minus when it is as shown in the insert of Fig. 9. The pole shape, which will have a flux wave with a zero third harmonic, can also be obtained from Fig. 9. For

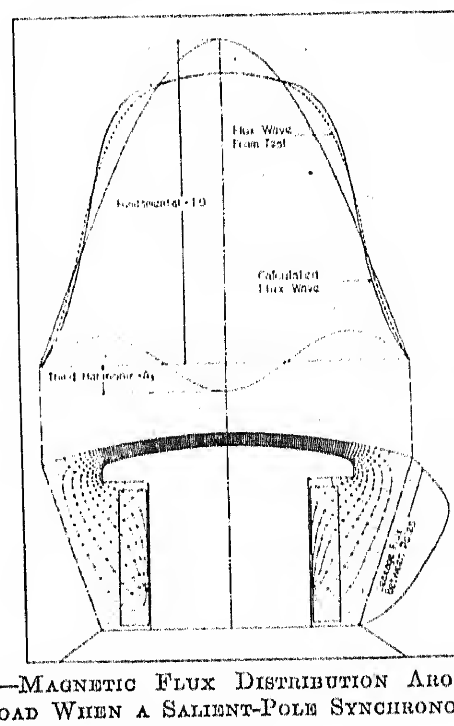

FIG. 7—MAGNETIC FLUX DISTRIBUTION AROUND A POLE AT NO LOAD WHEN A SALIENT-POLE SYNCHRONOUS MACHINE IS EXCITED BY ITS FIELD WINDING

example, if the ratio of the minimum gap to the pole pitch is 0.02, and if the ratio of the maximum to the minimum gap is 1.5, then the ratio of the pole arc to the pole pitch should be 0.67 to obtain a flux wave at no load which has no third harmonic.

Calculation of the Open Delta Voltage and the Delta Circulating Current of a Synchronous Machine at No

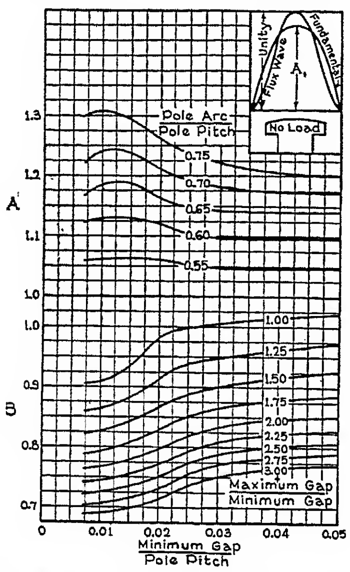

FIG. 8—FUNDAMENTAL OF THE NO-LOAD FLUX WAVE IN THE AIR-GAP OF A SALIENT-POLE SYNCHRONOUS MACHINE

Maximum value of actual flux wave equals unity
Fundamental $A_1 = A \times B$

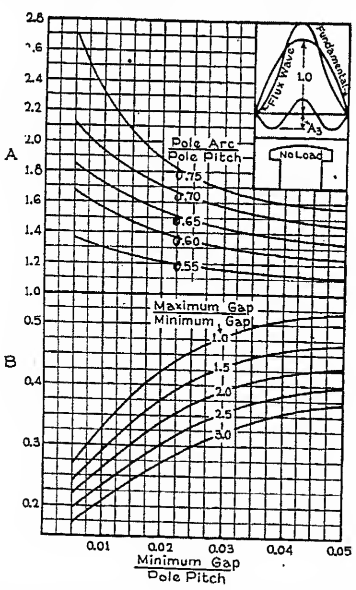

FIG. 9—THIRD HARMONIC OF THE NO-LOAD FLUX WAVE IN THE AIR-GAP OF SALIENT-POLE SYNCHRONOUS MACHINE

Maximum value of fundamental equals unity
Third harmonic $A_3 = A \times B - 0.6$

Load. A very interesting application of the flux wave third harmonic curves, Fig. 9, is the calculation of the voltage which appears at no load at the open corner of a delta-connected armature winding whose coils do not have a two-thirds pitch. It is well known that only the third harmonic or multiples of the third harmonic voltage can appear at the open delta. Since the multiples of the third harmonic flux wave are usually small, and since both the armature coil pitch and distribution further decrease the voltage produced by these flux multiple third harmonics, the multiple third harmonic voltages can be neglected. Thus, the calculation of the third harmonic voltage at the open corner of a delta-connected armature winding is very simple, if the amplitude of the flux third harmonic is known.

Let

E = Normal phase voltage of the armature winding at no load

A_3 = Amplitude of the flux wave third harmonic expressed as a decimal fraction of its fundamental Fig. 9

k_p = Armature coil pitch coefficient for the fundamental

k_d = Armature coil distribution coefficient for the fundamental

k_{3p} = Armature coil pitch coefficient for the third harmonic

k_{3d} = Armature coil distribution coefficient for the third harmonic

E_3 = Open delta voltage (third harmonic)

then

$$E_3 = 3 E A_3 \frac{k_{3p}\, k_{3d}}{k_p\, k_d}$$

This method of calculating the third harmonic delta voltage assumes that there is no saturation in the magnetic circuit and it ignores the effect of the stator and the rotor slots. These factors, however, are quite small in most machines. The three-phase machine whose pole shape is shown in Fig. 7 had 18 slots per pole, armature coil pitch 0.777, ratio of minimum gap to pole pitch 0.037, ratio of pole arc to pole pitch 0.674, ratio of maximum to minimum air-gap 1.22, and phase voltage of 3810 volts.

Thus

$$k_p = 0.939 \quad k_d = 0.955$$
$$k_{3p} = 0.49 \quad k_{3d} = 0.646$$

From

$$\text{Fig. 9, } A_3 = 1.44 \times 0.475 - 0.6 = 0.084$$

therefore

$$E_3 = 3 \times 0.084 \times 3810 \frac{0.49 \times 0.646}{0.955 \times 0.939} = 339 \text{ Volts}$$

$$E_3 \text{ by test } = 300 \text{ Volts}$$

The delta circulating current at no load is

$$I_3 = \frac{E_3}{\text{Third harmonic synchronous impedance}}$$

Calculation of Air-Gap Ampere-Turns, Using the Flux Distribution Coefficients K_ϕ and K_λ. In order to predetermine the no-load air-gap ampere-turns accurately for a pole whose pole arc radius is less than the radius of the armature face, two flux distribution co-

efficients must be obtained. It is well known that if the flux wave has a flat top, more flux (lines per pole) is required to give a certain effective voltage at the terminals of the armature winding than for a peaked flux wave. In order to obtain the flux per pole accurately, therefore, it is necessary to modify the flux equation which assumes a sinusoidal flux distribution and to introduce the flux distribution coefficient[4] K_ϕ which is the ratio of the area of the actual no load flux wave to the area of its fundamental.

Messrs. Doherty and Shirley introduced this flux coefficient K_ϕ in 1918[4], and they obtained the values of K_ϕ from flux distribution plots (see Fig. 36 of Messrs. Doherty and Shirley's paper) which assumed that the flux density varied inversely as the distance (in a straight line) from the pole face to the armature core. This, of course, is an approximate solution of the problem. Fig. 10 gives the values of K_ϕ which were obtained from the 75 hypothetical flux plots similar

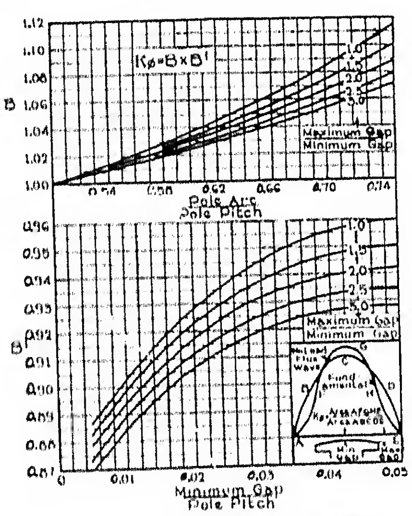

FIG. 10—FLUX DISTRIBUTION COEFFICIENT K_ϕ

to Fig. 7 where the flux distribution was obtained by actually plotting the tubes of flux. These values of K_ϕ practically check the values of K_ϕ given in Messrs. Doherty and Shirley's paper.

The introduction of K_ϕ thus gives the actual flux per pole for any flux wave. The next step is to find the average air-gap density over the pole face in order to find the necessary ampere turns to force this flux across the air-gap. It is very convenient to know the flux which passes directly out from the pole and into the armature, as shown by the shaded area, in the insert of Fig. 11. This flux is equal to K_λ times the flux per pole where K_λ is the ratio of the area $G\ B\ C\ D\ F$ to the area $A\ B\ C\ D\ E$ in Fig. 11. The average air-gap density over the pole (Region $G\ F$, Fig. 11) is K_λ times the flux per pole divided by the area of pole face. The air-gap ampere turns can now be obtained accurately since the air-gap coefficient, Fig. 2, and the reluctance of the air-gap are known.

4. *Reactance of Synchronous Machines and Its Application*, Doherty and Shirley, A. I. E. E., TRANS. Vol. XXXVII, p. 1209.

The two flux distribution coefficients K_ϕ and K_λ, calculated from the predetermined flux wave, made it possible to predetermine very closely the performance characteristics of a two-speed salient-pole synchronous motor[5]. This two-speed motor had irregular shaped poles arranged in pairs whose flux waves deviated appreciably from a sine wave at either speed.

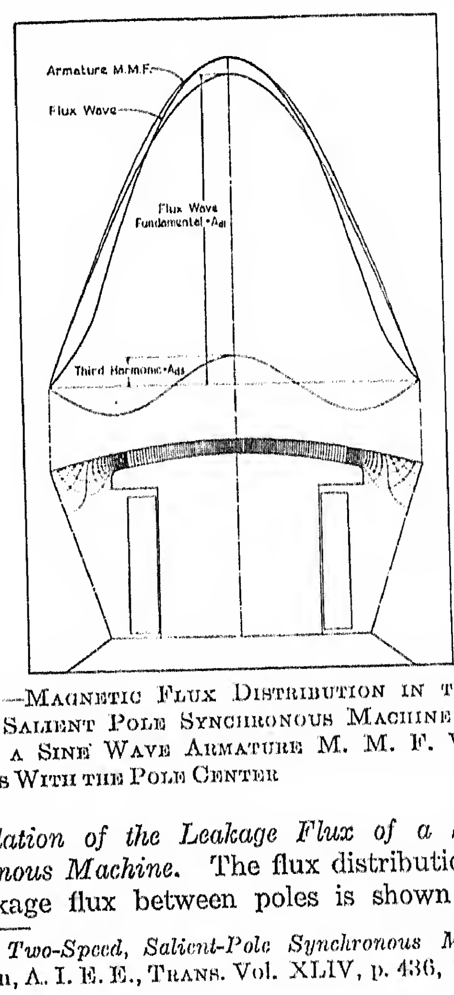

FIG. 12—MAGNETIC FLUX DISTRIBUTION IN THE AIR-GAP WHEN A SALIENT POLE SYNCHRONOUS MACHINE IS EXCITED ONLY BY A SINE WAVE ARMATURE M. M. F. WHOSE AXIS COINCIDES WITH THE POLE CENTER

Calculation of the Leakage Flux of a Salient-Pole Synchronous Machine. The flux distribution curve of the leakage flux between poles is shown in Fig. 7.

5. *A Two-Speed, Salient-Pole Synchronous Motor*, R. W. Wieseman, A. I. E. E., TRANS. Vol. XLIV, p. 436, 1924, Figs. 15, 16, 17, 18.

This curve is plotted on the interpolar center line and it neglects the small amount of leakage flux in the lower corner of the pole. The ratio of the area under the leakage flux distribution curve to the area under the main flux distribution curve in Fig. 7 plus 1 gives the leakage coefficient which is 1.16 for this pole. This coefficient should be increased slightly to allow for the small end leakage flux.

III. Magnetic Flux Distribution in the Air-Gap When a Salient-Pole Synchronous Machine is Excited Only by a Sine Wave Armature Magnetomotive Force Whose Axis Coincides With the Pole Center

Fig. 12 shows the flux distribution in the air-gap when a salient-pole synchronous machine is excited only by a sine wave armature magnetomotive force

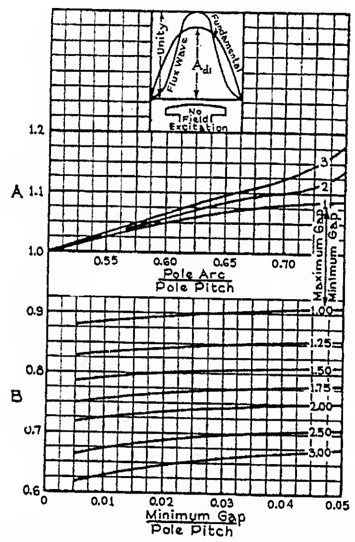

Fig. 13—Fundamental of the Air-Gap Flux Wave When a Salient Pole Synchronous Machine is Excited by Only a Sine Wave Armature M. M. F. Whose Axis Coincides with the Pole Center

Maximum value of actual flux wave equals unity
Fundamental $A_{d1} = A \times B$

whose axis coincides with the pole center. The abrupt break in the spacing of the flux lines is simply a change in scale for convenience in plotting and for allowing more flux lines to be drawn in the interpolar space. The armature flux wave in Fig. 12 is peaked while the field flux wave, Fig. 7, for the same machine is decidedly flat topped. The peaked flux wave in Fig. 12 is the flux wave which balanced polyphase armature currents tend to produce at zero power factor. The flux wave fundamental, Fig. 12, is 0.94 times the maximum value of the flux wave and the flux wave third harmonic is 0.092 times the maximum value of the fundamental.

Calculation of the Fundamental and the Third Harmonic in the Flux Wave Which Polyphase Armature Currents Tend to Produce at Sustained Short Circuit. Seventy-five hypothetical flux plots were made similar to Fig. 12 for the same range of pole shapes as previously described. These armature flux waves were analyzed for their fundamentals and third harmonics, the values of which are shown in Figs. 13 and 14. In Fig. 13, the fundamental A_{d1} is expressed as a decimal fraction of the maximum value of the flux wave which is taken

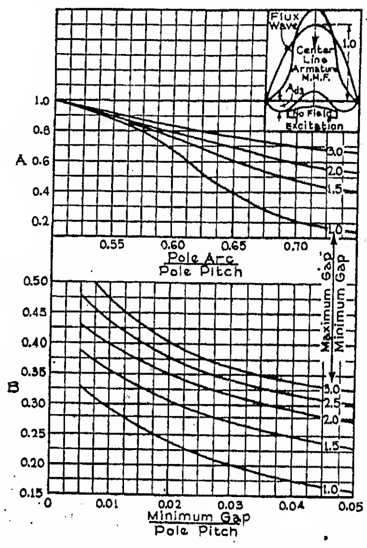

Fig. 14—Third Harmonic of the Air-Gap Flux Wave When a Salient-Pole Synchronous Machine is Excited Only by a Sine Wave Armature M. M. F. Whose Axis Coincides with the Pole Center

Maximum value of fundamental equals unity
Third harmonic $A_{d3} = -A \times B$

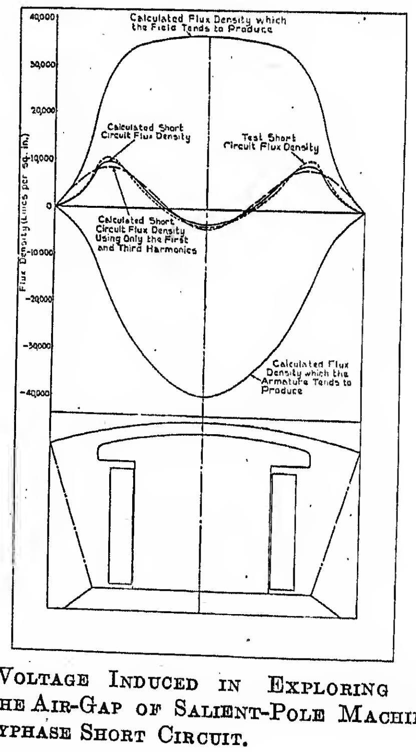

Fig. 15—Voltage Induced in Exploring Conductor Placed in the Air-Gap of Salient-Pole Machine at Sustained Polyphase Short Circuit.

as unity. In Fig. 14, the third harmonic A_{d3} is expressed as a decimal fraction of the fundamental which is taken as unity.

Predetermination of the Flux Wave in the Air-Gap of a Salient-Pole Synchronous Machine at Sustained

Polyphase Short Circuit. When a polyphase salient-pole generator is short-circuited, the armature m. m. f. is in opposition to the field m. m. f. If the armature resistance is neglected, the sustained air-gap short-circuit flux, which travels in synchronism with the pole, can be obtained readily by subtracting the armature flux wave in Fig. 12 from the field flux wave, Fig. 7. This short-circuit wave is shown in Fig. 15. Fig. 16 shows

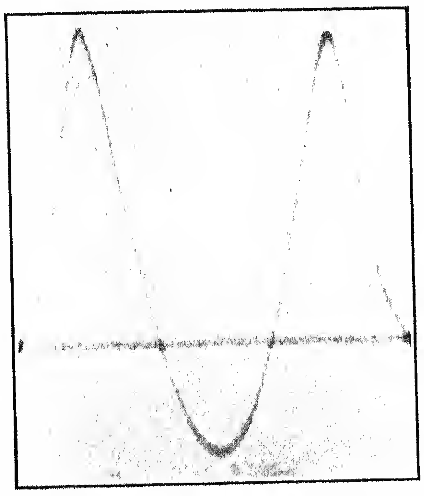

FIG. 16.—VOLTAGE INDUCED IN EXPLORING CONDUCTOR PLACED IN THE AIR-GAP OF A SALIENT-POLE MACHINE AT SUSTAINING POLYPHASE SHORT CIRCUIT

the actual short-circuit flux wave obtained with an exploring conductor placed on the armature surface and this wave is also plotted in Fig. 15. The flux wave, Fig. 16, must include such flux waves which are not in synchronism with the pole and, therefore, this wave must be slightly different from the calculated flux wave in Fig. 15.

Calculation of the Stray Core Loss in the Armature Teeth of a Salient-Pole Synchronous Machine at Sustained Polyphase Short Circuit. The short-circuit flux wave can be predetermined approximately by combining the fundamentals and third harmonics of the field flux waves, Figs. 7, 8, and 9, with the armature flux waves, Figs. 12, 13, and 14. Fig. 15 shows the short-circuit flux wave obtained by this method. The stray core loss in the armature teeth of a salient-pole machine at sustained polyphase short circuit can now be predetermined. The problem can be simplified by neglecting the fundamental which is usually small and using only the resultant third harmonic flux.

The full-load flux wave of a synchronous condenser at zero power factor either over or under excited can also be predetermined by this method.

IV. MAGNETIC FLUX DISTRIBUTION IN THE AIR-GAP WHEN A SALIENT-POLE SYNCHRONOUS MACHINE IS EXCITED ONLY BY A SINE-WAVE ARMATURE MAGNETOMOTIVE FORCE WHOSE AXIS IS IN QUADRATURE WITH THE POLE CENTER

Fig. 17 shows the flux distribution in the air-gap when a salient-pole machine is excited only by a sine wave armature m. m. f. whose axis is in quadrature with the pole center. The effect of saturation and of the stator and rotor slots is neglected. The armature flux wave is made up principally of a fundamental and a large third harmonic. The flux wave fundamental is 0.54 times the maximum value of the armature m. m. f., and the flux wave third harmonic is 0.43 times the maximum value of the fundamental.

Seventy-five hypothetical flux plots similar to Fig. 17 were made of the air-gap flux which the armature currents tend to produce when the armature m. m. f. is in quadrature with the pole center. These flux waves were analyzed for their fundamentals and third harmonics, the values of which are shown in Figs. 18 and 19. In Fig. 18, the armature flux fundamental

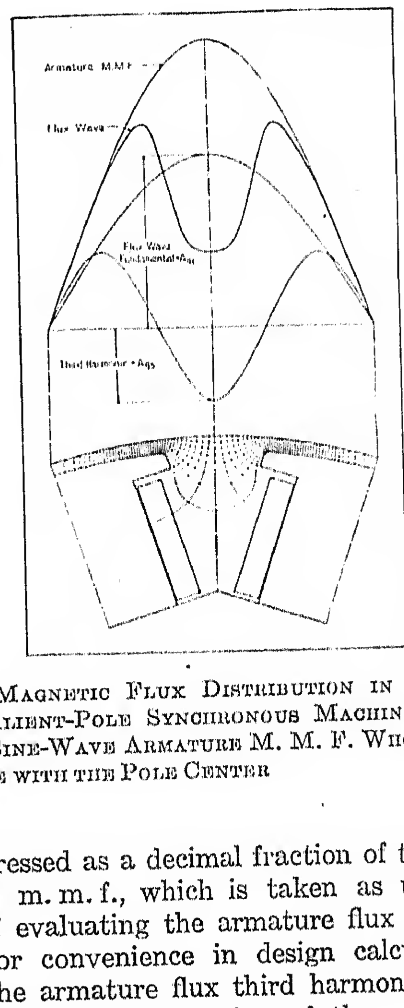

FIG. 17—MAGNETIC FLUX DISTRIBUTION IN THE AIR-GAP WHEN A SALIENT-POLE SYNCHRONOUS MACHINE IS EXCITED BY ONLY A SINE-WAVE ARMATURE M. M. F. WHOSE AXIS IS IN QUADRATURE WITH THE POLE CENTER

A_{q1} is expressed as a decimal fraction of the armature sine wave m. m. f., which is taken as unity. This method of evaluating the armature flux fundamental is done for convenience in design calculations. In Fig. 19, the armature flux third harmonic A_{q3} is expressed as a decimal fraction of the armature flux fundamental which is taken as unity.

Calculation of Displacement Angle of a Salient-Pole Synchronous Machine. It is well known that an a-c. generator rotor leads its voltage, and a synchronous motor rotor lags behind the line voltage. The power or displacement angle of lead or lag is caused by the armature flux distorting the field flux. The fundamental A_{q1} which can be obtained from Fig. 18 is thus a

measure of this distortional effect[6]. The harmonics of the armature flux have no distortional effect on the field flux fundamental, and since the harmonics of the field flux are usually small, the displacement angle can

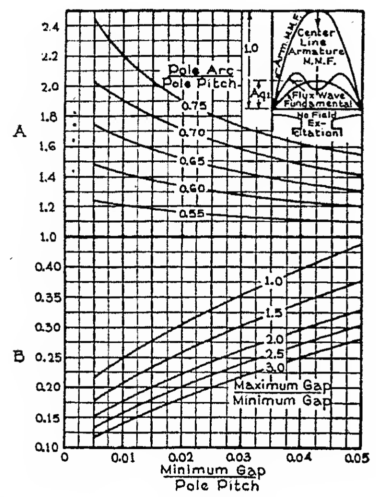

FIG. 18—FUNDAMENTAL OF THE AIR-GAP FLUX WAVE WHEN A SALIENT-POLE SYNCHRONOUS MACHINE IS EXCITED BY ONLY A SINE WAVE ARMATURE M. M. F. WHOSE AXIS IS IN QUADRATURE WITH THE POLE CENTER

Maximum value of armature m. m. f. equals unity
Fundamental $A_{q1} = A \times B$

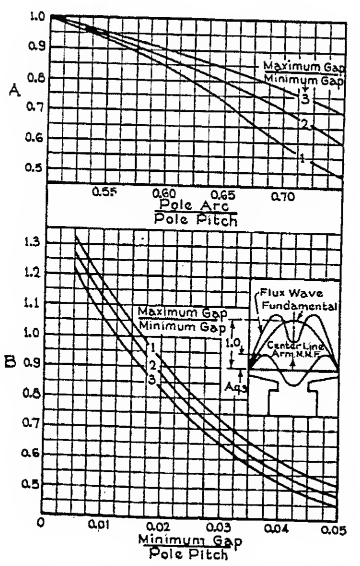

FIG. 19—THIRD HARMONIC OF THE AIR-GAP FLUX WAVE WHEN A SALIENT-POLE SYNCHRONOUS MACHINE IS EXCITED BY ONLY A SINE WAVE ARMATURE M. M. F. WHOSE AXIS IS IN QUADRATURE WITH THE POLE CENTER

Maximum value of armature flux fundamental equals unity
Third harmonic $A_{q3} = A \times B$

be obtained by combining properly the armature flux fundamental A_{q1} with the field flux fundamental A_1.

Furthermore, by combining the fundamentals and third harmonics A_1, A_3, A_{d1}, A_{d3}, A_{q1}, and A_{q3}, which can be readily obtained from Figs. 8, 9, 13, 14, 18, and 19, the air-gap flux wave of a salient-pole synchronous machine can be approximated for any load condition.

Additional practical applications of plotting magnetic flux distribution curves will be given in a future paper.

The author gratefully acknowledges the assistance of Mr. L. P. Shildneck in plotting some of the flux distribution curves.

Discussion

PAPERS ON GRAPHICAL DETERMINATION OF MAGNETIC FIELDS

(STEVENSON AND PARK, JOHNSON AND GREEN, WIESEMAN)
NEW YORK, N. Y., FEBRUARY 8, 1927

C. H. Linder: Any simple experimental method of magnetic field plotting is very useful in connection with a mathematical investigation of flux distribution. The accompanying Figs. 1 to 9 demonstrate the efficacy of the iron-filing method for determining the general form of a magnetic field.

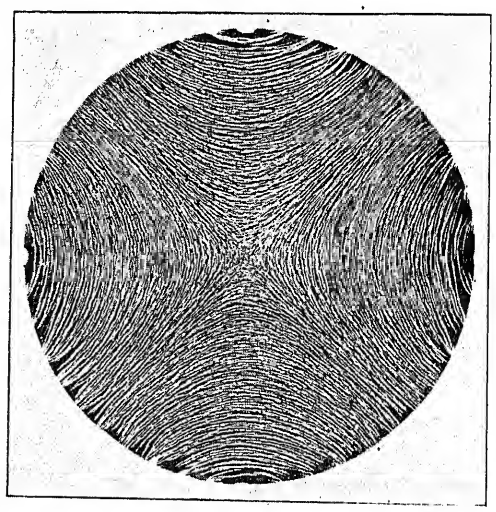

FIG. 1

This is a four-pole induction motor with the rotor removed and the stator windings excited with three-phase currents for a particular instant of balanced operation. The iron filings are aligned to indicate the 4 poles of the stator winding. The tuft of the filings around the circumference of the stator is due to the presence of the stator teeth.

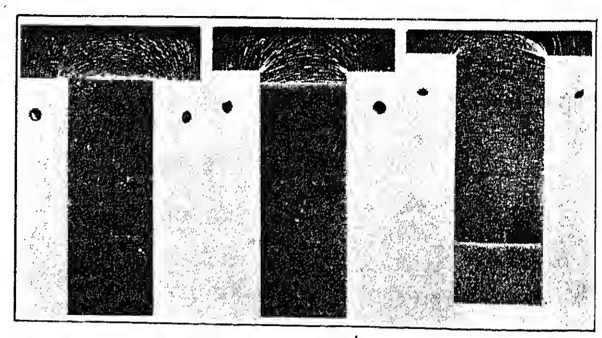

FIG. 2

The calculation of slot reactance is usually made on the assumption that a horizontal element of current in the slot produces no flux between the element and the bottom of the slot. The only flux produced by the horizontal element of current must cross the slot above the element, assuming no saturation. In these three cases the current is confined to a horizontal copper strip. Intense magnetic field exists above the element, whereas below no field is indicated by the filings.

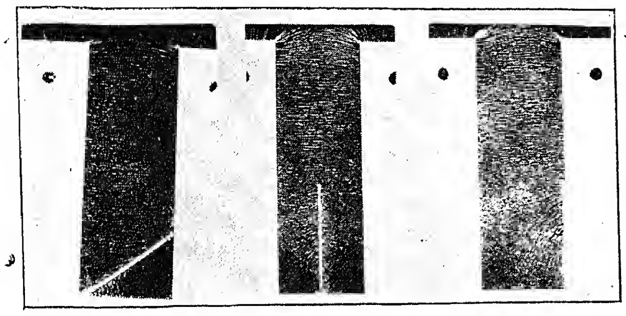

Fig. 3

The strip of current carrying copper along the side of the slot in the right hand figure represents, after a manner, the current in the field winding of a salient pole machine. The flux indicated by the iron filings is equivalent to the field pole leakage flux. Evidently, the flux density increases from zero at the bottom of the slot to a maximum at the top of the current element. The center and left hand exposures have no practical application, but merely indicate flux distributions with the current element in two positions.

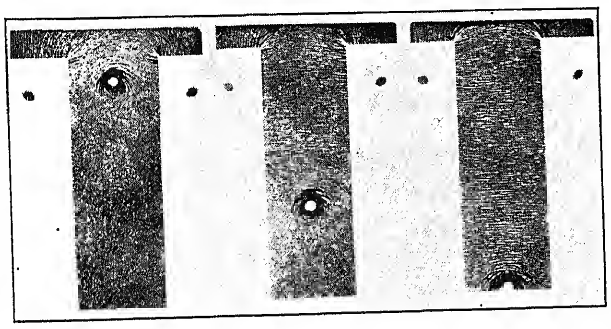

Fig. 4

By superposing the magnetic fields produced by a current carrying conductor located at a number of positions in the slot, the resultant magnetic field due to a current carrying armature coil can be obtained. Superposition of fluxes is only allowable where saturation does not exist.

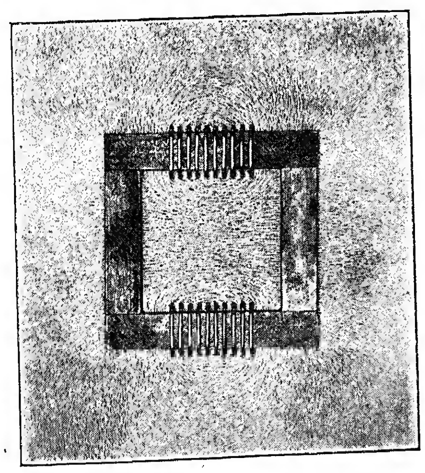

Fig. 5

A number of theoretical magnetic circuits have been studied, the magnetic field being plotted mathematically, graphically and experimentally. Such a circuit of rectangular form is shown here. The coils on the perpendicular legs are magnetized to send flux upward. Full potential, therefore, exists between the top and bottom horizontal arms. This accounts for the large amount of leakage flux in the perpendicular gap between the coils.

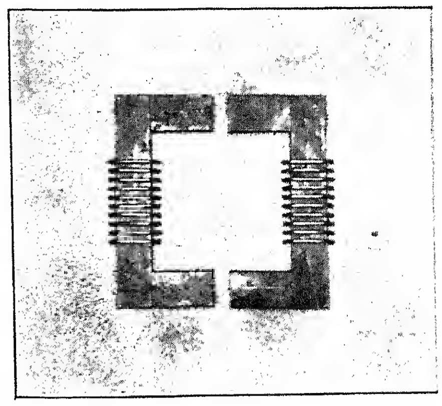

Fig. 6

This circuit is identical with No. 5 except for the air-gaps inserted in the horizontal arms.

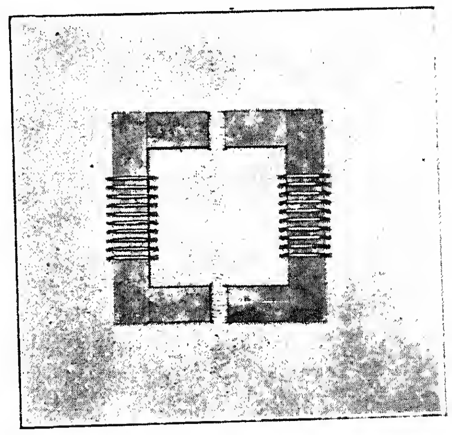

Fig. 7

This is similar to No. 6 except that the coils on the perpendicular arms are magnetized in the same direction; that is, with magnetomotive forces adding. The resultant flux around the circuit is the sum of that which would be produced by considering each coil alone, neglecting saturation. The flux density in the gap is very great, indicated by the tufting of the flux at the gaps.

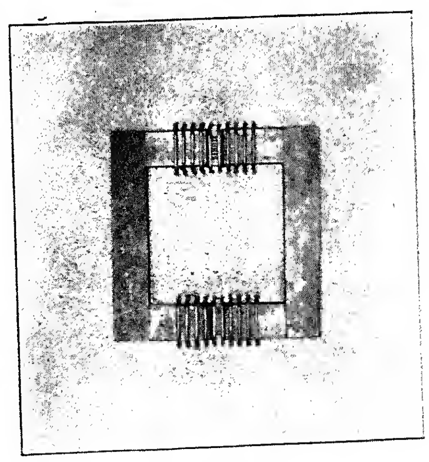

Fig. 8

The air-gaps are situated under the excited coils. Before this field was photographed extreme difficulty was experienced in an attempt to construct the field graphically. The difficulty was one of magnetomotive force distribution.

C. M. Laffoon: The graphical method of mapping electric and magnetic fields has been used by designing engineers for a large number of years to determine the physical dimensions and performance characteristics of electrical machines. In most instances, no particular effort was made to insure that the flux distribution satisfied all of the theoretical conditions, yet very accurate and reliable results were obtained. This was particularly true in calculating the magnitude and shape of the e. m. f. waves of rotating electrical machinery.

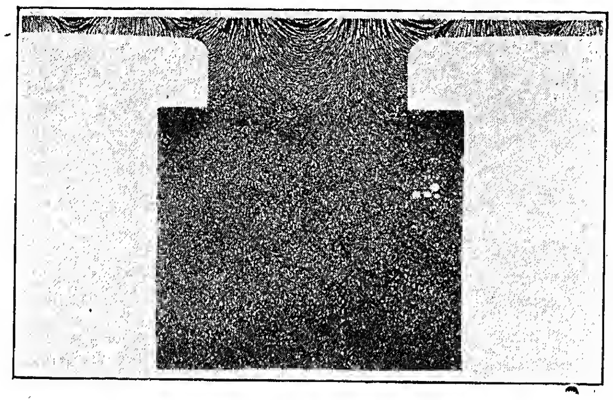

Fig. 9

The stator and a portion of two field poles of a synchronous machine with a fifth harmonic cosine of magnetomotive force impressed along the stator periphery. The flux distribution shown is the result. This particular circuit was employed in certain studies made in conjunction with the preparation of the paper "Synchronous Machines—Part I" by Messrs. Doherty and Nickle.

It has only been during the last two or three years that special consideration has been given to the problem of determining the distribution of the magnetic field in the space occupied by and adjacent to the electric conductors, with greater accuracy and refinement, by means of both mathematical and graphical methods of analysis. There can hardly be any question but that the mathematical method of analysis is the most rigorous and scientific, yet in most cases the graphical method is simpler and more convenient to use, and gives equally reliable results. It is for this reason that our own efforts have been confined to the use of the graphical method.

In Mr. Wieseman's paper, the graphical determination of magnetic fields has been applied to salient pole synchronous machines for the case in which the magnetization is produced by either the stator or rotor windings alone. The flux distribution for these cases are also given in the paper on *Additional Losses in Synchronous Machines*, by Mr. Calvert and myself. It is interesting to note that the results are essentially the same in the two papers. We have also applied the graphical method of determining magnetic fields to turbine-generators in connection with studies on additional losses and leakage reactances. In this connection, the distribution of the magnetic field in the following parts of the magnetic circuit of a turbine generator have been determined:

1. Air-gap space for the following load conditions:
   a. No load with rotor excited to give normal voltage,
   b. No load with the stator excited to give normal voltage,
   c. Full load at power factors of zero, 80, and 100 per cent.
2. End-bell space under the same load conditions as for No. 1.
3. Rotor and stator core at no load with the rotor excited to give normal voltage.

Part of these results are given in our paper on *Additional Losses in Synchronous Machines*. Some of the remaining cases will be referred to in a discussion by Mr. J. F. Calvert.

J. F. Calvert: In making flux plots, the greatest assistance that one can have is another drawing of a similar field. If a sufficient number of type cases can be solved then the solution of any particular problem becomes quite easy. It is probable that twenty or thirty of these reference solutions would cover practically all of the special types of problems which could be found in making the two dimensional figures for rotating apparatus. In electrical machines the arrangement of the magnetomotive

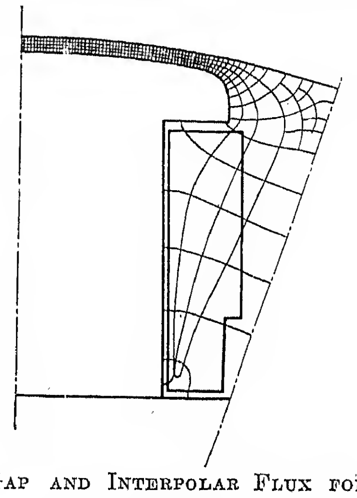

Fig. 10—Air-Gap and Interpolar Flux for a Ten-Pole Machine

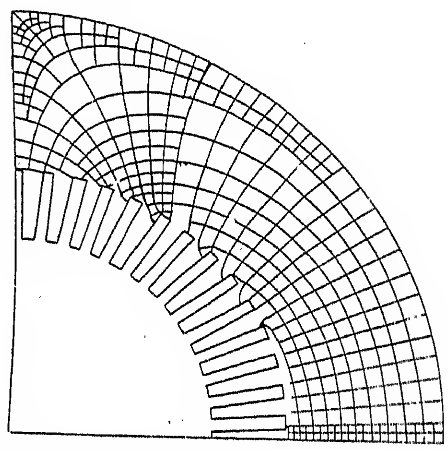

Fig. 11—Flux Distribution in the Core of a Two-Pole Turbine Generator on the Assumption of Uniform Permeability

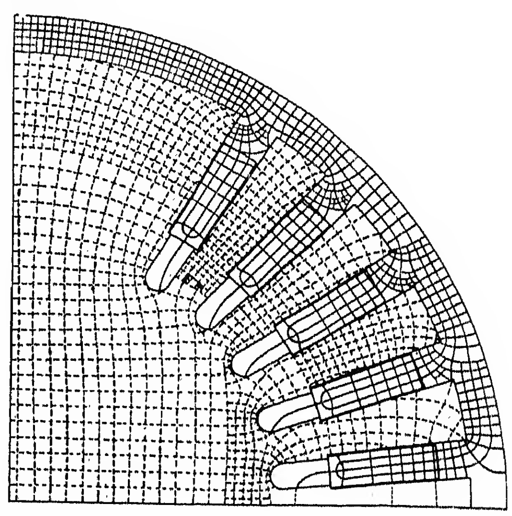

Fig. 12—Flux Distribution in the Rotor of a Two-Pole Turbine Generator

forces and the iron surfaces are usually such as to render a mathematical solution either very difficult or in many cases wholly impossible at the present time. Therefore, it would seem that a good procedure would be to project the work by graphical solutions which should later be verified or corrected by mathematical solutions whenever possible.

Somewhat recently we have been doing work along similar

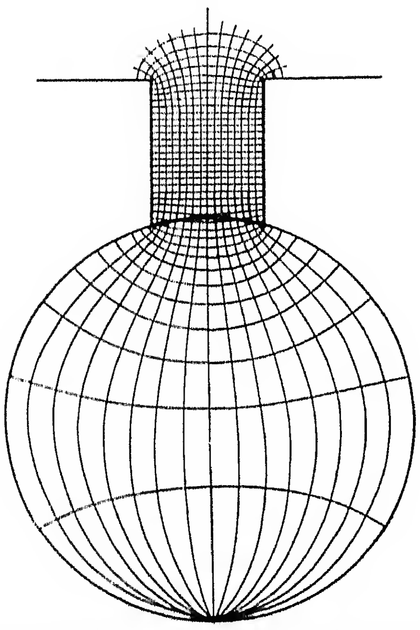

FIG. 13—FLUX DISTRIBUTION ACROSS A ROUND SLOT WHEN THE CONDUCTOR IS IN CONTACT WITH THE IRON

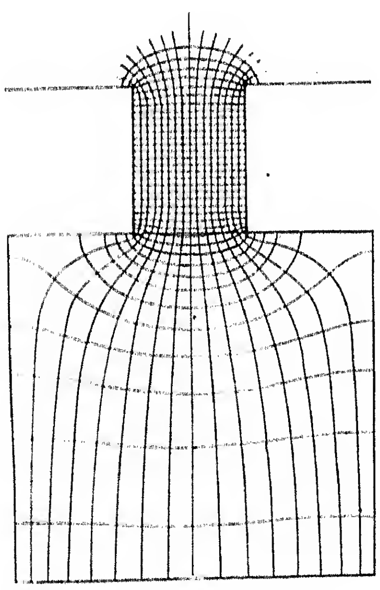

FIG. 14—FLUX DISTRIBUTION ACROSS A RECTANGULAR SLOT WHEN THE CONDUCTOR IS IN CONTACT WITH THE IRON

lines to establish graphical solutions, but our work was done primarily in connection with loss studies. The theoretical basis of our work is described in the latter part of a paper on *Additional Losses of Synchronous Machines*. Examples are shown there of the application of the theoretical principles for plotting fields in the interpolar space on salient pole machines, and in the air-gap and end-bell zones of non-salient pole machines. In the latter solutions for non-salient pole machines, both the stator and the rotor windings are assumed to be carrying currents.

In Figs. 10 to 15 accompanying this discussion are shown graphical solutions to some other magnetic problems of interest. In the figures showing the flux distribution inside of the damper bars under steady conditions, the exact location of the kernel or center is rather difficult. The location of this point makes a considerable difference in the appearance of the picture, but usually makes very little difference in the total amount of flux and much less difference in the flux turn interlinkages. Mathematical solution, however, should locate these points beyond a doubt.

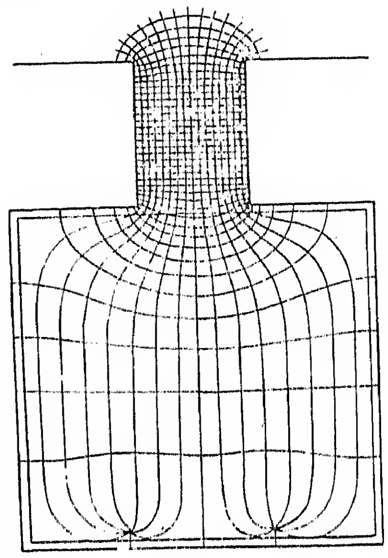

FIG. 15—FLUX DISTRIBUTION ACROSS A RECTANGULAR SLOT WHEN THE CONDUCTOR IS NOT IN CONTACT WITH THE IRON

J. S. Woodward (contributed after adjournment): In discussion of the paper by Messrs. Stevenson and Park, Mr. J. F. Calvert presented two figures showing the flux distribution in a slot containing a conductor carrying current. The correctness of these two flux plots presented was questioned, and Messrs. Stevenson and Park asked me to calculate the distributions by the mathematical theory, outlined in their paper. The result of such calculation is shown in Figs. 16 and 17 herewith.

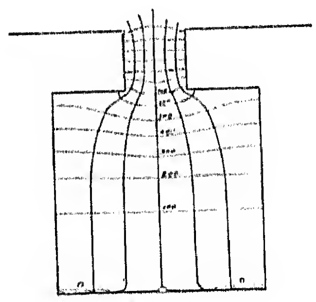

FIG. 16

Fig. 16 shows the flux distribution in a slot where the copper and iron are in contact with each other. Here, the calculations show there are two kernels, or foci, of the lines of no work, located in the lower corners of the slot.

Fig. 17 shows the flux distribution for the case of copper and iron insulated from each other, and here, there is but one kernel located on the vertical center line slightly above the bottom edge of the copper.

In both cases the flux lines at any appreciable distance from the kernel are very nearly flat, and the lines of no work are nearly vertical as they approach the bottom of the slot. Near the bottom, they turn sharply toward the kernel and are crowded together in the bottom of the slot. An enlarged view of the flux

in the bottom of the slot is shown in the accompanying Figs. 18 and 19, which refer to Figs. 16 and 17, respectively. The sharp curvature of the lines of flux and also of the lines of no work is of particular interest as it illustrates the general statement made in Part II of the paper as to the action of these lines in the vicinity of the kernel.

The two cases under discussion are of interest, as they bring up the question of the location of the kernel. In free-hand plotting, the location of this point is important as it furnishes a basis for

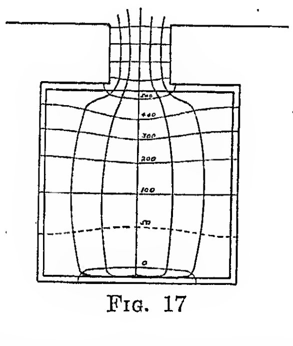

FIG. 17

drawing in the lines of no work. The location of the kernel is determined by the boundary conditions of the copper.

In Fig. 16, were the slot of infinite depth and not partly closed at the top, the flux would go straight across the copper and the kernel would become the line at the bottom of the slot. If the slot were open at the top and not of infinite depth, the flux would be concave downward and there would be one kernel located on the vertical center line of the slot.

In Fig. 16, where the top of the slot is partially closed, the flux is concave upward, and this condition, carried to the bottom of the slot, causes the flux leaving the sides of the slot near the bottom to enter the iron before reaching the vertical center line and as a result there are two kernels, one in each lower corner of the slot.

In Fig. 17, if the slot were not partially closed at the top there would still be but one kernel, located on the vertical center line, but this kernel would be farther from the bottom edge of the copper than is the case in the figure. Partially closing the slot causes the flux near the top of the slot to have a curvature that is concave upward, thus tending to depress the kernel.

In Fig. 17, it may be observed that the curvature of the flux lines reverses approximately at the line marked 100. From there down, the curvature is concave downward; hence the effect of the insulation predominates and we have but one kernel, located as shown. It is possible to obtain two kernels in the general case of a partially closed slot, when the conductor is insulated from the iron, by making the insulation thinner or by

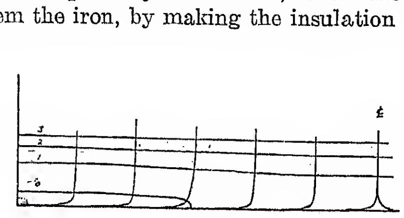

FIG. 18

making the depth of the slot smaller in comparision with the width.

In locating the kernel from a plot made by the mathematical formula, where the flux lines close to the kernel are very flat, two considerations may be followed. First, the general location of the kernel will be clearly indicated, as it is known to be in the region of lowest flux density, the density at the kernel being zero. Secondly, the flux lines surround the kernel, and the rate of change of flux, along any line passing through the kernel will change from positive to negative as the kernel is passed. Hence, by taking $\partial r/\partial x = 0$ for a value of (y) known to lie near the kernel, the (x) coordinate of the kernel will be obtained to a high degree of approximation. Then, taking $\partial R/\partial y = 0$ along this (x) coordinate will be determined to good accuracy. The accuracy can be made as great as desired by repeating this process.

Th. Lehmann (communicated after adjournment): By their ingenious extension of Professor Rogowski's method of calculation to interpolar fields, Messrs. Stevenson and Park have shown that in certain cases the Fourier method has some advantages over the method of conformal representation, even though the latter method can be used to solve Poisson's equation, as has already been shown by E. B. Christoffel[1].

But I maintain that Messrs. Stevenson and Park have furnished by their work a very welcome check on the graphical method of determining lines of force. The result of this comparison is satisfactory, and the same is true of the very cleverly arranged experimental check by Messrs. Johnson and Green, which corroborates perfectly the sketches of the lines of force plotted by Messrs. Wieseman and Shildneck.

The fact that it was possible for Mr. Wieseman to obtain by the graphical method values which check within 1 per cent with Mr. Carter's equation for air-gap reluctance of infinite teeth, shows eloquently the great accuracy which can be obtained by the graphical method if it is used methodically and with judgment.

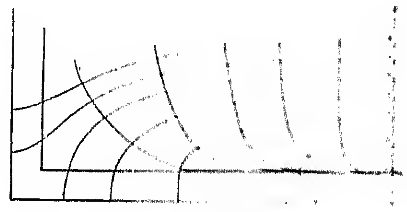

FIG. 19

Further, the charts and functional curves given in these papers for air-gap reluctance, tooth harmonics, reactances, etc., will be of service to practical engineers, and will save them a great deal of work, for which much credit should be given to the authors.

One might perhaps think that the assumption of infinite permeability in the iron would reduce somewhat the practical use of the sketches of lines of force given by the authors.

I am of the opinion that, in spite of this, these sketches are still interesting and valuable, even in the case where the poles are saturated, for the following two reasons. First, the saturation of the poles does not seem to have more than a slight influence on the interpolar flux for a given useful armature flux, even though the body of the pole absorbs as much as 30 per cent of the total ampere-turns. Further, even if one desires to take account of the influence of saturation, the sketches of the lines of force for $\mu = \infty$ can still be used as a basis.

I will later show how, with the aid of a sketch of lines of force obtained on the assumption of infinite permeability, one can deduce rigorously the actual distribution of the field when the circuit is saturated.

The sketches of lines of force given by the authors are, therefore, still of actual practical interest, even when there is considerable saturation in the iron, and it has seemed worth while to me to emphasize this fact.

J. F. H. Douglas: In one of the three papers a preference is expressed for graphical methods and I wish to say that with this new development of a means of treating the interior of copper, locating the flux and lines of zero work in that way, we have perhaps the most valuable contribution that has been made to the subject for many years.

1. E. B. Christoffel, Annali di Mathematica, 1867, ser. II, Vol. I, fasc. 1°, p. 89.

The test methods which I have used—namely, the use of high-resistance templets—are inadequate for such cases . Nevertheless, I cannot quite pass the matter without protesting that the difficulty attached to making tests with templets is somewhat exaggerated. It is a very speedy method, both for determining total reactance and also for determining flux densities to any point of the boundary.

I have used all three methods and templets, and I find the labor with templets somewhat less than in the case of using graphical distribution, and decidedly less than that using the functions of complex variable.

I do not think that the possibilities of the functions of complex variable, however, have been fully appreciated. Generally the writers feel it incumbent to evaluate the whole field of force. Where problems of boundary densities are concerned, which alone would be of interest in loss calculations, and where problems of the total reactance or permeance of the field is in question, then there is a very neat way of handling Schwartz's and Christophel's theorem, which I don't recall having seen in print. That is a method of graphical integration around the boundary. Schwartz's and Christophel's theorem is a very simple matter of formulating, provided the boundaries are straight line boundaries, but extremely difficult to integrate, except for the simplest cases. Nevertheless, on the boundary, the functions are wholly real and a graphical integration is easily possible.

I ask Mr. Wieseman one or two specific questions. I should like, either now or in the written closure, information as to whether Fig. 2 checks my 1915 work[2] and whether Fig. 3 checks[2] my 1924 work.[3]

I should like also to make one or two detailed comments. In Mr. Wieseman's paper is the statement: "If the number of teeth spanned by a pole varies, a certain amount of flux pulsation is necessary."

There is one shape of pole which will avoid all pulsations when used with armatures of any amount of slotting and every amount of slotting; namely that pole shape which gives a perfect sine wave on the equivalent armature circuit. Such a punching could be used with any amount of slotting opposite, without pulsation. The proof of this proposition was given in the appendix of the paper read by Douglas and Kane in Chicago two years this coming June.

A rough calculation of Mr. Wieseman's coefficient as $A\,q\,1$ and as $A\,D\,1$ for complete range of pole pitches, air-gaps, and pole-face curvatures used seems to lie within the range of 40 to 60 per cent. It seems that the problem of obtaining extremely high pull-out torque (I mean pull-out torques greatly in excess of present ratings) is not yet possible without a radical change of pole design.

It may be that there are some particular combinations of pole pitch, air-gap, and pole curvature which will give smaller ratios of the transverse coefficient, but it should now be clear that in order to develop extremely sturdy synchronous motors, it is needful that the ratios of $A\,q1$ to $A\,d1$ should be brought very much less.

Vladimir Karapetoff: (communicated after adjournment) The mathematical treatment in Appendix C may be given also in the language of vector analysis. While the authors are justified in using ordinary partial derivatives, so as to make the theory comprehensible to a larger circle of engineers, yet, with an ever increasing interest in vector analysis among younger engineers and physicists, the alternative abbreviated treatment, added below, may not, for the sake of completeness, be out of place. Several elementary works on vector analysis are now available, so that the exposition is given without proofs or definitions. The great advantage of this new "short-hand" language is that no axes of coordinates are used (crutches or scaffolding, as some vector analysis enthusiasts call them), and the quantities concerned are dealt with directly in their magnitude and direction in space, thus bringing out more clearly the physical relationships.

By the definition of vector potential

$$\mathbf{H} = -\nabla \times \mathbf{R} \tag{1}$$

According to the magnetic-circuitation law

$$4\,\pi\,\mathbf{i} = \nabla \times \mathbf{H} \tag{2}$$

Substituting **H** from (1) in (2), gives

$$-4\,\pi\,\mathbf{i} = \nabla \times (\nabla \times \mathbf{R}) \tag{3}$$

Since the vector potential is defined through its curl only an additional condition may be imposed; namely, that **R** is a solenoidal vector ($\nabla\,.\,R = 0$).

Hence

$$\nabla \times (\nabla \times \mathbf{R}) = \nabla\,(\nabla\,.\,\mathbf{R}) - \mathbf{R}\,(\nabla\,.\,\nabla) = -\nabla^2\,\mathbf{R} \tag{4}$$

Consequently, Eq. (3) becomes

$$4\,\pi\,\mathbf{i} = \nabla^2\,\mathbf{R} \tag{5}$$

which is identical with Eq. (30) in the paper, ∇^2 being the Laplacian operator. If, in Eq. (2), H were expressed in rational units, the factor $4\,\pi$ would be entirely absent from the equations, thus still further simplifying the result.

In a two-dimensional field, according to Eq. (1), if the component of **H** in a certain direction is zero, **R** must be constant in the perpendicular direction. This follows directly from the definition of the curl as a line integral. Consequently, the equation of a line of force is **R** = const.

At a point in the two-dimensional field, consider the direction n in which R varies most rapidly. We then have from Eq. (1), for the absolute value of H:

$$H = \partial\,R / \partial\,n \tag{6}$$

so that

$$d\,R = H\,d\,n \tag{7}$$

This result indicates that an increment of R is equal to the flux between two lines of force to which the two values of R refer; Eq. (33) in the paper.

R. W. Wieseman: Perhaps the most interesting, as well as the most important, application of graphical flux plotting at the present time is the calculation of the quadrature synchronous reactance of a salient-pole machine. As a matter of fact, the value of the quadrature synchronous reactance can be predetermined only by a field plot. This quadrature synchronous reactance is one of the several coefficients which appear in the paper *Synchronous Machines*, Part II, 1926, by Messrs. Doherty and Nickle.

In a polyphase machine, the armature currents produce a sine wave of flux which travels in synchronism with the poles. When the armature m. m. f. axis coincides with the pole axis (for example, at zero power factor), the flux which the armature currents tend to produce is much more than the armature flux when the armature m. m. f. axis is in quadrature with the pole. Thus, the direct synchronous reactance is more than quadrature synchronous reactance.

Let the normal fundamental flux per pole = ϕ and let the normal armature currents produce a flux ϕ_q in the quadrature axis.

Let the fundamental of this armature flux = ϕ_{q1}

Let X_{lq} equal the armature leakage reactance (expressed as a decimal fraction) in the quadrature axis.

Then the quadrature synchronous reactance $X_q = \dfrac{\phi_{q1}}{\phi} + X_{lq}$.

The values of ϕ_{q1}, as well as many other coefficients, are given in this paper.

With reference to the Laffoon and Calvert discussion: I note that they also prefer the graphical method of obtaining the flux distribution and the flux distribution coefficients for design calculations.

Mr. Douglas stated that the templet method is very speedy, and that the labor involved with templets is somewhat less

2. *Potential Gradient and Flux Density*, by J. F. H. Douglas and E. W. Kane, TRANS. A. I. E. E., 1924, p. 982.
3. *The Reluctance of Some Irregular Magnetic Fields*, by J. F. H. Douglas, TRANS. A. I. E. E., 1915, p. 1067.

than in the case of using the graphical method. There are a few simple cases of magnetic-flux distribution where the templet method can be used to advantage, especially in illustrating flux fringing to students. When, however, the flux distribution is to be obtained in the many different magnetic parts of dynamo machinery, I prefer the graphical method, and I have found that the results obtained by this method are quite accurate.

Mr. Douglas requested information as to whether Figs. 2 and 3 checked his work. In Mr. Douglas' 1915 paper, the ratio of the slot width to the tooth width is very much larger than is used in Fig. 2 of my paper. Consequently, no check can be made. Fig. 6 in the article by Messrs. Douglas and Kane, in 1924, practically checks my Fig. 3.

Mr. Douglas stated that the flux pulsations can be avoided with armatures having any number of teeth, if the pole gives a perfect sine wave of flux on the equivalent armature circuit.

Salient-pole machines practically never have perfect sine flux waves and, therefore, this method of eliminating flux pulsations cannot be used.

A. R. Stevenson: Messrs. Laffoon and Calvert are right in saying that the graphical method is the most convenient one for use in the everyday designing of electrical machinery, but the mathematical method is of importance in the preparation of the 20 or 30 typical flux plots which Mr. Calvert mentioned as being of great assistance in sketching similar fields. Although these typical flux plots can be determined to any degree of accuracy by the graphical method, in some cases it takes a great deal of experimental sketching before the general outline of the distribution can be determined; whereas, in such cases, the mathematical method will sometimes give a more accurate answer with less work, in less time.

The best articles on graphical plotting are contained in the long series of articles by Lehmann, mentioned in the bibliography of our paper. He carried the graphical method of plotting much farther than we did, including in the problem the saturation in the iron. If anyone desires to study the graphical method further, he could not do better than to refer to Lehmann's work.

Mr. Calvert, in his discussion, has submitted six pictures of flux distributions sketched by the graphical method. The two showing the flux distribution in a square bar in a square slot did not look quite right to us. They are sufficiently accurate for all practical purposes; but we do not agree with the location of the kernels, and Mr. Woodward has submitting a discussion in which he shows the flux distribution in these same square bars in square slots, as determined by the mathematical method described in our paper.

Professor Douglas' discussion is of special interest because of the articles he has already published on this subject, especially with regard to the templet method of determining flux distribution and also because of his remarks about the use of the theory of functions of a complex variable in connection with these problems. The valuable work of Dr. Carter in this connection is well known, and is especially interesting because of the recent publication of another paper in which he applies the method to many new distributions which had not been attempted before.[4] The application of the Schwarz and Christoffel transformation is very difficult when it is necessary to integrate around more than four angles, and the suggestion by Professor Douglas of a graphical method of integration should be of great assistance in the application of the theory of functions of a complex variable to these problems.

The authors are very grateful to Dr. Lehmann for emphasizing that their sketches of magnetic lines of force are of actual practical value, in spite of the fact that saturation was neglected. The article by E. B. Christoffel, which he mentions, we think will be a valuable addition to the bibliography, although his discussion came in so late that we have not had a chance yet to look it up. The use of conformal representation for the solution of Poisson's equation has been done by St. Venat in the solution of the torsion of rods; see, for example, Love's "Theory of Elasticity." Herr M. Strutt, in the *Archiv fur Elektrotechnik*, April 7, 1927, has applied this method to the approximate solution of the case of a current-carrying rectangular iron conductor of constant (high) permeability.

Mr. E. E. Johnson: While the iron-filing method gives excellent indications of the form of the magnetic field, the field plots so determined must not be interpreted too strictly as regards field intensities. When making the iron-filing distributions, the filings, which are preferably of cast iron, are first distributed on some suitable plain surface, such as white paper. The m. m. fs. are then applied and the whole structure is gently tapped to allow the filings to take their proper conformations.

In the process of tapping, the iron filings in the near vicinity of highly magnetized iron surfaces have a tendency to skip along the paper and gather in clusters on those surfaces. Also, even in uniform magnetic fields of high intensity the filings cluster together in strings. This clustering leaves free open spaces, from which it might be inferred, on superficial examination, that the flux density is low at these points.

Mr. Green and I are very grateful for the comments of Mr. Laffoon and Mr. Calvert. The experimental method which we have used for determining the field distribution inside of current-carrying regions is not always convenient although there may be cases where it might with profit be employed. The method was used in the particular case of the alternator field poles as a check upon the work which Mr. Stevenson and Mr. Park did in their paper.

Design of Reactances and Transformers Which Carry Direct Current

BY C. R. HANNA[1]

Associate, A. I. E. E.

Synopsis.—It is usually necessary to place an air-gap in the core of a reactance or transformer which carries direct current in order to secure the greatest inductance. The work here reported points out a direct method of designing such reactances or transformers including the determination of the best value of the air-gap.

* * * * *

Introduction

The design of reactances or transformers in which considerable direct current flows is a problem of increasing importance. Interstage and output transformers for vacuum tube amplifiers, modulator chokes for radio-telephone transmitters, and reactances for rectifier filter circuits are examples. In all of these a high value of a-c. inductance is required, but the saturating effect of the direct current always causes the inductance to be lower than if it were not flowing. It is well known that in every such case an increase of inductance will result if an air-gap is introduced in the magnetic circuit. Where the steady m. m. f. is high, the best air-gap will be large; where it is low the best air-gap will be small, sometimes small enough so that the air spaces in the stacking of the core laminations are sufficient.

So far as the writer is aware, no direct method of predetermining this best air-gap has been presented. The usual method is to assemble a reactance or transformer and determine experimentally the best gap. The inductance for this best gap usually does not come to the required value, and a re-design is necessary. After several attempts, of course, the correct design can be determined, but a direct method of design is greatly to be desired.

The purpose of this paper is to set forth a straightforward method of solving this problem.

Method of Calculation

Use is made of the permeability curves, both normal and incremental, for the core material used. As an example, the calculation will be carried through for four per cent silicon steel. Curves of Fig. 1 show the normal and incremental permeability for different values of B. Incremental permeability values are for very small minor loops, and were calculated from information given in a paper by Spooner[2]. Values for very small loops are used because in many cases the requirements are that the inductance shall be equal to, or greater than, a certain value for any applied alternating voltage, no matter how small, and it is well known that the incremental permeability (and therefore the inductance), is smallest when the flux variations are small. Examples are the modulator choke in a radio-telephone transmitter, interstage and output transformers in audio amplifiers, etc. In the case of reactors for filter circuits where the pulsations are always large, advantage can be taken of the larger incremental permeability corresponding to the greater flux variations. The calculations here given do not include this case, but may serve as a guide in the design of such reactances. The magnitude of the flux variations must be known or determinable for such calculations.

The following notation will be used:

B = Steady flux density in iron and air-gap, gausses.
N = Number of turns in winding.
I = Direct current, amperes.
A = Area of core section and air-gap, cm.²
l = Length of iron path, cm.
a = Air-gap length, cm.
L = A-c. inductance, henries.

$$\mu = \text{Normal permeability} = \frac{B}{H}$$

$$\mu_\Delta = \text{Incremental permeability} = \frac{\Delta B}{\Delta H} \quad \text{where } \Delta B$$

and ΔH are the increments from tip to tip of a minor hysteresis loop.

We have

$$B = \frac{0.4\,\pi\,N\,I}{\dfrac{l}{\mu} + a} \tag{1}$$

and

$$L = \frac{0.4\,\pi\,N^2\,A \times 10^{-8}}{\dfrac{l}{\mu_\Delta} + a} \tag{2}$$

From (1)

$$N = \frac{B\left(\dfrac{l}{\mu} + a\right)}{0.4\,\pi\,I} \tag{3}$$

1. Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.
2. T. Spooner, "Effect of a Superposed Alternating Field on Apparent Magnetic Permeability and Hysteresis Loss," *Physical Review*, 1925.

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

Substituting in (2)

$$L = \frac{B^2\left(\frac{l}{\mu} + a\right)^2 A \times 10^{-8}}{0.4\,\pi\, I^2\left(\frac{l}{\mu_\Delta} + a\right)}$$

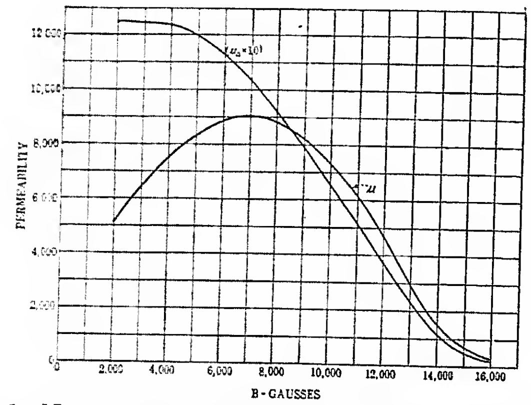

Fig. 1—Normal and Incremental Permeability for 4 Per Cent Silicon Steel

$$= \frac{B^2\left(\frac{1}{\mu} + \frac{a}{l}\right)^2 l\,A \times 10^{-8}}{0.4\,\pi\, I^2\left(\frac{1}{\mu_\Delta} + \frac{a}{l}\right)} \qquad (4)$$

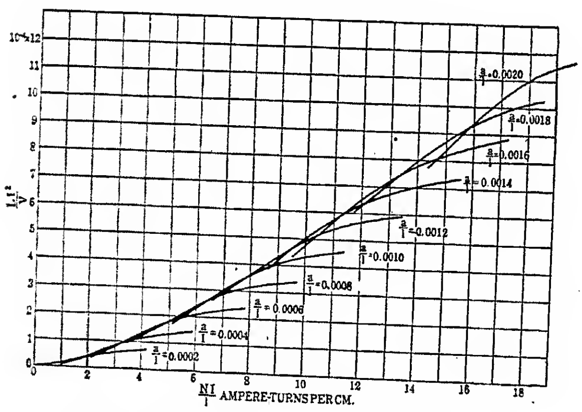

Fig. 2—4 Per Cent Silicon Steel

Letting $l\,A = V$, the volume of iron in the core,

$$\frac{L\,I^2}{V} = \frac{B^2\left(\frac{1}{\mu} + \frac{a}{l}\right)^2 \times 10^{-8}}{0.4\,\pi\left(\frac{1}{\mu_\Delta} + \frac{a}{l}\right)} \qquad (5)$$

Also from (1)

$$\frac{N\,I}{l} = \frac{B}{0.4\,\pi}\left(\frac{1}{\mu} + \frac{a}{l}\right) \qquad (6)$$

For any assigned value of $\frac{a}{l}$ (the per cent air-gap) equations (5) and (6) may be considered as parametric equations with B as the parameter, and a curve of $\frac{L\,I^2}{V}$ against $\frac{N\,I}{l}$ can be plotted. To do this, several values of B are assigned, and the values of μ

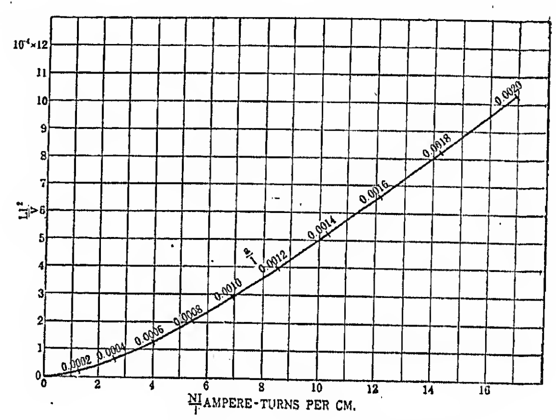

Fig. 3—4 Per Cent Silicon Steel

and μ_Δ corresponding to B obtained from curves of Fig. 1. These values are substituted in equations (5) and (6) to determine corresponding values of $\frac{L\,I^2}{V}$ and $\frac{N\,I}{l}$. $\frac{N\,I}{l}$ represents the steady ampere turns for each centimeter of iron length and $\frac{L\,I^2}{V}$ is

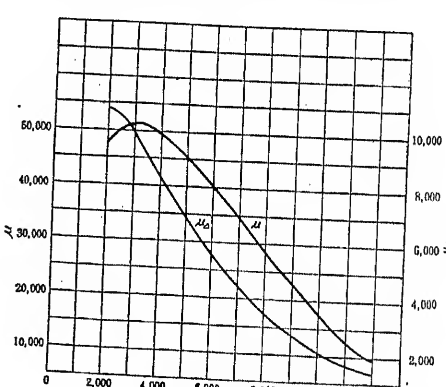

Fig. 4—Normal and Incremental Permeability Curves for Hypernik

a quantity which if divided by the square of the current gives the inductance per cm.[3] of core.

The family of curves, each for a different value of $\frac{a}{l}$, is shown in Fig. 2. It is seen that if $\frac{N\,I}{l}$ is increased, by increasing N or I or by reducing l, $\frac{L\,I^2}{V}$

is greater for larger values of $\frac{a}{l}$. Evidently the envelope of the family of curves gives the relation between $\frac{L\,I^2}{V}$ and $\frac{N\,I}{l}$ if the best value of $\frac{a}{l}$ is chosen. Since each curve of the family corresponds to a certain value of $\frac{a}{l}$, the point of tangency with the

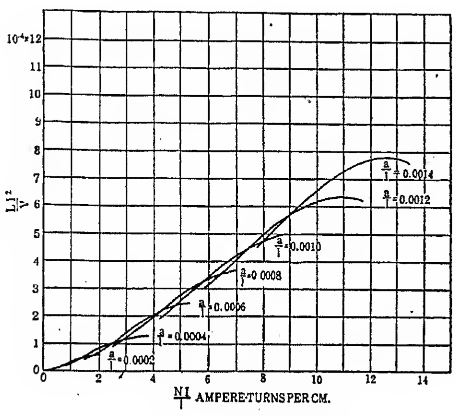

FIG. 5—HYPERNIK

envelope shows the value of $\frac{N\,I}{l}$ that requires this $\frac{a}{l}$. Hence along the envelope curve may be plotted a scale which shows the proper value of $\frac{a}{l}$. Fig. 3 shows the envelope curve with the $\frac{a}{l}$ scale along it.

Using this curve, it is quite simple to design reactances. Suppose a certain core size is chosen and a winding and air-gap are to be determined such that when a direct current I flows in the winding, the a-c. inductance will be L. The value of $\frac{L\,I^2}{V}$ is thus determined, and the corresponding value of $\frac{N\,I}{l}$ can be obtained from the curve. The core length l and the current I being known, N is determined. The value of $\frac{a}{l}$ can also be read from the curve, and thus the proper air-gap is determined.

To illustrate with a specific example, suppose

l = 14 cm.
A = 5.5 cm.²
L = 12 henrys
I = 0.05 amperes

then

$$\frac{L\,I^2}{V} = \frac{12 \times 0.05^2}{14 \times 5.5} = 3.9 \times 10^{-4}$$

From curve

$$\frac{N\,I}{l} = 8.43$$

$$N = \frac{8.43 \times 14}{0.05} = 2360$$

Also

$$\frac{a}{l} = 0.0012 \qquad a = 0.0168 \text{ cm.}$$

It may be that to obtain the 2360 turns in the given winding space the resistance will be too high. Where this is the case, a larger sized punching or perhaps more punchings of the same size should be used, so as to increase the iron section. The calculation should be carried through again in the same way, a few trials usually being sufficient.

It frequently happens that the greatest inductance possible is desired for a given core size. If I has a definite value as before, it is readily seen from the curve that the greater the number of turns the greater the inductance for a given volume of iron, provided the air-gap is increased as shown by the curve. Hence a coil with the greatest possible number of turns as de-

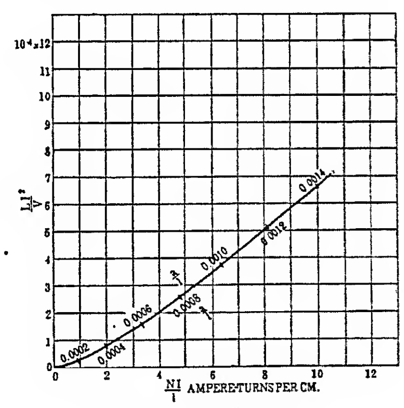

FIG. 6—HYPERNIK

termined by the permissible resistance or capacity of the winding should be employed.

For example, suppose with the core given in the first example, 4000 turns could be wound without exceeding the limiting value of resistance. If the current is as before.

$$\frac{N\,I}{l} = \frac{4000 \times 0.05}{14} = 14.3$$

From the curve

$$\frac{L\,I^2}{V} = 8.2 \times 10^{-4}$$

from which

$$L = \frac{8.2 \times 10^{-4} \times 14 \times 5.5}{(0.05)^2} = 25.2 \text{ henries.}$$

The value of $\frac{a}{l}$ to obtain this is 0.0018. Therefore

$a = 0.0018 \times 14 = 0.025$ cm.

The same calculation has been carried through for 50 per cent nickle iron. Curves of Fig. 4 show the normal and incremental permeability, the latter having

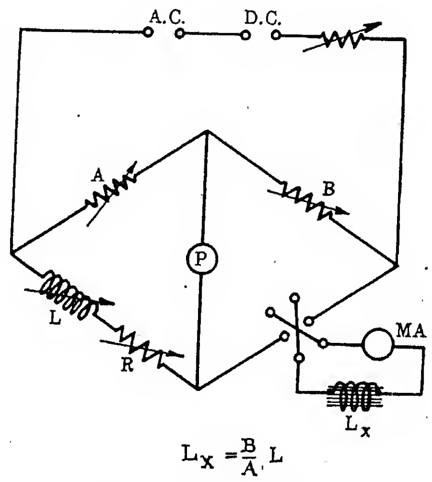

FIG. 7—A-C. BRIDGE

been calculated as before. The family of curves of $\frac{L I^2}{V}$ against $\frac{N\ I}{l}$ for different percentages of air-gap is shown in Fig. 5. Fig. 6 shows the envelope of this family with the scale of best $\frac{a}{l}$ values plotted along it.

The curves for both silicon and nickle iron have been used in the design of reactances and transformers and have been found accurate to a surprising degree when annealed punchings were employed. Inductance values were within 15 per cent of the calculated values. The best air-gap, not being critical, was always close enough so that no change from the calculated value was necessary.

ALTERNATE METHOD OF DETERMINING CURVES

It is seen readily that the curves may be determined from experimental data instead of by computation. Each curve of the family is the relation of $\frac{L I^2}{V}$ against $\frac{N\ I}{l}$ for a given value of $\frac{a}{l}$. If a core of uniform section is secured and a winding placed on it, its a-c. inductance for different values of direct current may be measured by means of an a-c. bridge as shown in Fig. 7. Holding the air-gap fixed, the data for one curve of $\frac{L I^2}{V}$ against $\frac{N\ I}{l}$ can be determined. The air-gap may then be changed and another set of data obtained, and so on until the whole family of curves is determined. Then the envelope with its $\frac{a}{l}$ scale may be drawn.

Fig. 8 shows two curves of the family for 50 per cent nickle steel that were determined in this way. The

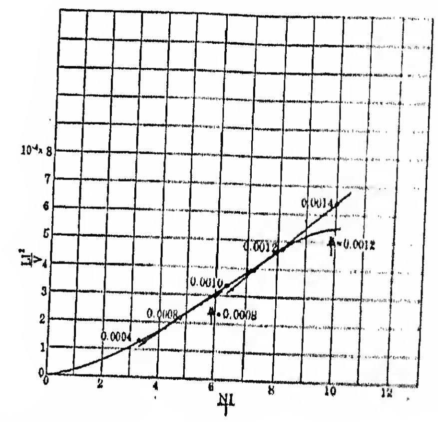

FIG. 8—EXPERIMENTAL CURVE FOR HYPERNIK

envelope is also shown and is found to agree fairly closely with the calculated envelope of Fig. 6.

In using the bridge, the direct current in the choke or transformer is varied by the resistance in series with the supply. A reversing switch is used to make sure that the induction in the core is that corresponding to the normal B-H curve. Small values of a-c. voltage are employed.

This method is best adapted to cases where the normal and incremental permeability values for the material are not available.

Discussion

D. C. Prince: The first question that came into my mind was, what is the real measure of these reactances? The reasoning that I went through is something like this: if we have a certain small variable current that is produced by a ripple voltage in the case of a rectifier or by whatever the alternating impulse is, and then we have a steady direct current that must be carried, the function of the reactor is to keep the ratio of the incremental current, the variable current to the direct current, as small as possible.

Or, looking at it the other way, we want to make the ratio of the direct current carried to the incremental current as large as possible. The incremental current will be inversely proportional to the reactance. So if we simply put a constant representing $2\,\pi\,F\,L$, we find that we can consider that the measure of the performance of our piece of apparatus is proportional to the product of current and inductance.

Mr. Hanna has considered that the current should be squared, and I will be interested in hearing why he squared it, but while I am about it, I might as well carry the story on, upon the basis

that we used, which was taking the first power of current instead of the square as our measure.

Referring to the accompanying Fig. 1, the product of inductance and current is taken vertically; the current is horizontal. Then for any particular air-gap we will get a curve of the sort, shown rising to a peak and then falling again. For the larger air-gap, the curve rises to a higher value at a higher current, and if we secure a number of such curves and then proceed to draw a curve that includes them, you will find that as the air-gap increases, the effectiveness of our inductance also increases, and it appears to approach a constant value somewhere in the neighborhood of corresponding to an air-gap of approximately 4 per cent of the total mean magnetic path.

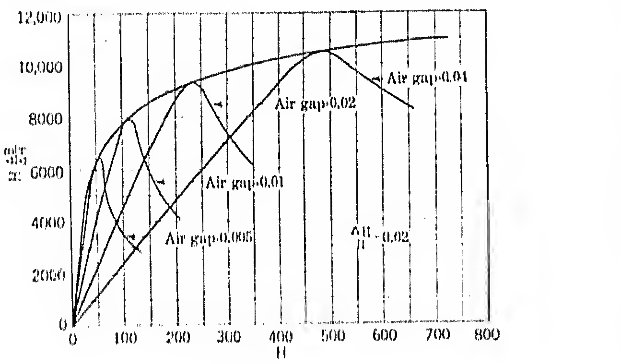

Fig. 1

That leads then to the question, "Why don't we always make the air-gap at least 4 per cent or more as long as the curve seems to be steadily climbing upward?" The answer to that is more or less suggested in Mr. Hanna's paper, although no direct attention was drawn to it. This small air-gap reactor giving its maximum inductance at a low value of current, when you design it is made almost wholly of iron, has hardly any copper in it. As you go in the direction of greater and greater air-gaps, you get larger and larger ratios of copper to iron, and if you are making a large piece of apparatus such as the reactor to smooth out the current from the rectifier, it becomes very important to strike a balance between the copper and iron. For very small pieces of apparatus of course that is less important, but for the larger things such as the chokes for radio transmitters and the filter reactor for rectifiers, the dominant thing is to strike a balance between copper and iron so as to get the most economical structure.

To that end we arrived at a plot slightly different from the one which Mr. Hanna has used. We plot inductance for the unit volume and air-gap, and then we have another plot giving the relation between the air gap and the ampere-turns as shown in Fig. 2 herewith. Taking such a plot as that, you simply assume a series of air-gaps for each one of which you can design a reactor immediately, and then having such a series the most economical one may be chosen, and the actual reactor built from it.

There is just one other point about the paper. Mr. Hanna has been dealing with very small increment of current, and as the alternating components increase, the effective reactance also increases, and we have thought it necessary, therefore, to have not one curve for the minimum variation in current but a group of curves so that we can design for what the demanded current pulsations are.

C. R. Hanna: I have converted one of the curves given in Mr. Prince's Fig. 2 to which he has called attention. The best air-gap is along the abscissas, one curve representing ampere-turns and the other $\frac{L}{N^2}$. These two curves could be properly converted into one if the scale of ampere-turns were plotted along the $\frac{L}{N^2}$ curve.

I took the lowest curve, interchanged air-gap with ampere-turns and multiplied ordinates by the square of the abscissas, converting his curves into the same form that I have given in my paper.

As has been brought out, he considered much greater values of steady magnetization or steady ampere-turns per centimeter than I did.

The lowest of the several curves was chosen because it represents the smallest percentage variation in current. That corresponds more closely to mine than any other because I considered very small minor hysteresis loops.

The derived curve when extrapolated came slightly lower than mine all the way. Of course, the difference in material might account for this, but I was wondering if it might not be in the way his maxima were arrived at.

D. C. Prince: As I understand it, Mr. Hanna has struck the one real difference in the fundamentals. The question is whether the curve in Fig. 1 goes through a series of peaks or is a curve that is tangent. Mr. Hanna has made his curve tangent to the family and not through the peaks, and his method is undoubtedly correct. That is, the two give slightly different values and in his terms you get slightly higher values if you take your curve tangent to the family than you do if you go through the peaks. However, he is dealing with small values of air-gap and the reactors that we actually build usually run more than 1 per cent air gap, and when you get more than 1 per cent air-gap, the tangent and the peak come so close together that the choice is immaterial.

C. R. Hanna: As Mr. Prince has pointed out, the envelope curve rather than the curve through the maxima should be used. Mr. Prince raises the question as to why $L\,I^2$ was used instead of $L\,I$ as in his work. I had no particular preference in the matter, but when the results are obtained by employing values of μ_Δ corresponding to very small changes in magneto-motive-force instead of those which correspond to a constant $\frac{\Delta I}{I}$, the results will inevitably be in terms of I^2 instead of I.

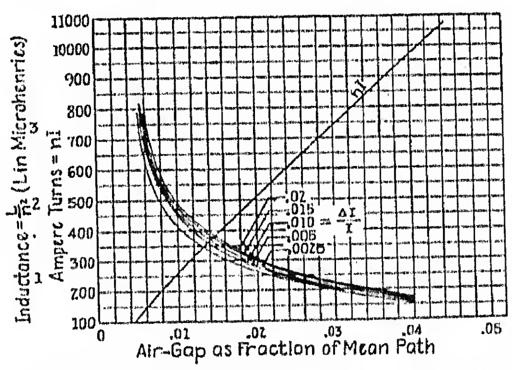

Fig. 2—Curve Showing Effect of Air-Gap on Inductance of Unit Reactor, (1-in. cube) With n Turns per Inch and Effect on Ampere-Turns for Least Pulsation Factor

J. F. H. Douglas: My interest in this topic is chiefly from the standpoint of Heising modulation choke coils. I wish to state that I think this paper is an important theoretical advance in the design of transformers and chokes carrying direct current. It gives a better gap for maximum inductance. However, I must point out that it is still a trial-and-error method for evaluating the necessary volume in the iron core.

The values of $L\,I^2/V$, which are roughly proportional to the energy storage per unit volume, indicate flux densities in the gap by rough calculations that I have made of only 24,000 lines per sq. in., or roughly 4000 gausses and represent an inefficient use of the iron material.

It is true in radio receiving apparatus that material cost is not such an important item, and the problem is economically handled in this particular case since the size of wire which is used though not stated here can hardly be much larger than No. 30 B & S gage, and the use of any smaller iron core would result in an impossible winding problem and an unworkable air-gap.

One of my senior students, Herbert Wareing, has designed and built and installed a Heising radio choke rated for an ultimate of 10,000 volts, 2 amperes and 60 henrys. The method that he used was one which, with slight modifications, I have taught for five years for low-frequency chokes and one which was derived from Professor Karapetoff.

I wish to say that I am opposed to empirical methods of design whenever rational foundation can be found. The rational foundation in Professor Karapetoff's method in the design of transformers and, I believe, chokes, is that of economical, specific, magnetic, and electric loadings and it should be gratifying to note its wide range of application.

There are other very important factors in the design of a Heising choke besides that of securing maximum inductance for a given core. Mr. Wareing reported to me that one important factor was leakage flux from the poles of the iron parts. Another was the distributed capacity between windings, and a third was the saturation which occurred when modulating low-pitched sounds of perhaps 20 or 30 cycles frequency.

The choke coil which he replaced resembled one of the old Edison bipolar dynamos, and it showed more inductance when the Keeper was entirely removed than when it was in place. The leakage flux alone saturated the legs at the corner point where they joined the yoke.

The choke that Mr. Wareing designed had a core weighing 220 lb. and copper coils of about 200 lb. The value of $L\ I^2/V$ was 74×10^{-4}, some six times greater than the maximum value recorded by Mr. Hanna's graph. The direct-current density was in the neighborhood of 60,000 lines per sq. in., roughly 10,000 gausses, the double air-gap $1\frac{1}{4}$ in., roughly 3 cm. the core 6 in. square, the length of the magnetic circuit, exclusive of air 46 in., and the ratio of air-gap to the mean magnetic path 2.7 per cent.

Obviously in Heising chokes of this rating we must use material efficiently, and a cut-and-try method for securing the iron core would not be entirely satisfactory. Since the installation of the choke coil, the music, by station W K A F where it is in use is reported to have much better quality of modulation than previously.

I would be interested to know whether the ratio of air gap to mean magnetic path for these higher magnetic densities checked the values that Mr. Hanna advocates, or whether it more closely checks those that Mr. Prince advocates.

Mr. Wareing intends to publish his results in one of the radio publications.

C. R. Hanna: In regard to Professor Douglas's discussion, I want to say first that the value of $L\ I^2/V$ does not represent the energy storage per unit volume because L is the incremental inductance of the winding while I is the steady magnetizing current. So his calculation of the flux density from that figure is not correct. He mentioned about 4000 gausses as the density he determined in this way. The actual densities for the range of ampere-turns per centimeter given in the paper are about 6000 or 7000 gausses. Of course the density is greater for larger values of $N\ I/l$. The scope of the paper was limited, however, to reactors and transformers having small steady m. m. fs.

Voltage Standardization of A-C. Systems
From the Viewpoint of the Electrical Manufacturer

BY F. C. HANKER[1] and H. R. SUMMERHAYES[2]

Member, A. I. E. E. Member, A. I. E. E.

Synopsis.—In outlining the history of voltage standardization, it is observed that there has been separate standardization of voltages of various types of apparatus, rather than standardization of a complete operating system. The results of a questionnaire answered by 22 operating companies are analyzed and the conclusion is drawn that the use of the old standard transformer voltages involved, in many cases, over-exciting the transformers or generators in order to maintain satisfactory voltage at the consumers' terminals. The reason is that the existing transformer voltage standards do not compensate for the line drop in transmission lines and feeders. The voltage standards of the International Electrotechnical Commission are set forth, indicating a partial agreement as to maximum system voltages with the proposed standards, although arrived at by a different method. The I. E. C. standardization, however, is not so complete as the proposed system.

In describing the proposed standards, certain basic principles are laid down as the conditions which must be fulfilled.

The proposed system of voltage standards starts with already standardized utilization voltages at the low end of the scale and suggests tranformer voltage ratings and ratios which will allow proper voltage to be supplied to the consumers without over-exciting any of the transformers or generators in the system, and ties in the transformer and apparatus voltages with system voltages, based on the A. I. E. E. definition of rated circuit voltages. The proposed standards thus cover the whole field of voltages of a-c. apparatus of all kinds and harmonize them with system voltages in such a way that all reasonable operating requirements may be met.

The salient features of the proposed standardization are as follows:

The system voltage is the same as the highest rated voltage of transformers supplying the system; it thus corresponds to the A. I. E. E. rated circuit voltage and fixes test voltage on all apparatus used on the system.

Step-down transformer secondary voltages from 115 volts up to 69,000 volts will be multiples of 11.5, excepting transformers supplying 2400-volt systems, which will be rated 2400 volts. Thus, typical step-down transformers will deliver

460 volts
6,900 volts
23,000 volts
69,000 volts

For higher voltages, step-down transformers will have secondary voltages in multiples of 11, thus:

88,000 volts
110,000 volts
132,000 volts
154,000 volts

complying with well established practise.

In order to enable the step-down transformers to deliver these voltages, their primaries will be rated in multiples of 11, thus:

6,600,
22,000, etc., up to 66,000 and above that

multiples of 10½, thus:

105,000
126,000
210,000, etc.

Step-up transformers, excepting the 2400-volt class, will have their high-tension windings rated in multiples of 11½ up to 69,000, and multiples of 11 above that, whereas their low-tension winding will be rated five per cent lower than the system voltages or generator voltages.

Thus, step-up and step-down transformers will not be interchangeable, but each will have the proper ratio for its purpose. To make them interchangeable would require 25-per cent range, which would involve too great an expense if applied to all transformers. Transformers of 25-per cent range may be required in many cases where power flows in either direction but such transformers should be of special design and this extra cost should not involve the whole line of transformers. The tabulation of voltages gives also the present manufacturers, standards for apparatus voltages, such as oil circuit breakers, disconnecting switches, etc. These standards for 88,000 volts and above correspond to the system voltages of multiples of 11. Below 88,000 volts they are somewhat higher than the recognized system voltages given in the tabulation in order to meet existing conditions in these lower voltages. The tabulation also gives motor voltages in multiples of 11, while the generator voltages, in order to allow for line drop, are multiples of 12 up to 2400 volts, and multiples of 11½ from 6900 volts up.

The last section of the paper gives a discussion of the economic advantages of voltage standardization, indicates the magnitude of the investments involved, and gives a general idea of the savings which may be made by standardization.

* * * * *

Introduction

The lack of a logical and coordinated voltage standardization of apparatus extending from the initial supply to the utilization device has resulted in an unnecessary expense to the industry. Standardization up to this time has been largely a matter of individual efforts on segregated types of apparatus. The result has been that while standards have been developed for the several types of apparatus, it is generally conceded that these do not harmonize in such a manner that standard apparatus can be coordinated readily into a complete operating system. For this reason there has been a considerable tendency for the users of apparatus to buy equipment of special voltage ratings to suit their own particular conditions. Since these conditions would naturally vary somewhat from operator to operator, the special apparatus ordered by them does not constitute a new but unofficial line of standards, but a truly special line of apparatus for each operating company.

Considerable attention has been given to this tendency to deviate from the established standards recognized by the A. I. E. E., N. E. L. A., and Electric Power Club, since although the use of special apparatus might be advantageous from the point of view of the individual operator, it nevertheless places a burden on

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

the industry as a whole, including those purchasers who believe they are being supplied with special apparatus at standard price. Users of standard apparatus help to bear this as well as the users of special apparatus, since the development costs and extra supervision and manufacturing costs caused by the production of specials tend to raise the cost of standard apparatus. The special tools often required for the production of specials also raise the investment in manufacturing plant, and this extra cost is usually borne by the standard as well as by the special product. Furthermore, special apparatus entails longer deliveries both on the initial apparatus and on renewal and repair parts.

There is no need to elaborate further on the nature of the disadvantages coincident with the widespread use of specials, for these are generally well known. The importance of these disadvantages, however, is perhaps not so well known, and it is in the interests of a wider appreciation of the advantages to be gained through complete and acceptable standardization that various official bodies have been working the last few years. This is all the more important in view of the fact that the N. E. L. A. has recommended system interconnection. A more or less detailed review of the history of voltage standardization follows in a later section.

Purpose

This paper is to present the viewpoint of the manufacturers on voltage standardization, and its purpose in greater detail is:

1. To outline the history of voltage standardization, pointing out that it has been separate standardization of various types of apparatus rather than standardization of a complete operating system.
2. To show by the results of a questionnaire how representative operating practise lines up with the existing standards.
3. To discuss the need for standardization of the complete system and the conditions which such a standardization must meet.
4. To present what is believed to be a workable set of standards which meet these conditions and to demonstrate their application to a typical system.
5. To discuss the advantages of standardization from the manufacturer's viewpoint and to indicate the benefits accruing to the industry as a whole.

History

As indicated in the introductory matter, progress in the voltage standardization of the complete a-c. electrical operating system, including generation, transmission, distribution, and utilization, has been largely a matter of the standardization of the several divisions of apparatus rather than a concerted standardization of the whole operating system.

High voltage standardization dates back to 1899, when the Standardization Rules of the A. I. E. E. recommended that the rated circuit voltage should be measured at the receiving end and that the recommended values should be 1000, 2000, 3000, 6000, 10,000, 15,000, and 20,000 volts. In order to take care of line drop, generators were to be rated at 1150, 2300, and 3450 volts, thus allowing a total transmission regulation of 15 per cent.

The recommended voltages were extended in the 1902 Standardization Rules to include 30,000, 40,000, and 60,000 volts in order to keep up with progress in high voltage transmission, the voltage still being measured at the receiving end.

The 1911 Standardization Rules made a sweeping revision in that it was decided to measure the circuit voltage at the sending end. The recommended voltages were no longer based on multiples of 10, but on multiples of 11, and the list was extended to include 88,000 and 110,000 volts. It was also recommended that transformers should transform between the listed voltages and that their ratios should be exact multiples of five. Since that time high voltages have always been measured at the secondary of the sending end transformers and have remained on a basis of multiples of 11, although extensions and additions have been made to the recommended list.

In 1914 the manufacturers of a-c. motors reached an Electric Power Club agreement whereby motor voltages became standardized at 110, 220, 440, 550, and 2200 volts, these standards representating the voltages at which the performance guarantees would be made and checked. It was recognized that it would be necessary to allow for variations in the supply voltage, and the apparatus was designed for successful operation at 10 per cent above and below the rated voltage although the performance would be affected where the voltage makes these allowable variations from normal.

Standardization of lamp voltages came later, due to the fact that in the manufacture of carbon lamps it was impractical to predetermine the voltage rating of units. This had to be determined by test after the product was made, and the various operating companies were encouraged to standardize on different service voltages in order to provide a market for all the lamps which the rating test showed to fall into classes suitable for these service voltages.

The tungsten filament lamp, however, proved not to be subject to these limitations, for its voltage rating can be predetermined with considerable accuracy before manufacture. With the rapid displacement of the carbon lamp by the tungsten lamp, therefore, there was an increasing tendency to standardize lamp voltage, since it was possible and highly desirable to standardize the factory output of tungsten lamps.

The Lamp Committee of the N. E. L. A., along with the lamp manufacturers, became increasingly interested in this standardization and urged the member operating companies of the N. E. L. A. to converge where possible upon whichever of three proposed lamp standards, namely 110, 115, or 120 volts, they could adopt most

economically. For the last twelve years the percentage demand for 115-volt lamps has steadily risen from 13.5 per cent to 44.6 per cent; and for 120-volt lamps, from 9 per cent to 31.3 per cent; while the percentage demand for 110-volt lamps varied between 20 per cent and 30 per cent during the period from 1913 to 1924 but is showing a gradual decline which reduced it to 16.5 per cent in 1925. The point of great significance, however, is that in those twelve years the percentage demand for odd voltage lamps has declined from 51.5 per cent to 7.6 per cent. Eighty per cent of this 7.6 per cent consists of 125-volt lamps which are probably used principally on d-c. systems.

Thus the trend in a-c. systems is quite definitely toward the use of 115-volt lamps, with 120-volt lamps a close second.

The tendency in the electric heating and household appliance field has been to express the voltage rating in terms of a voltage range rather than as a definite voltage. Actual examples of this method of rating are 100-114, 105-115, 111-120, and 115-120 volts taken from nameplates of well known appliances. This short list suffices to show that these voltage ratings cover ranges varying from 5 to 14 volts, and that little standardization has been attempted among the appliance manufacturers either as to the extent of the range or its location in the voltage scale.

The preceding outline gave a brief description of the situation which has developed with respect to utilization voltages during the past 10 or 15 years.

The operating companies are really interested in the standardization of service voltage rather than standardization of the utilization voltage, since their contract responsibility is to maintain a specified voltage at the service switch. The one depends on the other, of course, but it is natural that the power company should be interested in the supply and maintenance of its own definite commodity, which is voltage at the service switch rather than voltage at the lamp socket or motor terminals. In the interest of standardization of service voltage, the N. E. L. A. Subcommittee on the Standardization of Service Voltage undertook in 1920 to make an investigation of this question leading up to the recommendation of suitable standards, and preferably a single standard.

The factors which had to be taken into consideration in this investigation were:

1. Existing utilization voltage standards,
2. Existing distribution transformer voltage standards,
3. Regulation between transformer and service switch,
4. Regulation between service switch and lamp socket,
5. Economic advisability of modifying 1 or 2 or both.

What utilization voltage standardization had been accomplished by 1921 has been reviewed above, and may be summarized by:

Motors: Multiples of 110 volts, but will operate successfully on variations of $\pm$ 10 per cent in the supply.

Lamps: 110-, 115-, and 120-volt, the 115-volt predominating.

Appliances: No standardization.

The existing distribution transformer voltage standard was the triple rated 110, 115, 120 volt secondary. The great majority of these distribution transformers were of the 20:1 ratio, 2300-volt class, without taps in the primary, giving 240/230/220-120/115/110 on the secondary when suitably excited on the primary.

The average regulation between the transformer secondary and the service switch was found to be two per cent, and between the service switch and the utilization device one per cent for lamps and possibly double that for motors.

After considerable discussion between the Subcommittee, the Lamp Committee, and the member operating companies, it was tentatively recommended in the 1921 and 1922 Reports of the N. E. L. A. Electrical Apparatus Committee that the standard service voltage be such that the proper average voltage would be supplied to 115-volt lamps, with recognized departures for supplying the proper average voltage to 110-volt and 120-volt lamps, the latter being for only existing systems of that voltage. With any of these average service voltages it was intended to use 110-volt motors and electric household appliances having a voltage rating covering a range of from 110 to 120 volts, since these two classes of apparatus do not require the close correspondence between impressed voltage and normal rated voltage which lamps require for economical operation.

The "recognized departure" of service voltage corresponding to 110 volts at the lamp socket was admitted due to the number of companies that could not increase their delivered service voltage without exceeding the safe operating voltage of their generators; and the recognized departure of service voltage corresponding to 120 volts at the lamp socket was admitted due to the number of companies that felt they could not reduce their service voltage without losing considerable revenue on account of the reduced voltage running of lamps which their customers would be reluctant to replace before they were worn out. Furthermore, the lamp manufacturers were desirous of continuing the triple lamp standard which they had been at some pains to establish.

This scheme fitted in fairly well with existing distribution transformer voltages, except that on systems requiring 120 volts at the lamp socket the voltage at the transformer secondary must be between 123 and 124 volts to allow for the drop between transformer and lamp, and hence the excitation voltage impressed on the primary must be of the order of 2500 volts. This would work the iron rather heavily.

There was also some question raised as to the successful operation of 110-volt motors when the average service voltage was such that the average impressed

voltage was 120 volts, since this average feature implied that at times the impressed voltage might be two or three volts above 120 and thus exceed the 10 per cent tolerance allowed in the Electric Power Club rule. Operating companies stated they had never experienced any trouble of this nature, however, and the report remained on the basis of 110-volt motors.

It was recognized that the standardization of service voltage would be possible and of value only if it could be coordinated with the rest of the system all the way back to the generator. Accordingly, the final disposition of the Subcommittee report was that it was recommended in 1923 to be brought to the joint attention of the A. I. E. E., Electric Power Club, and N. E. L. A., with the idea that these agencies might cooperate in the future toward the voltage standardization of the electrical system from generator to utilization device.

Such a sweeping standardization of the complete system was evidently needed, since it was stated in the N. E. L. A. Electrical Apparatus Committee Report for 1924 that a recent investigation showed that less than 50 per cent of the transformers 200 kv-a. and above, being bought by the operating companies, conformed to the transformer voltage standards adopted jointly by the N. E. L. A. and Electric Power Club as formulated in 1919 and amended in 1922. This investigation was prompted by several operating companies that communicated to the N. E. L. A. their feeling that systems should be so arranged and apparatus so rated that a higher voltage should be obtainable at transformer secondaries than was now possible. The results of the investigation indicated that the standards as adopted were not ideally suited to operating conditions, since the operating companies were finding it to their advantage to purchase transformers which varied from the recommended standards.

The causes which produced these conditions became the object of an investigation by the Transformer Subcommittee of the N. E. L. A. Electrical Apparatus Committee in 1925. By means of a questionnaire to representative operating companies they inquired into the actual operating voltage at each point in a complete system, in an effort to find out what apparatus ratings would be best suited to operating conditions, to what degree existing apparatus standards would suffice, and what changes would be necessary in order that operating companies would find it to their advantage to buy apparatus conforming to a new set of standards rather than to buy special apparatus. The questionnaire inquired specifically into the voltage ratings of all generators and transformers on the system, the tap voltage rating used on the transformers, the actual operating voltage at the generators and on the primary and secondaries of all transformer banks and at the service switch, for conditions of light and maximum load and on the longest feeder and the shortest feeder, and the range of feeder induction voltage regulators, if used.

Replies were received from 22 power companies, representing the two cases: (a) systems where the feeders were fed directly off the generator bus at generator voltage and the stepping down to service voltage accomplished through two or more transformations, and (b) systems where transmission at high voltage intervenes between the generator bus and the distribution system. While there were several discrepancies in the figures submitted, it was felt nevertheless that in the main they were reliable and representative of general practise.

The salient points which the questionnaire developed were as follows:

1. Eleven of the twenty-two companies had transformers on their system over-excited by more than five per cent above the connected tap rating. In five cases this over-induction was 10 per cent or more above the connected tap rating.

2. Three companies reported their generators to be operating at more than five per cent above their normal rating, the maximum being nine per cent above normal. Thirteen of the remaining companies operate their generators above normal but not more than five per cent above the normal voltage rating.

3. Whereas feeder induction voltage regulators were required to operate at greater buck than boost in five cases in order to maintain satisfactory service voltage, and to operate at equal buck and boost in seven cases, there were twelve cases where they were required to operate at greater boost than buck.

The evidence was plain that the existing voltage standards did not allow the maintaining of voltage at the point of utilization under load conditions unless the voltage at the various generation and transformation points was maintained above normal. The explanation of this was that whereas the existing transformer voltage standards provide for the regulation in the transformer itself by means of taps in the primary, insufficient provision is made for compensating for the line drop in the transmission line and feeders, for, according to the standards, the rated secondary voltage of each transformer is equal to the rated primary voltage of the transformer at the receiving end of the line which the former supplies. Since induction regulators are generally used at only one point in the network, it is often impossible to keep the voltage at all transformation points within the desired limits.

In order to remedy this situation, the Transformer Subcommittee suggested to the Electrical Apparatus Committee as a basis for criticism and discussion, a system of standards where the rated secondary voltage of each sending-end transformer would be five per cent higher than the rated primary voltage of the corresponding receiving-end transformer, in order to allow partially, at least, for the drop in the line. The proposed standards included voltage ratings for generators, synchronous condensers, induction motors, and switching, control, and protective apparatus, in addition to transformer ratings, since the idea of coordinating all of the apparatus on the system

had been kept well in view from the beginning.

The Transformer Subcommittee had now reached the point at which the Subcommittee on Standardization of Service Voltage had arrived in 1923, namely, at the limit of its scope; and it was in order to refer the question to bodies in a position to come to authoritative agreements on the whole voltage question. Accordingly, action was commenced for making a very complete presentation of the entire problem to the industry as a whole, in order that concerted and general action might result after all interested parties had been thoroughly informed and afforded ample opportunity for presenting their views. The broadest vehicle for this presentation was considered to be a group of papers submitted before a convention of the American Institute of Electrical Engineers, these papers to be prepared by representatives of the operating companies, holding companies, consulting engineers, European engineers, and the manufacturers. From the discussion following these papers it was hoped that conclusive results would be obtained.

This paper is based on a memorandum which resulted from the cooperative action of the manufacturers. This memorandum will be quoted in full except for some introductory matter which has already been covered in the preceding paragraphs.

Before the presentation and discussion of the memorandum is taken up, however, some attention should be paid to the relation existing between American practise and the standards recommended at the 1926 meeting of the International Electrotechnical Commission, which took place in New York during April. These recommendations are summarized as follows:

I. Definition of "nominal high voltage": The nominal high voltage shall be the mean voltage at the consumers' terminals and shall be called nominal I. E. C. voltage of the network of that voltage range.

II. The maximum voltages at the generators and secondary terminals of transformers shall be considered as to be about 10 per cent higher than the mean voltages at the consumers' terminals. The values of the recommended nominal I. E. C. voltages and maximum voltages are included in the following table, the preferred voltages being in heavy type.

Nominal I.E.C. Voltages Mean Value at Consumers' Terminals	Maximum Voltages
1000	1100
3000	3300
6000	**6600**
10000	11000
15000	**16500**
20000	22000
30000	**33000**
45000	50000
60000	**66000**
80000	88000
100000	**110000**
150000	165000
200000	**220000**
300000	330000

It will be noted that these recommendations do not line up with present American practise, either as to the point at which the rated voltage of the circuit is measured, or as to the actual values of the voltage rating. The interested organizations and persons in America were at that time engaged in the consideration of a thorough revision of the whole subject of the voltage standardization of transmission and distribution circuits and of machinery and apparatus for those circuits. At the April meeting of the I. E. C. these studies had not arrived, however, at the stage where the American Committee had a definite program to offer. Neither did the American Committee feel justified in opposing progress on the part of other nations. It was believed that this situation was appreciated by the representatives of other nations and that the American Committee would on some later occasion be presenting before the I. E. C. the recommendations at which it would be arriving as the results of these studies.

Proposed System of Voltage Standards

The electrical manufacturers are interested in voltage standardization of apparatus to a perhaps even greater degree than the operators. While the latter are interested in the low prices, rapid shipments, and effective replacement and repair service made possible by standardization, nevertheless it is but natural they should be primarily interested in apparatus which will most perfectly meet their own particular requirements. Thus there is an inherent tendency for individual operating companies to set up standards of their own which might or might not agree with the practise of other operating companies.

The manufacturers, on the other hand, are desirous of a set of standards which will be universal for all customers, in order that their entire output might consist of standard lines of apparatus. The number of types could then be cut to a minimum, development costs reduced, and if proper standards were set up it would be possible to select standard equipment with the assurance that it could be incorporated into a system and form an operative whole.

With these interests in mind, the manufacturing companies which the authors represent have been at some pains to formulate a new set of voltage standards which are believed to be workable and possible of universal application. These will now be discussed in detail. The proposed standards were drawn up to meet the following five conditions:

(a) The new standards must provide apparatus capable of meeting most of the service requirements of a well designed and operated system.

(b) The voltages selected must closely resemble those now in use to permit a reasonable degree of interchangeability of new and old apparatus.

(c) The changes involved must not necessitate too great an expense in the development of new apparatus.

(d) Admittedly, universality of use is an essential end to be sought in all standardization. Usually

its complete attainment involves an excessive expenditure, and so is not economically desirable. It should be sought in so far as it can be obtained without burdening the cost of standard apparatus to obtain characteristics which will be used rarely.

(e) The new standards must provide apparatus that will meet, in spirit as well as in letter, all requirements as set forth in the standards of the American Institute of Electrical Engineers. The apparatus should not only be capable of meeting the test requirements of the A. I. E. E. Standards, but should readily lend itself to operation within the limits as defined by them. The design of electrical systems contemplating the use of apparatus under conditions more severe than sanctioned by the A. I. E. E. Standards should be discouraged.

The first four of the foregoing principles are self-explanatory but the last will permit of further elaboration. We have to deal here primarily with the test voltage to which apparatus is subjected and its relation to the normal operating voltage of the apparatus. In general, the A. I. E. E. Standards specify a potential test of twice the rated voltage of the apparatus plus 1000 volts in the case of rotating apparatus and transformers (excepting current transformers) and 2¼ times rated voltage plus 2000 volts in the case of switching equipment, bus supports and current transformers. Except where specific mention is made to the contrary apparatus is designed to be operated at substantially its rated voltage, certainly not materially above it. The ratio of test to rated voltage has been selected to introduce a reasonable factor of safety, presumably as the result of theoretical consideration and operating experience. To operate normally above rated voltage is to decrease the recommended factor of safety, and to decrease the factor of safety is to introduce a hazard to life and property not sanctioned by the A. I. E. E. Standards. Or, to put it another way, those who operate apparatus above its rated voltage, operate it with a factor of safety less than the engineers responsible for the A. I. E. E. Standards deem advisable. Can any other conclusion be drawn? It can probably be said, without fear of contradiction, that the practise of encroaching on the universally accepted factors of safety is more prevalent in the electrical arts than in others. Who would contemplate normally operating a steam boiler above its rated pressure? Simply to ask the question is to answer it. The present system of voltage standards has in no small degree contributed to the present undesirable practise. In the case of an average system composed of generators, transformers and motors, rated in accordance with the present voltage standards, either the generators and transformers must be operated above their rated voltages or a sub-normal voltage will prevail at the motor when the system is loaded.

In addition to encroaching on the factor of safety relating to test voltage, the operation of generators and transformers for considerable periods of time at pre[ssures] exceeding their rated voltage may result in ove[r]heating and tends towards reduced life and low[er] reliability. Such operation may also distort th[e] voltage wave and lead to interference with communica[tion] circuits. The operation of oil circuit breakers a[t] pressures materially exceeding their rated voltage ma[y] involve marked reduction in their interrupting capacity.

As individual pieces of apparatus are interconnecte[d] electrically to form any operative system, it is incum[bent] upon the designers to determine the maximum voltage at which the system will be normally operate[d] and to be certain that this will not materially exceed th[e] accepted factors of safety for the individual pieces o[f] apparatus of which it is composed. At present th[e] most important rule—if not the only rule in th[e] A. I. E. E. Standards defining "Rated Circuit Voltage" appears in the Transformer Section (13-119). It ha[s] been suggested in the Standards Committee to issue a new general rule, resembling the present one, reading substantially as follows:

Rated Circuit Voltage: For the purpose of fixing a value to be used in designing and testing electrica[l] apparatus, the rated voltage of a circuit (or system) i[s] defined as the highest rated voltage of the apparatu[s] supplying it. By "circuit voltage" is meant the voltage from line to line as distinguished from line to neutral. This voltage rating applies to all parts of the circuit. The actual operating voltage of the circuit may vary from the rated circuit but should not exceed it.

Such a rule as this and those pertaining to the individual pieces of apparatus would definitely set the rated voltages of apparatus, their test voltages and maximum operating voltage if they are to be operated as parts of a common system.

The present voltage standards, excepting apparatus rated 2300 volts and below, call for apparatus whose voltage ratings are expressed in even multiples of 11; for example, 6600-volt, 13,200-volt, 44,000-volt, etc. These voltages apply to motors, transformers (both their primary and secondary windings) and generators, with the exception that in some cases transformers are given a double rating. The second transformer rating simply permits their use at approximately five per cent over-voltage without any change in their voltage ratio. The transformer ratios referred to, of course, are no load or turn ratios. It is usual practise to equip step-down transformers, whose voltage rating exceeds 2300 volts, with four 2½ per cent primary taps below rated voltage. A simple system, employing the present voltage standards, is shown in Fig. 1.

In this elementary but representative system, the voltage ratings of generators, motors, and step-up and step-down transformers are shown as multiples of 11, excepting that the substation transformers supplying the 2300-volt distribution lines are rated 2300 volts, and the distribution transformers are given the usual triple rating of 2400-2300-2200 volts.

The voltage drops assumed are as follows:

132-kv. line	10	per cent approx.
66-kv. line	7½	per cent approx.
13.2-kv. line	5	per cent approx.
2300-volt line	5	per cent approx.
230-115 mains	3	per cent to lamps
and services	6	per cent to motors
Power transformers	5	per cent
Distribution transformers	2	per cent

This diagram shows that with the generator operated at rated voltage the voltage at the 115-volt lamps would be only 102 volts at full load on the system, and the voltage at motors 10 per cent low, even if each transformer is operated on its lowest high-tension tap and a regulator boosting 10 per cent is allowed for. The generators, will be equipped with the equivalent of two 2½ per cent taps in the primary windings below rated voltage to provide additional range for compensating for the voltage regulation of the transformers and to avoid over-excitation of generators. A cursory study of the simple principles of voltage standardization as illustrated in Fig. 2 will show that the deficiencies of the present standards have been eliminated. Here, the windings from which power flows have voltage ratings approximately five per cent greater than those at which power is received. It is believed that ample provision has been made in the voltage ratings of apparatus, ratios of transformation, and transformer taps to meet most normal conditions of system design and operation. It will be noted that in Fig. 2, while the generators are

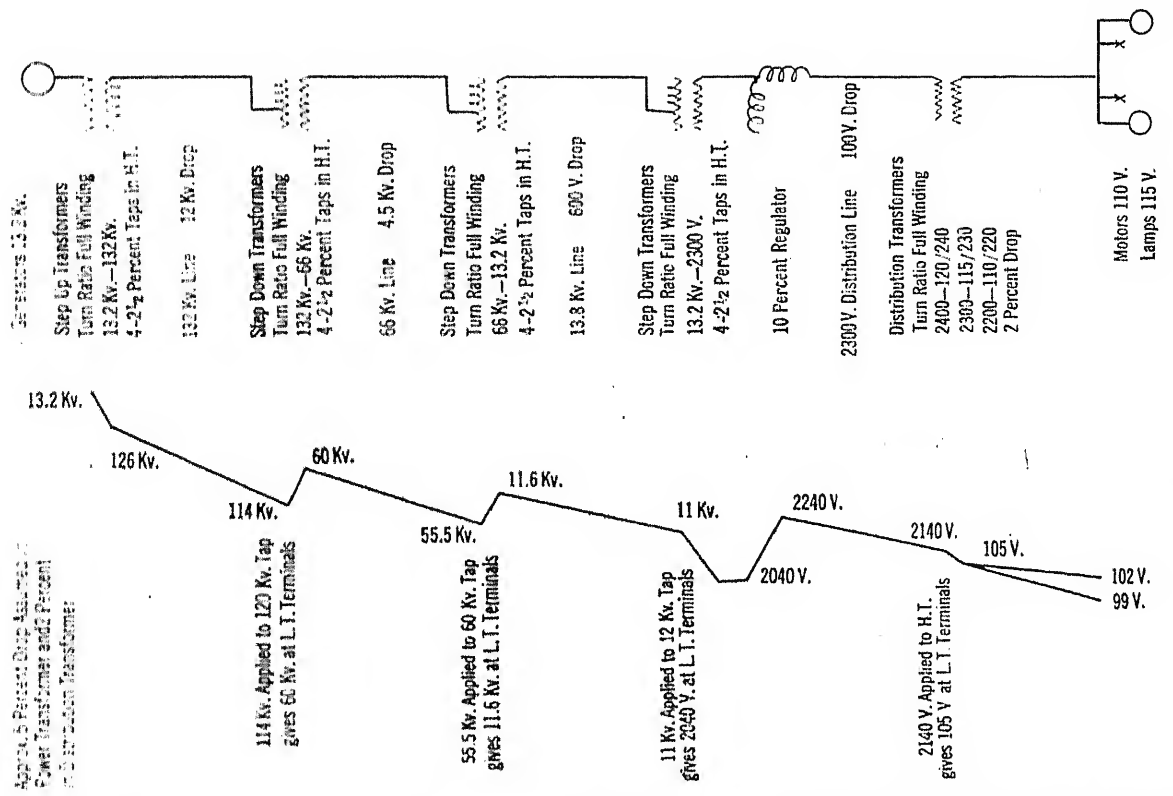

FIG. 1 TRANSMISSION AND DISTRIBUTION CONNECTION AND VOLTAGE CHART—OLD STANDARD VOLTAGES—FULL LOAD

alternative at present is to over-excite the generating end of the system. It is this that is now so commonly done. If we assume motor and lamp voltages as fixed, it would seem obvious that the principal faults with the present system are that transformer ratios (ratios of primary to secondary) are too high and generator potentials too low.

The new system of standard voltages here proposed contemplates a change in the principle of the present system. An example of the new system is shown in Fig. 2. Here, as in the present system, step-down transformers (in fact all used at the receiving ends of lines) will be equipped with the equivalent of four 2½ per cent taps in the primary windings. below rated voltage. Step-up transformers, for location adjacent to operated at rated voltage, and rated voltage is supplied to lamps and motors, there are still remaining taps in reserve in the transformer banks, and only half the boost in the regulator is used. So much for the principle involved in the proposed system—now let us consider the actual voltage values it is proposed to assign to the several voltage classes. These are shown in the accompanying tabulation. They are admittedly a compromise with the present standards. The motor voltages now in use have been retained. In the lower voltage range generator voltages will not be changed; in the upper they will be increased approximately five per cent. Step-down transformers having primaries rated 2300 volts, in which class fall the millions of kv-a. capacity now in use for lighting service,

will not be changed. It is proposed to change the ratios of all others so that they will readily conform to the new system. Even here it has been possible to retain ratios (when using tap connections) that will permit paralleling new with old units to a limited extent.

By the definitions previously quoted, the rated system voltage becomes the rated voltage of the generators or secondaries of the transformers supplying the system. It will be noted in the accompanying tabulation that above 4150 volts recommended system voltages are approximately multiples of 11.5 up to and including 69,000 volts; above they are multiples of 11.0. This is a compromise based on a study of existing systems and the cost involved in changing manufacturers' present standard designs. There are so many step-down transformers in the 66,000-volt class and

the high voltages as on the low. of the higher values would prob redesign of most of the present particularly that of oil circuit b of which, along with the specia their manufacture, would be an exp industry.

The previously cited proposed Circuit Voltage" provides that t should not exceed the rated circ an extremely difficult, if not imp meet in normal operating prac condition, the generating end of normally operated below the rat provision is to be made to have a r range to overcome abnormal vol

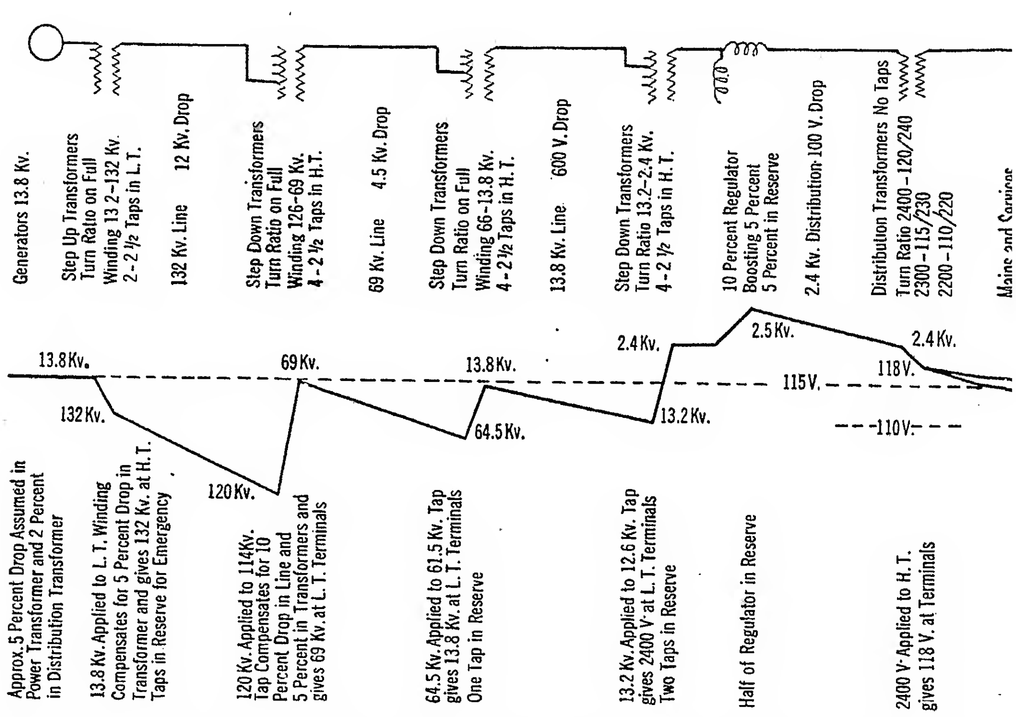

FIG. 2—TRANSMISSION AND DISTRIBUTION CONNECTIONS AND VOLTAGE CHART—NEW PLAN—

below whose primaries are multiples of 11.0 that it was thought inadvisable to change their voltage ratings, and it was necessary therefore to increase the system voltage ratings and step-up transformer secondary voltages for these classes to multiples of 11.5. The manufacturers' present standard switching equipment (up to and including 73,000 volts) has ample margin in their voltage ratings to permit the proposed increase in system voltage ratings without necessitating changes in their design. Above 69,000 volts, the practise now in general use of standard system voltages that are multiples of 11.0 seems to be satisfactory. While there are theoretical reasons to indicate that a single standard based on voltages which are multiples of 11.5 should be established above 69,000 volts, general practise still indicates that this is not as necessary on

the sources of generation and utili gency conditions, such as the loss parallel group of transmission lines Standards recognize a not dissimil case of motors and transformers (s 7-700, 13-500). In the case of mo specify that they should operate su load at any voltage not more than 1 below rated voltage; in that of tran should operate successfully at rated on full winding at five per cent ab This might be interpreted as a reco that under usual conditions it is not to operate apparatus at rated voltag that this recognition be extended apparatus. To make the range 20

case of motors, will be costly and probably unnecessary.

It is here suggested that a 10-per cent range be recognized in the case of generators, synchronous condensers, transformers, and apparatus (excluding motors) employed in generating, transmission and distribution systems with the exception of maximum rated apparatus (including under column titled "Apparatus"). It is recommended that these classes of apparatus, which are normally rated, be designed to operate successfully (but not necessarily within the guaranteed limits set for operation at rating) at rated load at any voltage not more than five per cent above or below rated voltage. Of course, apparatus will be operative below 95 per cent of rated voltage, but at reduced capacity. Such a change in the A. I. E. E. Standards will necessitate the manufacture of apparatus capable of operating at rated kv-a. output throughout the voltage range from 95 to 105 per cent of rated voltage. It is expected that the five per cent range above rated voltage will be reserved to meet emergency conditions. In other words, systems will be designed to operate normally at a voltage not to exceed their rated voltage. High potential tests will be based, as at present, on the rated voltage of apparatus, or, more accurately, on the "rated circuit voltage" of the system of which the apparatus forms a part. Maximum rated apparatus as given in the attached tabulation, *i. e.*, circuit breakers, disconnecting switches, etc., already contains the necessary tolerances in their maximum ratings and should not be used above such ratings.

It is expected that the rated voltages proposed here for step-up and step-down transformers, the essential feature of the plan, will make it possible to standardize apparatus so that it will meet most existing operating conditions without the necessity, which now prevails, of exceeding the established rating limits of the apparatus. Operators, under most conditions, will find it possible, when employing the proposed standard apparatus, to deliver rated voltage to apparatus at all points of their systems without exceeding the rated voltages of their systems.

The accompanying tabulation, with the foot-notes included with it, presents a brief summary of the proposed new system of voltage standards. A few further explanatory remarks might prove helpful in understanding it. The first column presents a list of the proposed "Rated Circuit Voltages." These set the maximum normal operating voltages of systems. It is proposed to permit operation at five per cent above these values but, as just mentioned, it is suggested that this margin be reserved for emergency operation. The second and third columns hardly need further explanation. In

GENERAL NOTE

Guarantees of efficiency, heating, overload, etc., and over-voltage tests of all apparatus should be based on the rated voltage of the apparatus with the exception of step-down transformers, the over-voltage tests on which should be based on rated secondary voltage; and a primary voltage five per cent greater than rated voltage.

SPECIFIC NOTES

"A"—Generators and synchronous condensers should be designed to deliver rated kv-a. output at rated power factor and frequency throughout a range of five per cent below to five per cent above rated voltage.

"B"—Induction motors should be designed to deliver rated h. p. throughout a range of 10 per cent below to 10 per cent above rated voltage at rated frequency.

"C"—Apparatus, as here used, includes oil circuit breakers, disconnecting switches, current transformers, insulators, bushings, and fuses. The voltage ratings of potential transformers should be the same as the recommended system voltage ratings; their secondaries should be rated approximately 115 volts to permit the employment of the now existing even ratios of transformation. Above 73,000 volts, apparatus should be designed to operate successfully at five per cent above rated voltage during emergencies. Up to and including 73,000 volts, apparatus is maximum rated. For maximum rated apparatus the operating voltage of the system on which it is used should not exceed the rated voltage of the apparatus even during emergency operation.

"D"—Lightning arrester voltage standardization recommendations have been omitted pending further study.

"E"—Transformers should be designed to operate during emergencies at five per cent above rated voltage, the over-voltage being obtained by over-excitation and not through the use of taps. They should be equipped with taps as follows:

(a) Step-up transformers should be equipped with the equivalent of two 2½ per cent full capacity taps in the primary windings to provide additional range for compensating for the voltage regulation of the transformers and to avoid over-excitation of generators.

(b) Step-down transformers should be equipped with the equivalent of four 2½ per cent full capacity taps in the primary windings to provide additional range for compensating for line voltage drop.

"F"—When possible, 11,500-volt systems should be discouraged in favor of 13,800-volt ones.

the fourth column the heading "Apparatus" is employed in a restricted sense, in the absence of a better term, to include oil circuit breakers, disconnecting switches, current transformers, insulators, bushings, and fuses. Years ago manufacturers standardized "apparatus" voltages up to and including 73,000 volts on the basis of maximum ratings, which is to say, without a five per cent over-voltage margin. The values were chosen after a study of the operating voltages of the then existing systems. The investigation revealed a conspicuous absence of voltage standardization in the range considered and maximum voltage values therefore were chosen somewhat above the more common voltages in use to include the numerous groups operating above the average voltages. The voltages of systems operating above 73,000 volts were fairly well standardized as multiples of 11.0, and so for these groups manufacturers standardized apparatus voltages as multiples of 11.0, but included a five per cent over-voltage operating margin for emergency operation. Higher values and greater over-voltage margins were considered but rejected because there seemed to be no logical reason or necessity to justify burdening users with the greater expense of higher voltage apparatus, particularly as all high-voltage apparatus is inherently expensive. Such is the explanation of why apparatus up to 73,000 volts is maximum rated and above nominal rated. The fifth and sixth columns, headed "step-up transformers," include the voltage ratings of transformers used at generating stations, where the potential drop between the generators and transformers is nil The seventh and eighth columns refer to transformers used at the receiving ends of lines. Most of these will be step-down units. There are a few instances where step-up transformers must be installed at the ends of transmission lines. The voltages and taps of these should be selected from the seventh and eighth columns Of course, the transformer voltages given in the tabulation are no load or turn-ratio voltages.

Economic Advantages of Voltage Standardization

The proportion of standard and special apparatus now in use is indicated by Fig. 3, which shows the kv-a. of transformers produced by two manufacturers up to May 30, 1926, arranged according to high-voltage rating, for transformers 250 kv-a. and over, and 44,000 volts and above. The total kv-a. at standard voltages, namely, 44, 66, 88, 110, 132, 154 and 220 kv., is 51 per cent, and the kv-a. at special voltages 49 per cent.

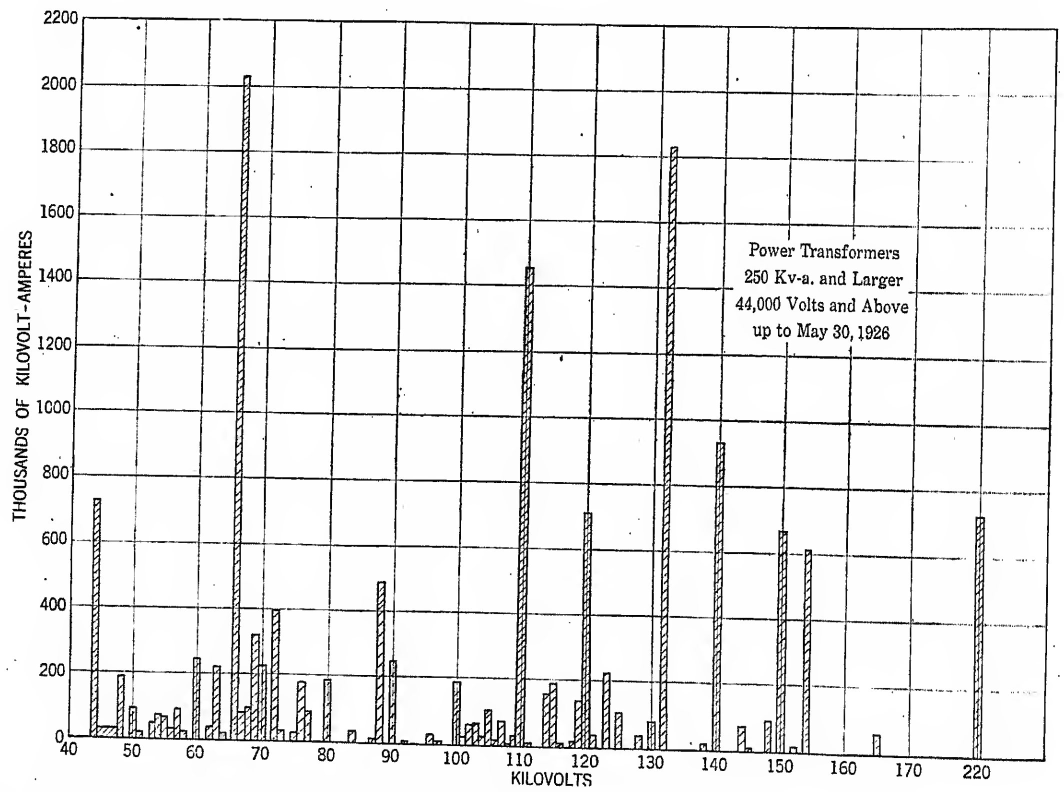

Fig. 3—Chart Showing Total Capacity of Installed Power Transformers of Various Voltages

Since the chart does not take into account transformers which have special low voltage ratings, it appears that at least half the transformers are special as to voltages and the specials are of still greater percentage if other features are counted.

The situation is not quite so bad in most other lines of apparatus, but even industrial motors which might be expected to be as completely standardized as any line, due to the large demand and the number and the relatively small size of the units, are found to include

20 per cent special units. It is of interest to note in this connection that a study made by one manufacturer shows that these 20 per cent require 60 per cent of the total shop supervision, whereas the 80 per cent standard units require only 40 per cent of the supervision. Switchboards, on the other hand, are practically 100 per cent special when considered as a complete unit, although of course the equipment mounted on them is mostly standard. This is to be expected since hardly any two generating stations or substations are sufficiently alike to require the same switchboard.

Truck type switchboards are a notable exception to this, however, since the individual cells and trucks lend themselves very readily to standardization. Unfortunately, there is a tendency here for various operating companies to standardize on a design worked up by themselves, rather than to standardize on the manufacturers' designs, so that so far as the manufacturer is concerned, each order is special. An example of what this means in price is found in a recent case where a large order of trucks and cells built according to the purchaser's designs cost eight per cent more than if they had been built according to the manufacturer's standard designs for exactly the same duty.

It is of great interest to consider some figures which have been worked up on the development costs for some selected types of apparatus, on the assumption that each unit is completely special in every particular. These figures are presented because their magnitude is truly surprising and indicates in somewhat startling fashion the seriousness of this problem of the production of special apparatus in modern manufacturing establishments. By development cost is meant the cost of patterns, dies, special tools, supervision, engineering, and drafting. For various classes of electrical equipment such as large power apparatus, truck type switchboards, industrial apparatus, etc., these costs vary from 150 per cent to 900 per cent in excess of the first unit cost of a similar standardized line of apparatus.

In order to visualize the amounts which special apparatus has cost the electrical industry, data have been compiled from statistics in the United States Census and other sources that show the investments up to date in various classes of electrical apparatus used in the generation, transmission, distribution, and utilization of electricity.

From these it is estimated that there is roughly two billion dollars worth of electrical apparatus now in operation in the United States, of which somewhere between 20 per cent and 50 per cent is special, depending on the particular type, with the exception of lamps which are only about eight per cent special. If all the specials had been eliminated, the industry would have experienced, from two causes, a worth while reduction in this two billion dollars, the effects of which are roughly evaluable:

1. Standard apparatus would not have had to bear part of the development cost of the specials,

2. The increased sale of standards to take the place of the specials would have caused a further reduction in their price in accordance with the law of quantity production.

Estimates by various methods indicate that the effect of the use of special apparatus has been to increase the total investment in electrical apparatus by from 100 to 200 millions or from five to ten per cent of the total.

The proposed standardization of system voltages and apparatus voltages fitting in with the already standard utilization voltages should have a marked effect in the reduction of these extra investments in the future. This standardization should also make available considerable economies in the industry through facilitating interconnection and reducing the extra investments required for interconnection.

Conclusions

1. The present system of voltage standards is not suited to operating conditions since insufficient allowance is made for voltage drop in lines and transformers.

2. The extensive use of special apparatus for maintaining proper voltage at the load, supports this contention.

3. The use of special apparatus is undesirable since it raises costs, delays deliveries, reduces interchangeability of apparatus from point to point of a system or connected systems, impedes the policy of system interconnection recommended by the National Electrical Light Association, and reduces the efficiency of renewal and repair part service.

4. A new system of voltage standards is proposed whereby all apparatus on the system will be rated to conform to the following transformer ratings: Up to and including 69,000 volts, the primaries of transformers will be rated on the basis of multiples of 11 (except the 2300-volt class), and the secondaries on the basis of multiples of 11.5; above that voltage the primaries will be rated on the basis of multiples of 10.5, and the secondaries on the basis of 11. This will allow for approximately five per cent greater voltage drop in lines and transformers than is now possible without reducing the voltage at the load. All other apparatus on the system will be rated in accordance with these voltages.

5. It is expected that the adoption of these proposed standards would eliminate the use of apparatus which is special with respect to voltage, and would therefore help remedy a situation which has cost the public from $100,000,000 to $200,000,000.

6. It is believed that the plan set forth here will fulfill the five conditions set forth in earlier paragraphs and furnish an escape from the present embarrassing dilemma, and it is hoped that those interested in this question of a-c. voltage standards will accept and consider this proposal in the spirit in which it is offered,

namely, simply as a basis of discussion, as a seriously and comprehensively thought out plan of voltage standards for all apparatus employed in transmission systems. It will fully serve its purpose should it lead ultimately to a rational set of standards which can be employed with a reasonable degree of success in new systems and throughout an appreciable part of existing ones.

Discussion

For discussion of this paper see page 205.

Voltage Standardization

From a Consulting Engineer's Point of View

BY R. E. ARGERSINGER[1]

Member, A. I. E. E.

Synopsis.—The author points out certain reasons why specifications for purchased equipment have not followed the manufacturers' existing standards and recommends certain changes in standards for system and apparatus voltages. The importance of having transformers interchangeable as step-up and step-down units is pointed out and, by means of five per cent taps above and below rated voltages in both windings, it is proposed to obtain sufficient flexibility for such interchangeable use. The paper gives a comparison between transformers designed as suggested above and transformers designed according to the manufacturers' recommendations, and the suitability of the suggested tap range is pointed out.

A recommendation is also made that the number of ratings of oil circuit breakers should be reduced.

VOLTAGE standardization is of value to the consumer principally in two ways; first, that equipment may be used under a variety of operating conditions, and second, that it may be obtained more quickly and at less cost.

If the first result can be secured, the electrical manufacturer's production problems should be so simplified that the second would follow readily. It should be remembered that in discussing the possibility of securing apparatus, such as transformers, at lower prices by standardization, comparisons should be based on the cost of equipment actually purchased at present rather than on the cost of the present standard transformers since it appears that less than half the transformers purchased are standard.

The present standards have not been closely followed because, first, the operating companies in general have given too little consideration to simplifying their requirements, and second, in designing for standardization the manufacturers have placed too much emphasis on cost reduction and have paid too little attention to flexibility of use.

The transmission line data published in the *Electrical World* for January 3, 1925, list eighteen different circuit voltages between 44,000 and 220,000 kv. Other variables have been brought into the situation until one manufacturer now lists 63 different oil circuit breaker ratings between 15,000 and 220,000 volts. Some of these are subject to two and some to three modifications for altitude so that something like one hundred fifty presumably standard breaker ratings are listed for the voltage range indicated, and these do not include the *H* breaker or other low-voltage indoor switches. On the other hand, in their laudable effort to reduce costs, the manufacturers have standardized a range of transformer taps that is not sufficiently flexible for general purposes and have limited too closely the allowable range of terminal voltages.

In the N. E. L. A. *Bulletin* for September, 1926, a proposed plan is offered as a remedy for existing conditions, but it appears to be open to several objections[2]. First, it is not simple; here are at least two, and in most cases three, standard equipment voltages for each system voltage. Second, it is not flexible. Standard transformers and breakers should be interchangeable through the greatest possible number of applications. Transformers should be rated in terms of standard system voltages and should be capable of use between any two systems whose voltages are included in the nameplate rating of the transformer, from which it follows that they should be interchangeable as step-up or step-down units. Third, it does not appear to offer sufficient simplification in manufacturing processes to yield enough benefit to the purchaser to cause him to specify standard equipment.

In an endeavor to meet these objections and at the same time to adhere as closely as possible to present practises, the following scheme is suggested:

First. Standard voltages should be as given in Table I.

1. Chief Electrical Engineer, Stone & Webster, Inc.

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., Feb. 7-11, 1927.

2. See also *Voltage Standardization of A-C. Systems from the Viewpoint of the Electrical Manufacturer*, by C. F. Hanker and H. R. Summerhayes, A. I. E. E. Winter Convention, February 1927.

Second. All apparatus except motors should be rated at a standard system voltage.

All motors for use on systems of 600 volts and less should be rated at approximately 8½ per cent less than system voltage. All motors for use on systems above 600 and not exceeding 13,800 volts should be rated at approximately 4½ per cent less than system voltage.

Third. Each winding of all large power transformers should have one full capacity 5 per cent voltage tap above and one full capacity 5 per cent voltage tap below rated voltage. Small power and distribution transformers should be rated in accordance with existing standards.

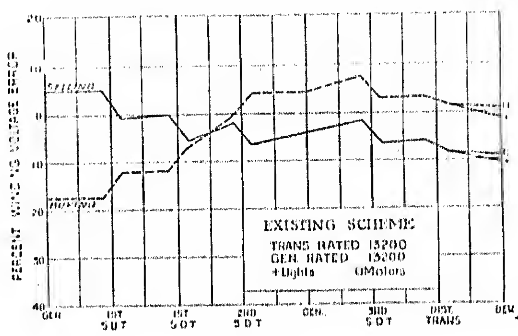

Fig. 1

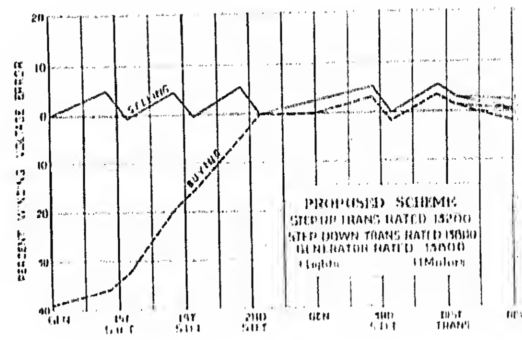

Fig. 2

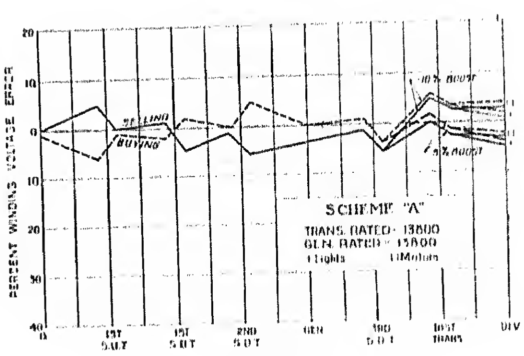

Fig. 3

Fourth. All generators, synchronous condensers, synchronous converters, arc rectifiers, small power and distribution transformers should operate at rated

load without exceeding rated temperature rise through a range of from 95 to 105 per cent rated voltage.

All large power transformers should operate at rated load without exceeding rated temperature rise when excited at 7½ per cent above the rated voltage for the winding terminal to which the circuit is connected.

All motors should operate at rated load without exceeding rated temperature rise through a range of from 90 to 110 per cent rated voltage. All circuit breakers, disconnecting switches, fuses and instrument transformers should operate at rated current without exceeding rated temperature rise when used at 7½ per cent above rated voltage.

Fifth. Proposed definition of rated circuit voltage. Rated voltage of a circuit or system is the highest rated voltage of the apparatus supplying it and should be stated in terms of line-to-line voltage. In order to conform to A. I. E. E. Standards, the dielectric tests of all apparatus connected to a system should be based on rated circuit voltage.

Sixth. The A. I. E. E. standard dielectric tests for oil circuit breakers, disconnecting and horn gap switches and current transformers, should be modified so that all such equipment for use on all system voltages of more than 600 and less than 110,000 will be tested at two and one-half times rated voltage plus 2000 volts, tests for similar equipment built for 110,000 volts and above to remain as at present.

Following the general method outlined in the N. E. L. A. Bulletin, a comparison has been made of system transformer arrangements based on the use of (a) existing standards, (b) those proposed in the Bulletin and (c) those proposed herewith and designated "Scheme A." Conditions which will obtain when buying, as well as when selling, power, have been analyzed. Results are shown in Table II.

Considerable stress has been laid on the matter of buying power because with the rapid increase in system interconnections, it is almost essential to have transformers wound so that they may transfer energy in either direction. It is also desirable, in order to keep pace with the demands of a growing system, to have transformers suitable for transferring from one part of the system to another. All large power transformers should be designed, therefore, for use either as step-up or step-down units.

Curves have been plotted as shown in Figs. 1, 2, and 3 to indicate approximately in per cent the variation of the actual circuit voltage from the winding voltage at various points in the system designated as generator (GEN.) first step-up transformer (1st S. U. T.), first step-down transformer (1st S. D. T.), distribution transformer (DIST. TRANS.), device (DEV.), etc. Fig. 1 gives the variations in per cent between actual voltage and winding voltage when using transformers built to existing standards; Fig. 2, similar data, using transformers as proposed in the Bulletin; and Fig. 3, using transformers according to Scheme A.

Table III shows the maximum variation in per cent between actual circuit voltage and rated circuit voltage measured at the transformers but omitting distribution transformers.

It is possible with transformers designed according to Scheme A that voltages approximately 13 per cent above rating (7½ per cent over-excitation) may be impressed on the winding. It appears that there are many transformers built to existing standards now in operation at equal over-voltages and the record of trouble does not seem to indicate the necessity of increasing the transformer dielectric test. In rating oil circuit breakers at a standard system voltage instead of at a considerable over-voltage, as is the present custom with breakers below 110,000 volts, encroachment should not be made on the existing insulation factor of safety and the proposed change in the circuit breaker dielectric test therefore has been offered.

While not strictly a matter of voltage standardization, there is an opportunity for a very considerable reduction in the number of standard circuit breaker ratings if careful standardization is undertaken. By following the proposed system voltages and by elimination of many current, as well as rupturing capacity ratings, the number of standard ratings and list of standard breakers could be so shortened that the increase in production of breakers having duplicate ratings should produce a considerable reduction in manufacturing costs.

CONCLUSIONS

The data seem to indicate that the so-called Scheme A is preferable for the following reasons:

First. The number of standard voltage ratings is reduced.

Second. The flexibility of apparatus is increased. The transformers are practically interchangeable as step-up or step-down units and should be suitable for use on any well-designed system of the same rated voltage.

Third. The rated voltages of the transformers are close to the corresponding rated system voltages.

Fourth. The actual operating voltages are close to the winding voltage.

Discussion

For discussion of this paper see page 205.

Standardization of Voltage Ratings
For Power Systems and Equipment

BY A. E. SILVER[1]
Fellow, A. I. E. E.

and

A. L. HARDING[2]
Associate, A. I. E. E.

Synopsis. This paper undertakes to analyze the voltage practises and requirements of alternating current power systems with the aim of arriving at voltage standards that adequately correct and extend present standards.

Utilization, or receiving terminals, is taken as the point of reference and for designation of system, circuit, and equipment voltages.

For this analysis and development of voltage standards a comprehensive chart, showing operating voltage limits of representative systems, is given in Plate 1. A tabulation summarizing the proposed standard voltage ratings is given in Table XI.

FUNDAMENTAL CONSIDERATIONS

IN the preparation of this paper the authors endeavor to express the results of their experience in dealing with the voltage problems of a number of alternating current power systems well distributed throughout the United States. These systems, while not serving the largest metropolitan areas, do include a wide diversity in size and kind which makes them perhaps representative of usual requirements.

It is not the purpose of this paper to demonstrate the inadequacy of existing standards of equipment voltage ratings, a condition already recognized by manufacturers and operators. Nor is it the purpose to elaborate on the benefits of standardization of equipment voltages. The resultant economy through reduction in a multiplicity of types, through efficiency and convenience in manufacture, in the handling of spare parts, and in flexibility in use, is self-evident.

The purpose of this paper is to develop and propose a schedule of standard voltages believed to meet actual operating requirements and practises in alternating-current power systems. The authors endeavor to deal with the problem without undue adherence to A. I. E. E. or other existing standards wherever experience places the adequacy of any such standards in question. It is believed desirable that in any such standardization, the opportunity be taken to correct inadequacies of this kind.

It must be recognized that many systems, particularly among those that are larger and of pioneer origin, are non-standard, and probably for a long time will continue non-standard, as regards any revised general voltage standards that may be worked out. It seems impracticable to develop voltage standards with sufficient steps to include all of these systems. Some of these will doubtless continue with their individual standards, and move toward general standards only as the opportunity to benefit arises from time to time in the natural course of replacements or reconstruction. Voltage standards, when determined, will in practise, fall short of universal application. They will in effect be schedules of preferred voltages serving as a guide to the maximum practicable uniformity of practise.

The system or class voltages now recognized and established by usage in the United States are as given in Table I.

The inadequacies of present standards of equipment voltages seem to have come about from lack of sufficient appreciation of the relation between voltage levels and functions of a modern power system. For example, take the case of present standard transformers which were developed for distribution service purposes. Many users have purchased these distribution ratio transformers and applied them at supply substations and even for step-up purposes. Experience shows that they cannot be used successfully for all three of these functions. Many of the conditions obtaining on present systems, of equipment operating at voltages seriously in excess of rating, have doubtless come about in this way.

It is reasonable and in accord with operating conditions to define the fundamental reference plane for all voltage standardization of a given class, or the "nominal system voltage," as the mean voltage at utilization terminals, that is, at receiving terminals. This is the plane where the central station company meets the consumer, the "counter" where the product of the industry is delivered. The consumer is interested only in the voltage at his utilization terminals, not at some

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

point in the complex supply system which he does not understand. A power company which purchases its energy is interested in the voltage maintained at the point where it is received, not at some remote point in the system of the transmission company. The present habit of designating system voltage in terms of generation or supply voltage gives an undue appearance of non-uniformity of voltages among systems. This is because generation voltage is used extensively as a means of taking up the voltage "slack" of the system, so that efforts to maintain uniform utilization voltage may bring substantial differences between voltage values at the respective points of generation. The point of utilization is thus the point of practical voltage reference. It is the logical point to establish as nominal or designation voltage.

In the usual power channel between the point of utilization and the source, there are essentially three voltage steps or levels, that of the utilization and distribution zone, that of the high voltage distribution zone, and that of the remote source or transmission zone. In building up a practical schedule of standard voltage ratings for equipment to fit these three zones and to give essentially nominal voltage at receiving terminals, first consideration should be given to actual operating requirements and practises. However, standard equipment ratings now in use should be retained as far as may be reasonably practicable, although this will require that suitable correction be made in some of these standards which now limit effective and efficient power supply under existing and modern methods.

Obviously, standardization in voltages of utilization equipment such as lamps, appliances and motors, where the great bulk of equipment is used, is basic. Voltage standardization for distribution equipment is of next importance, voltage standardization for transmission and high voltage equipment is of least importance. The latter applies in that portion of the system where inequalities can best and most economically be adjusted because units affected are relatively few in number and of large size. It is logical then that a study intended to review, to revise, and to better coordinate existing voltage standards should progress from the utilization end of the system.

Utilization Requirements

The basic assumption in this paper is a standard lamp and appliance rating of 115 volts and a standard motor rating of 220 volts. No conclusions are drawn as to the suitability of 115 volts as a lamp standard, as compared with 110, 120 or any other voltage, but rather the 115-volt rating is taken as essentially averaging present usage and recommendations of the National Electric Light Association Lamp Committee. Being a fundamental of voltage standardization, this 115-volt rating should be confirmed or some other thoroughly considered value definitely decided upon. If by reason of further study the 115 volt lamp standard should be changed, corresponding adjustments must be made in those values here given which are built upon this basic value.

In practise small utilization demands are served extensively from combined three-phase motor and lighting secondaries arranged in the 3 wire delta or 4 wire star system. The delta circuits probably constitute the usual distribution arrangement; however, the more recent rapidly extending and advantageous use of 4 wire secondary networks establishes the star system as an important distribution circuit arrangement, particularly in areas of heavy load density. Lamps and appliances of 115 volts, 220-volt motors and distribution step-down service transformers, particularly of the 2300-volt class, are in extensive use on both of these systems. It is essential that standardization be such that lamps, appliances, motors, and service transformers can be used interchangeably on both delta and star systems.

Table II indicates voltage conditions obtaining when present utilization equipment designed for and rated at

TABLE II

OPERATING VOLTAGES OF UTILIZATION EQUIPMENT

Average approximate per cent departures from present nameplate rated voltages

Lamp socket or terminal voltage	Lamps rated 115 v	Motors rated 110/220 v	Service transformers rated 115/230 v
110–220 delta	− 5	0	− 3
110–190 star	− 5	− 15	− 3
115–230 delta	0	+ 5	+ 2
115–199 star	0	− 10	+ 2
120–240 delta	+ 5	+ 10	+ 7
120–208 star	+ 5	− 5	+ 7

115 volts (or 110/220 volts for motors) is used at each of the three voltages, 110, 115, and 120. The values in the table give an approximate picture of the necessary excitation range of equipment, without intending any expression as to the correctness of present nameplate ratings in respect to service results. The minimum departures from rated voltage obtain with the 115-230 volt delta and 115-199-volt star terminal voltages considered jointly.

The Distribution System

By definition, as previously noted, nominal system voltage is the mean voltage of equipment at utilization terminals or receiving terminals. It follows that in the ideally designed and operated distribution system nominal voltage of 115 will always obtain at that lamp or appliance so located in the distribution system as to receive the mean voltage of all lamps and appliances, that is to say, the divergence from the standard of 115 volts at the lamp terminals will be the same percentage for that lamp in the distribution system nearest the supply source, as it is for that lamp in the distribution system most remote from the supply source.

A typical distribution circuit comprises house wiring,

service taps, secondary mains, service transformers, primary mains, primary feeders, and feeder regulators. To these various parts of the circuit are assigned assumed percentage limits of voltage drop, which are believed to conform reasonably to good practise.

These assigned values of voltage drop for a distribution system are given in Table III.

In developing voltage standard schedules, it is necessary to lay down a background comprising the limits of the various factors that must be covered and coordinated in the spread of such standards. To be worth while, these standards must anticipate future development and growth so far as practicable; that is, standards established now must not only be adapted to present needs but also must be developed with thorough consideration of future needs. Plate 1 is a chart indicating these limits sufficiently, it is believed, to serve as a guide in building voltage standards, at least tentatively, although further survey and analysis of actual conditions is desirable if not essential to final standardization.

Plate 1 includes typical 2300 and 13,200 nominal voltage distribution with primary feeders serving primary load centers, remote from the supply source.

TABLE III

LIMITS FOR DISTRIBUTION SYSTEM VOLTAGE DROPS IN PER CENT

	Heavy load	Light load
House wiring	2.0	0.5
Service tap	1.0	0.25
Secondary main	2.0	0.5
Service transformer	2.5	1.0
Primary main	2.0	0.8
Primary feeder	8.0	2.5

Note: Heavy load is taken at 0.9 power factor. Light load is taken at 25 per cent of heavy load and at 0.75 power factor.

In the 2300-volt portion of the chart, there are assumed distribution or service transformers of the present 20:1 ratio and 115 volts delivered under all loads at the lamp receiving mean voltage. It will be noted that this system requires a variation in voltage at the supply station bus of from 2398 volts at light load to 2674 volts at heavy load, or a mean voltage of 2536.

In the 13,200-volt nominal system shown on the chart, if there are assumed service transformers of the present ratio, 120:1, and 115 volts delivered at the lamp receiving mean voltage as before, there will be required a variation in voltage at the supply station from 14,400 volts at light load to 16,010 volts at heavy load or a mean voltage of 15,200 volts. Obviously, these values are excessive and untenable. For reasons that will be explained more fully later, a voltage of 13,900, that is, approximately 5 per cent above nominal, is considered the upper limit of permissible mean voltage for a distribution system of this voltage class. It follows that a change from the present standard transformer ratio for this class is essential. Assuming a ratio of 110:1, that is, 13,200:120-volt distribution transformers, it will be noted that the system requires a variation in voltage at the supply substation bus of from 13,190 volts at light load to 14,705 volts at heavy load or a mean voltage of approximately 13,900 volts.

Note A: As regards voltage regulation calculations by referring to Plate 1 and Table III, if we call X the per cent voltage drop from the secondary of the step-down service transformer to the mean voltage lamp, then from this lamp the voltage will rise X per cent to the secondary of the service transformer, 2.5 per cent through the transformer and 1.2 per cent back to the primary feeder load center. The lamp having the highest voltage will have the voltage of this load center reduced by 2.5 per cent through the transformer and 1 per cent through the service tap. Similarly the lamp having the lowest voltage will have this load center voltage reduced by $2 + 2.5 + 2 + 1 + 2$ or 9.5 per cent.

Now calling C the percentage departure from normal voltage, for the lamps, we have:

$+ C$ (highest voltage lamp) $= (X + 2.5 + 1.2 - 2.5 - 1)$

$- C$ (lowest voltage lamp) $= (X + 2.5 + 1.2 - 2 - 2.5 - 2 - 1 - 2)$

$$+C = X + 0.2$$
$$-C = X - 5.8$$
$$X = 5.8 - C$$
$$C = 5.8 - C + 0.2$$
$$C = 3.0$$
$$X = 2.8$$

That is, the lamp having mean voltage will be so located that the voltage drop from the secondary of the service transformer to the lamp will be 2.8 per cent.

It is an important consideration that, next to utilization equipment, step-down service transformers represent the largest single class of standardized equipment in use today on alternating current power systems. It is accordingly essential to practical standardization to utilize these present ratio step-down service transformers, so far as practicable.

As has been shown it is practicable to utilize present ratios in the 2300 volt class. These transformers, now so extensively in use on nominal 2300 volt distribution systems, can be used for delivering rated voltage to standard 115-volt lamps. While this requires increasing the excitation of the transformers above nameplate rated value, it does keep within limits which experience has shown permissible. Reference to Plate 1 will indicate the voltage limits encountered in practise. Adoption of a 120-volt lamp standard would necessitate carrying the excitation of these transformers still higher and probably excessively above the voltage limits for which they are suited. While no modification in present 2300-volt service transformer ratios is necessary and full benefit of interchangeability with existing equipment of this class can be retained, the nameplate rating should be revised to 120-volt secondary, *i. e.*, 2400:120 volts.

For service transformers in the 13,200-volt class, and in fact all distribution classes except the 2300- and 4600-volt classes, new ratios and ratings must be assigned if excessive bus voltages and excessive feeder regulator ranges are to be avoided. As has been shown the proper ratio in the 13,200-volt class is 110:1, 13,200:120, and similarly for other classes.

On the foregoing basis, step-down service transformer ratings as in Table IV are proposed.

From Plate 1 it also becomes evident that feeder regulators, oil circuit breakers, disconnecting switches, lightning arresters, and other miscellaneous equipment used on distribution systems, under limiting load conditions may be subjected to operating voltages approximately 10 per cent, and in some cases 15 per cent, in excess of nominal system voltage. The proposed ratings for general apparatus are somewhat adjusted where practicable, in order to retain some existing voltage ratings of this apparatus. It is understood that all equipment, transformers and generators included, is designed for successful operation, with an emergency tolerance of 5 per cent above voltage rating. The proposed ratings closely approximate and in most cases coincide with existing ratings for general apparatus. In practical application some elimination and consolidation to reduce the number of classes may be found feasible. It will be noted also that the proposed ratings extend so as to overlap and include, on the same basis, equipment used in the transmission zone of voltages. As will be shown later, these ratings are suitable for use in the transmission zone.

TABLE IV
PROPOSED STEP-DOWN SERVICE TRANSFORMER VOLTAGE RATINGS

Nominal system or class voltage	High voltage*	Low voltage*
115	..	120
230	..	240
460	480	480
575	600	600
2300/4000 Y	2400/4150 Y	2300/4000 Y
4,600	4,800	4,600
6600/11,430 Y	6600/11,430 Y	6600/11,430 Y
11,000	11,000	11,000
7620/13,200 Y	7620/13,200 Y	7620/13,200 Y
13,200	13,200	13,200
22,000	22,000	..
33,000	33,000	..
44,000	44,000	..
66,000	66,000	..
88,000	88,000	..
110,000	110,000	..
132,000	132,000	..

The high voltage winding has two 5 per cent full-capacity taps except that all taps are omitted in the classes 2300-volt and below.

*All values are at nominal except 4600 volt and below in the high side and 575 volt and below in the low side. These values are raised approximately 5 per cent to more nearly conform to voltages actually encountered in practise.

The proposed voltage ratings for general apparatus are given in Table V.

The receiving voltage at a centrally located supply substation should be logically nominal system voltage as by definition this receiving point becomes essentially a major utilization terminal.

A power company may supply several distribution substations and customer service substations from the same feeder. It is of course not feasible to deliver nominal system voltage to all simultaneously. Assuming a maximum limit of 10 per cent total voltage drop of feeders extending across a major load area and assuming nominal system voltage at the central or mean point of that load area, the feeder voltage at the beginning, or leading edge, of the receiving zone will be at approximately 5 per cent above nominal, the far limits at 5 per cent below nominal.

Under these conditions, it is obvious that step-down transformers at the leading edge of a major load area would operate on full winding, those at the load center would operate on a 5 per cent tap and at the far limits of the area on a 10 per cent tap.

As indicated on Plate 1, in order to maintain constant voltage at the mean lamps, feeder regulators may be called upon to operate between the limits given in Table VI. Present standardization of 10 per cent buck and 10 per cent boost for feeder regulators, is, therefore, reasonably adequate. Without the change in service transformer ratios in the 13,200-volt class, heretofore discussed, a feeder regulator operating range of at least 20 per cent all on the boost side, is required.

Table VI shows conditions imposed on feeder regulators.

It is assumed as the basis of the voltage chart, Plate 1, that constant voltage is held at the supply substation bus at the beginning of the distribution zone, by generator voltage variation. Essentially constant voltage, held by synchronous condensers or otherwise, at some such point imtermediate between utilization and generation, is necessary to avoid a prohibitive corrective range of feeder regulators. The profile on Plate 1 shows the relative values and spread of voltage progressively back through the system, for both heavy and light load conditions.

TABLE V
PROPOSED VOLTAGE RATINGS FOR FEEDER REGULATORS, OIL CIRCUIT BREAKERS, LIGHTNING ARRESTERS AND OTHER MISCELLANEOUS APPARATUS

Nominal system or class voltage	Apparatus voltage rating*
115	125
230	250
460	500
575	625
2300/4000 Y	2500/4330 Y
4,600	5,000
6600/11,430 Y	7500/13,000 Y
11,000	12,000
7620/13,200 Y	8500/15,000 Y
13,200	15,000
22,000	25,000
33,000	37,000
44,000	50,000
66,000	73,000
88,000	96,000
110,000	120,000
132,000	145,000
154,000	170,000
220,000	240,000

*These apparatus voltage rating values are approximately nominal plus 10 per cent.

It should be noted that these profiles are not plotted directly in terms of voltage drop, as customary. Instead, they are plotted in per cent variation from

nominal voltage. The purpose is to bring out more clearly the improved relations maintained between voltage levels and nominal voltage and the corrective benefits throughout the system, gained by utilizing the transformer ratios proposed in this paper. If these voltage profiles were carried back from utilization terminals to generator terminals, using the present standard single ratio transformer throughout, the voltage departure from nominal would be much greater

TABLE VI

OPERATING VOLTAGE RANGE FOR FEEDER REGULATORS

Approximate per cent buck and boost

Location of regulator (Refer to Plate I)	2300-volt circuits: Present ratio distribution transformers 20:1	13,200 volt circuits: Present ratio distribution transformers 120:1	Proposed ratio distribution transformers 110:1
Distribution at end of load area	+ 6.5 (− 12.5)	+ 21.5 (+ 7.5)	+ 14.5 (− 1.5)
Distribution at center of load area	+ 6.5 (− 10.0)	+ 17.5 (+ 5.5)	+10.0 (− 3.0)
Distribution at beginning of load area	+ 6.5 (− 7.5)	+ 13.5 (+ 3.5)	+ 5.5 (− 5.0)
High voltage distribution at end of load area	+ 6.5 (− 6.0)	+ 14.0 (+ 0.0)	+ 6.0 (− 6.0)
High voltage distribution at center of load area	+ 6.5 (− 4.5)	+ 14.0 (+ 4.0)	+ 6.0 (− 4.5)
High voltage distribution at beginning of load area	+ 5.5 (− 2.0)	+ 13.5 (+ 6.5)	+ 5.5 (− 2.0)

than shown. In fact, the departure from nominal would be increasingly upon the excess voltage side and at the generator terminals would reach 18 per cent above nominal at heavy load and 4.5 per cent above at light load.

The High-Voltage System

The preceding discussion, starting from utilization requirements and working back through the distribution system, determines the necessary bus voltages at the supply substation. If this supply is derived from transmission or high voltage distribution circuits, then the low voltage windings of supply substation step-down transformers must deliver this required voltage.

Plate 1 includes a representative high voltage distribution system (66,000 volts nominal), comprising high voltage service transformers, supply substation transformers, transmission circuits and step-up transformers. Plate 1 also extends further to include a representative transmission system, (132,000 volts nominal), serving this high voltage distribution system from a remote generating source. Generating equipment may be used on any or all of the several supply buses in the composite picture. Many combinations other than those shown on Plate 1 are possible. This chart is intended only to set forth representative limits adequate for voltage standardization purposes.

To the respective parts of representative transmission and high voltage distribution systems are assigned assumed limits of voltage drop as given in Table VII.

These values of Table VII determine the necessary

TABLE VII

LIMITS FOR HIGH VOLTAGE SYSTEM VOLTAGE DROPS IN PER CENT

	Heavy load	Light load
Step-down supply substation transformer	5.0	2.0
High-voltage step-down service transformer	5.0	2.0
High-voltage distribution feeder (to center of high-voltage distribution zone)	5.0	2.0
Transmission line (to beginning of high-voltage distribution zone)	5.0	2.0
Step-up transformer	5.0	2.0

Note: Heavy load taken at 0.9 power factor average, light load taken at 35 per cent of heavy load and at 0.85 power factor average. The values of per cent drop given above also take to account load diversities, power factors, load factors, and line charging characteristics

voltage ratings of supply substation step-down transformers at ratios as given in Table VIII.

Plate 1 indicates the necessary voltages on the generating station high-voltage buses which thus determines the high-voltage rating of step-up transformers. The low-voltage rating of these transformers must for standardization purposes be consistent with the voltage

*Rated at nominal.

†4600 volts and below rated at nominal + 10 per cent.
6900 volts and above rated at nominal + 5 per cent.

rating for generators as described in later paragraphs. The voltage ratings for step-up transformers given in Table IX will satisfy these conditions assuming excitation of the low-voltage winding to be normal when overcoming transformer regulation.

At a generating station bus a step-up transformer is often used to serve a long high-voltage transmission to a remote load area. A high-voltage rating to provide for 10 per cent voltage drop in transmission seems a reasonable upper limit for standardization purposes.

Step-up transformers will operate normally on taps

when located at the edge of the receiving or load area so that the transmission zone in effect is eliminated.

Table IX provides for the foregoing conditions.

While separate types are proposed to meet the foregoing three functional duties of transformers, it is recognized that by providing a broader tap range with increased iron to enable full voltage excitation on under-

All high-voltage windings have two 5 per cent full-capacity taps.
*Rated at nominal.
†Rated at nominal + 10 per cent.

voltage taps, any two or all three of these types can be consolidated into a single standard. For example, to consolidate the service type and the supply substation type requires a high-voltage winding rated at nominal voltage with a 15 per cent full capacity tap range and 20 per cent total tap range and capable of normal excitation with full normal voltage impressed on the 95 per cent tap. Similarly, to consolidate all three types requires a high-voltage winding rated at 10 per cent above nominal voltage with a 25 per cent full capacity tap range and 30 per cent total tap range, and capable of step-down duty at normal excitation with full normal voltage impressed on the 85 per cent tap. The extent to which these three types should be consolidated, if at all, in final standards, is essentially an economic problem that must be decided by thoroughly weighing the benefits of interchangeability against the increased cost and other factors concerned.

A study of the limits shown on Plate 1 indicates that voltage ratings of oil circuit breakers, disconnecting switches, lightning arresters, and other miscellaneous apparatus as previously shown in Table V meet the requirements and operating practises of the high voltage system.

While the proposed ratings raise the present test voltages for general apparatus in the higher voltage classes, redesign of this apparatus is not necessarily required. Much of this apparatus is now operating successfully at voltages in excess of nameplate rating. In determining test voltages for these various types of equipment, it is assumed of course that designers will make allowance for differences in fundamental characteristics. Furthermore, as rapidly as advance of knowledge will permit, it is essential that the effects of impulse and other transient voltage phenomena be taken to account.

Generation Requirements

Generators, in many and perhaps the usual cases, deliver directly into supply buses and may operate at fixed voltage with feeder regulators or at variable voltage without regulators, within the limits shown on Plate 1. They must also coordinate with the low-voltage ratings of supply substation step-down transformers and step-up transformers, as previously proposed in Tables VIII and IX respectively. Furthermore, they must be suitable for use in industrial or isolated plant application.

Table X gives proposed generator voltage ratings to cover these requirements.

While synchronous condensers closely resemble generators in form, they are different in operating characteristics. They require special consideration in the matter of voltage rating and their comparatively limited use makes standardization at the present time probably premature.

Summary Tabulations of Proposed Voltage Ratings

The foregoing analyses are tabulated, for convenient reference, in Table XI, which assembles the proposed voltage ratings for equipment for alternating current power systems. In this tabulation are shown voltage

TABLE X
PROPOSED GENERATOR VOLTAGE RATINGS

Nominal system or class voltage	Normal voltage rating*	Rated operating voltage range ± 10%
115	120	110–130
230	240	220–260
460	480	440–520
575	600	550–650

steps and values considered sufficient to cove: the range of system conditions reasonably subject t: standardization.

In reading the values in these tabulations, it shoul be borne in mind that ideal precision has been avoide as impracticable. It is believed that the frequen approximations employed are within reasonble limits o precision considering the many variables and in consistencies being dealt with.

Conclusions

1. Present voltage standards for alternating current power systems and equipment are inadequate as they do not fit the needs and practises of representative power systems. This condition is generally recognized.

2. In developing general voltage standards, it must be recognized that there are some systems, particularly those of pioneer origin, which, because of large size and individual characteristics of voltage, will doubtless continue their individual standards and move toward general standards only as the opportunity to benefit arises from time to time in the natural course of replacements and reconstruction. General voltage standards will, in effect, be schedules of preferred voltages, serving as a guide to the maximum practicable uniformity of practise.

3. In developing voltage standards, a fundamental is to establish a suitable reference level or plane for voltage designation. The present practise of a reference level established at the point of generation is not suitable. As voltage "slack" of the system is most frequently taken up at the generating stations, this method of designation gives an undue appearance of non-uniformity of voltages as between systems. At utilization, or receiving terminals, is the point of maximum inherent voltage uniformity because this is the plane where the product is delivered and service is gaged. Uniformity of product at the point of delivery is the goal of system design and operation. Therefore, the fundamental reference plane for all voltages of a given class, or "nominal system voltage," is defined as the mean voltage at utilization terminals, that is, at receiving terminals.

4. Another fundamental is to segregate the power system along functional lines into zones of different voltage levels. It is especially essential in arriving at standards for transformer voltages and ratios that the correct relation between the zones of distribution, high voltage distribution and transmission be clearly understood.

5. A third fundamental is to adhere to present standards and practises in so far as reasonably adequate. However, where experience shows that any related standards including those of the A. I. E. E. are incorrect or insufficient, any needed corrections and extensions should be made.

6. A standard lamp and appliance rating of 115 volts and a standard motor rating of 220 volts are assumed. No conclusions are drawn as to the suitability of these voltages as compared with 110, 120 or any other lamp voltage. The 115 volt rating is taken as essentially averaging present usage and recommendations of the N. E. L. A. Lamp Committee. The definite establishment of a suitable value for lamp socket voltage is basic and should constitute an initial step in developing general voltage standards.

7. In practise, there are two outstanding systems of power and lighting secondaries, the three-wire delta and the four-wire star. It is important that standard utilization equipment be fully interchangeable as between these two systems of supply.

8. A chart is given, Plate 1, which brings out voltage relations between the essential features of power systems, together with operating voltage limits, as a means of determining the spread of operating voltages that must be provided for in general voltage standards. Basic assumptions for this chart include constant voltage held at the mean lamp terminal of each distribution feeder load area, by means of feeder regulators, and constant voltage held at some other plane intermediate between utilization terminals and generating station by generator voltage variation. The chart shows a profile of voltages progressively through the systems.

9. Tabulations in Table XI summarize the proposed standard voltage ratings for systems and various types of equipment. A foot note shows the relations, in percentages, between the proposed standard system and equipment voltages. However, in the tabulated values, frequent approximations are accepted in the interest of closer adherence to present standards. The more important features of the voltage standards proposed in Table XI include:

a. The present 20:1 ratio for 2300-volt distribution transformers is retained but normal rated voltages are raised from 2300:115 to 2400:120.

b. Both ratio and normal rated voltages are changed for the distribution transformers of the 13,200 volt class.

c. Three types of transformers are established for each voltage class, each having a ratio specific to its own functional duty. These types are service step-down, supply substation step-down, and step-up.

d. Transformer ratings are such, in relation to circuit voltages, that excitation on full winding is correct when the transformer is located at the beginning or leading edge of a load area. Taps in 5 per cent steps are provided for compensating regulation across the load area.

e. The present range of 10 per cent buck and 10 per cent boost for feeder regulators is retained.

f. Normal rated voltage for generators is raised approximately 5 per cent from present standards, and a normal operating range from plus 10 per cent to minus 10 per cent is required.

g. Present normal rated motor voltage is retained, and a normal operating range from plus 10 per cent to minus 10 per cent is required.

h. General apparatus, such as feeder regulators, switching equipment and lightning arresters, are rated for normal operation at 10 per cent above nominal system voltage.

i. A 5 per cent emergency tolerance above rated maximum operating voltage for all equipment is required.

10. The proposed standard voltage ratings for all equipment above 66,000 volts are higher than present

			2400 v class and below–no taps others 2–5% full capacity taps		2–5% full capacity taps 1–5% reduced capacity tap			2–5% full capacity taps		

Notes: Except for service transformers up to and including 4800 volts, which are deviated to adhere to ratios now in use, the voltage ratings of all transformer primaries coincide with the value of nominal system voltage. Except for this deviation and some other approximations, to more closely coincide with existing standard ratings, the values in this table bear essentially uniform relations to values of nominal system voltage as follows:

Lamps and appliances	—at nominal	Service transformers	Supply substation transformers	Step-up transformers
Motors	—at nominal minus 5%	High voltage—at nominal	High voltage—at nominal	Low voltage —at nominal
General apparatus	—at nominal plus 10%	Low voltage—at nominal	Low voltage —at nominal plus 5%	High voltage—at nominal plus 10%
Generators	—at nominal plus 5%			

Generators and motors have a normal operating range of 10 per cent above and 10 per cent below rated voltage.

Feeder regulators have a normal operating range of 10 per cent boost and 10 per cent buck.

For transformers in general excitation is normal when the voltage impressed on the primary terminals under full rated load is sufficient to overcome regulation and maintain rated voltage on the secondary terminals.

All equipment has an emergency tolerance of 5 per cent above rated maximum operating voltage.

*As between the 6600/11,430 Y, 11,000 classes and the 7620/13,200 Y, 13,200 classes, it is recommended that so far as practicable, preference be given to the 7620/13,200 Y, 13,200 classes with the aim of eventual elimination of the 6600/11,430 Y, 11,000 classes. Possibly other eliminations may eventually be found advisable.

†Present nameplate ratings.

ratings. Because much of this equipment now in service is of necessity being operated at voltages above present ratings with reasonably satisfactory results, no extensive redesign of equipment should be imposed by these requirements. Revision of nameplate data should frequently be sufficient.

11. It is not undertaken to offer test voltage requirements for the proposed voltage standards. Doubtless, some increases and changes from present standards will be required. The standardization of test voltage practises must be deliberate. This will call not only for changes in the A. I. E. E. standardization rules but also must take into account the effects of is impulse and other transient voltage phenomena, the present knowledge of which, though advancing, is limited.

Discussion

For discussion of this paper see page 205.

Voltage Standards for Electrical Distribution

H. B. GEAR[1]
Fellow, A. I. E. E.

Synopsis.—*This paper discusses the necessity for standardizing voltages and advocates the utilization voltage as the most logical reference base. It suggests that the ratios adopted should be uniform at all voltages. It also proposes that there should be a recognized standard for transformers in which the direction of energy flow is subject to change.*

THE necessity of standardization of utilization voltages has been recognized and accepted since the days when electric lighting systems competitive with different lamp voltages and operating frequencies constituted such an obstacle to progress that standard voltages and frequency became a commercial necessity.

Systems operating at 55 volts for lighting were discarded for 110 volts, and a 220-volt rating was chosen for use where energy was taken chiefly for power purposes.

In later years, processes of lamp manufacture were so improved as to permit the concentration of lamp output into three voltages—110, 115, and 120 volts. A steady increase in the 115-volt output, and a decrease in the relative outputs of 110- and 120-volt lamps has been in progress since that time.

Utilization voltage standards are now so well recognized that a multitude of household and motor-driven appliances have been produced in quantities and at prices which would have been totally impossible without standardization.

Utilities in many states are required by regulatory bodies to adopt a utilization voltage standard and to maintain regulation within prescribed limits above or below such standard.

This to a considerable extent, fixes the voltages in other parts of the system and makes the utilization voltage the natural base of reference.

The proposal to establish ratings which are integral multiples of 115 is a recognition of the fact that the utilization voltage is the most logical base of reference in an electricity supply system.

The utilization voltage is one which must be kept as nearly constant as possible through all ranges of load, and this is the only part of the system of which this is true.

Electricity supply systems have developed during the past quarter of a century from simple groups of distribution feeders, with one voltage level above the utilization pressure, to extended systems serving large areas with two or three voltage levels above the utilization pressure.

We are now in the process of constructing a superpower network through which these areas are being tied together, and which, in some cases, adds another voltage level to those already in service.

Each additional transformation, with its accompanying line, has added to the drop in voltage and necessitated provision of taps or other means of compensating for the added drop.

The result has been that apparatus is being operated at voltages above that for which it was designed, special windings have been specified, generators are being overexcited at certain hours, and the manufacturers have felt it necessary to call a halt for the discussion of remedial measures.

As an illustration of what is taking place in some systems, they present a diagram of voltage drops in the various parts of a system having five transformations between the generator and the consumer, with a total of about 50 per cent voltage drop between generator and consumer.

The drops chosen for illustration are average values and do not represent cases which could be found in practise involving greater drops.

It is obvious that the maintenance of voltage regulation under such conditions is a difficult problem with the best of equipment, and when there is imposed the limitation that the apparatus must not be subjected to over-voltage, the limitation will quite surely in many cases be exceeded.

Proposed Changes in Practise

The manufacturers have presented a scheme for accomplishing this by increasing secondary voltage ratings to multiples of 115 instead of 110, as at present rated.[2]

This provides a no-load pressure about 5 per cent above that given by the present standard and a full-load pressure, which offsets the drop in the transformer and delivers at full load the same pressure which is derived from transformers of the present standard at no load.

Taps are to be provided in the primary coils, as at present, to care for situations where the drop in connecting lines requires more compensation.

It is proposed that generator regulation be held within a range, from plus 5 to minus 5 per cent of standard rating.

1. Commonwealth Edison Co.

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

2. *Voltage Standardization of A-C. Systems from the Viewpoint of the Electrical Manufacturer*, by F. C. Hanker and H. R. Summerhayes, A. I. E. E. Winter Convention, February, 1927.

Some Limitations of the Proposal

The example presented shows the application of the new plan under full-load conditions, where a single series of circuits is involved

The complete picture of an average system would reveal other circuits taken off at the generating station delivering energy at the generator voltage level. It would also include additional lines taken off at the 132/66/13.2-kv. levels, having various percentages of line drop, which must be taken into account in fixing the setting of transformer taps.

Inevitably there will be certain of these branches which will deliver a pressure above or below normal during certain parts of the day.

In the particular circuit shown, the pressure at quarter load would be from 10 to 12 per cent above normal at the utilization circuits, assuming that the generator pressure was reduced from 13.8 to 12.8, as proposed, during the light load period and the feeder regulator were run at full choke. In addition to this, the transformer and line equipment at the 69-kv. and 13.8-kv. levels are also operating at 10 to 12 per cent above the proposed maximum voltage ratings.

This, of course, can be avoided by the use of tap changing devices operable under load, and it is quite apparent that such auxiliary equipment must be included in the completed picture of the situation.

The necessity of having a considerable range of control between light-load and full-load conditions suggests the desirability of having as wide a range as is economically feasible in the generator voltage. It is proposed to get a range of 10 per cent by operating at pressures below normal (down to minus 5 per cent) during light load, and at pressures above normal (up to plus 5 per cent) during hours of heavy load.

This will prevent over-excitation of generators if transformer taps are connected to give the necessary boosting voltage to compensate for full-load drop. At light load periods, tap changers will be required where the total compensation in transformers is more than the combined range of generator and potential regulators.

It is proposed that the voltages above 69 kv. be left as multiples of 110.

The stage of development thus far attained may be such that it is a difficult matter to make a change now, but to those of us who have not until recent years been brought into pressures above 69 kv., it comes as something of a shock to learn that if we subject our 132-kv. equipment to any pressure above 132 kv., we are exceeding the manufacturer's rating and presumably taking a risk in operation which is not shared by the manufacturer.

The manufacturer's explanation that it is not necessary to use the multiples of 11.5 in fixing rated voltages at pressures above 69 kv. is lacking in any reasons sufficient to warrant a break of so fundamental a character in the proposed standards.

Whether the 132-kv. equipment in service has been designed for a maximum pressure of 132 kv. or not, much of the existing 132-kv. equipment is so related to the system of which it is a part that inevitably it must be subjected to pressures up to 138 kv. or higher, under the normal conditions of daily operation.

The proposed plan of adding 5 per cent to the secondary as a part of the fixed ratio of a transformer obviously can not be followed on lines where the direction of flow of energy is changed from time to time, as is often the case in tie-lines between power stations.

In such lines the transformers must meet the voltage requirements of both step-up and step-down transformers. Also, they are often so related to each other that, in order to transfer energy in the desired amount without displacing the general level of system pressure, they must be equipped with pressure taps adjustable under load.

This requires pressure taps giving a range of 15 to 20 per cent in either direction to deliver proper pressure at the bus of the receiving station.

Observance of Standards

It is obvious that if a standard is to accomplish its purpose, it must be one which will be generally recognized as practicable of application and feasible in operation.

The failure of previously adopted standards to be generally observed seems to have resulted, in part, from a lack of adaptability of apparatus to working conditions, and perhaps from a lack of appreciation on the part of some engineers of the wide range of voltage drops which have been introduced in recent years into distributing systems.

The lack of adaptability has been met as nearly as is possible by the manufacturer's proposal to increase voltage ratings to a point where they will be similar to pressures which are normally encountered in practise.

The discussion of this subject in connection with the proposed changes has and will further serve to bring a greater number of engineers face to face with the situation in a way which will be beneficial.

The adoption of standards which automatically add voltage for full-load conditions will draw attention to the necessity of providing means of preventing overvoltage at light loads.

Conclusion

Voltage standards are a basic necessity for utilization equipment and are the basis of voltage throughout the system.

The manufacturer's proposal offers a decided improvement over present standards, but should treat all voltages on a uniform basis.

There should be a recognized standard for transformers used in interconnections where the direction of flow is subject to change.

When standards have been fixed which are applicable without radical change in existing equipment, they will, no doubt, be accepted and adopted by users of equipment.

Discussion

For discussion of this paper see page 205.

Voltage Standardization

Its Relation to the Interconnected Power Companies of the Southeast

BY H. J. SCHOLZ, W. W. EBERHARDT, and S. MURRAY JONES[1]
Associate, A. I. E. E. Associate, A. I. E. E. Associate, A. I. E. E.

Synopsis. *Voltage standardization has long been recognized as desirable, and to date no definite standards have been accepted and applied. An attempt is now being made to coordinate the recommendations of the different power companies and manufacturers with a view towards adopting definite voltage standards for all apparatus.*

A proposal has recently been submitted by the manufacturers which is not applicable in its entirety to conditions in the Southeast, and this paper contains a counter-proposal submitted as being more readily acceptable to the interconnected power systems of the Southeast.

I. Introduction and Justification for Voltage Standardization

A proposed set of voltage standards appeared in 1922, but lack of cooperation on the part of both manufacturers and operators prevented any general acceptance of them. This was partially due to the fact that insufficient consideration was given to existing apparatus. In 1922 the power companies of the United States were valued at $4,500,000,000, while today they are valued at $9,000,000,000. This tremendous increase, appearing largely as new equipment, indicates the truth of the statement that the longer standardization remains a nonentity, the more complicated will be its final acceptance. Very few operating companies have attempted to eliminate what might be termed off-standard voltages in order to conform to the 1922 standards; in most cases, however, they cannot be justly criticized for this. Time was required for a realization of the savings to be had and as they have grown closer together, the benefits to be derived from standardization have presented themselves. Today most companies are willing to accept any such standards resulting in either financial gains to them or improvements to their service.

No time need be wasted in consideration of standards to be put into effect immediately. No operating company can afford to change its present equipment over night. Standardization in its final form will come about by virtue of a slow influx of semi-standard equipment which, when the absorption is complete, can be operated on standard voltages. This transition period will cover a number of years. Modifications or extensions to present properties made necessary in order to be in accord with any accepted standards must be consistent with proper financing and engineering practises, and any expense incident to such changes must not exceed the monetary values of standardization.

The efficiencies of electrical equipment are in most instances probably as high as will be attained, so that further large economies must be looked for in the development of radically new apparatus, in increasing the load factor of present equipment, and in standardization. The recent acceptance of lamp standards has gone far to bring about the present low cost and greater efficiency of lamps which the public now enjoys. In a like manner, actual savings in the cost of generating and transmission equipment will be evidenced by the standardization of voltages.

It is not to be expected that any expense incurred by carrying out the features of standardization will be returnable immediately in the form of huge savings, but economies will result from the enormous reductions in capital investment required over a long period of time, as compared to what would be necessary were the present policies to continue. The value of voltage standardization has also been emphasized by the benefits which may be obtained therefrom on interconnected systems. Interconnection will be practised more extensively in the future than at present, of course, because of the resulting economies. For example, in the territory covered by the interconnected Southeastern systems there are three distinct water-sheds covering very extensive areas over which the rainfall varies in different rivers in such a way that excess hydro capacity in one section can be used at times to assist systems in other sections in meeting their demands or in filling their storage reservoirs, thereby reducing the amount of reserve steam capacity required and also utilizing water which would otherwise go to waste. In addition to these economies, which are very great, the interconnected systems have been able to improve voltage regulation and service to their customers.

The economic and commercial justification for the standardization of all types of equipment has been proved many times and has ultimately resulted, in practically all cases, in simpler manufacturing methods and a lower cost of the product to the purchaser. There can be no doubt, therefore, as to the feasibility of standardization of voltages by the power companies. Any standards must be adaptable, however, to the large amount of equipment which has already been installed

1. All of the Alabama Power Company, Birmingham, Alabama.

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

and, to be of any value, must be accepted by the majority of operating companies.

II. General Problems Confronting Southeast in Standardization

Table I gives the present rated circuit voltages of the interconnected companies in the Southeast and shows the conditions to be met in recommending any set of standards. It should be noted here that some of these systems are being operated at voltages slightly higher than those indicated in Table I. A map, Fig. 1, shows the transmission systems of these companies.

Before proceeding further, some of the general problems confronting the acceptance of a set of general voltage standards will be presented, and these problems should be borne in mind when referring to the standards which the writers have recommended as best suited for this territory. The generation in this section during a normal year is approximately 60 per cent from run-of-river hydro plants (some having storage capacity) and 40 per cent from steam reserve plants. The average annual load factor of the hydro electric stations is from 30 to 60 per cent, and of the steam electric stations from 10 to 40 per cent. Generating plants are located both adjacent to, and remote from, load centers, and may be operating during different seasons of the year as base load plants or as voltage boosting stations.

With such operations as outlined above, due mainly to location and types of plants, the annual load factor on the main high voltage circuits is low (approximately 30 per cent) as compared to systems the generation of which is entirely from base load steam plants, or from hydro plants where the river flow is not seasonal. For this reason a higher voltage drop on the transmission

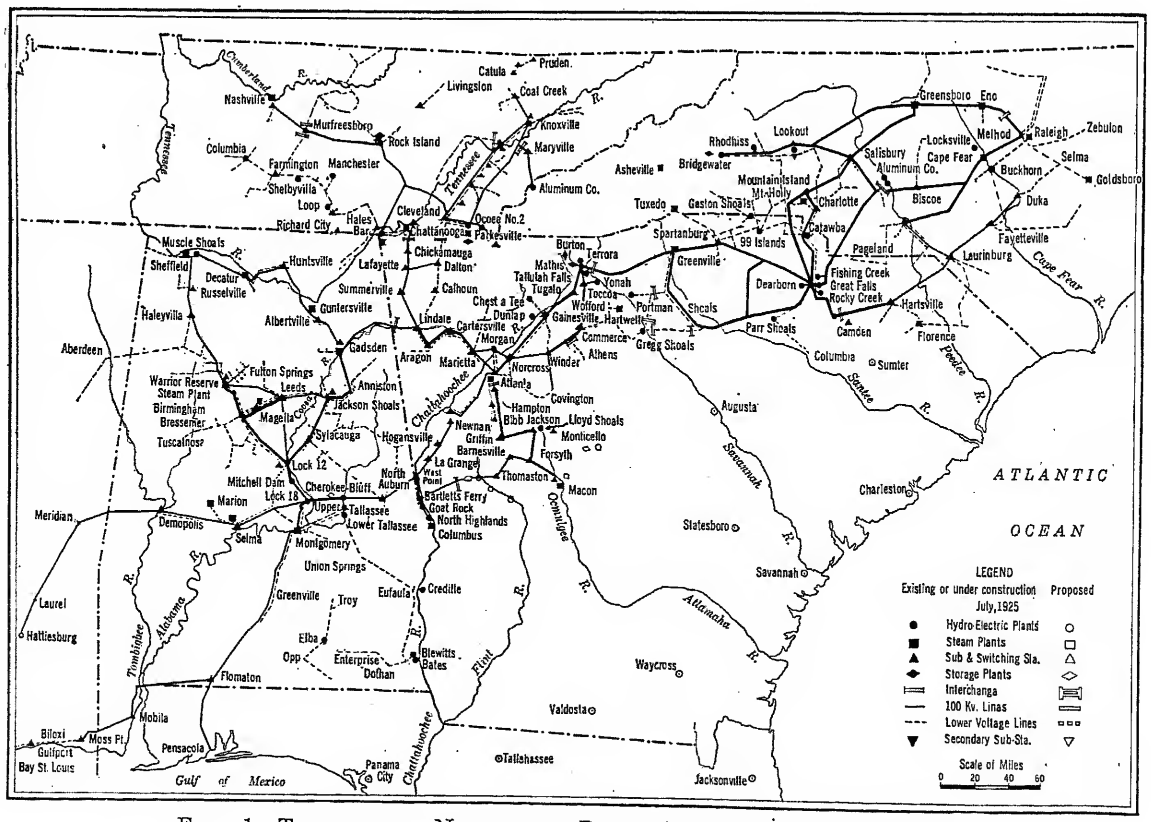

FIG. 1—TRANSMISSION NETWORK OF POWER SYSTEMS OF THE SOUTHWEST

circuits may be considered economical and is at present accepted, as compared to that which is economical on lines between base load plants and load centers.

Lengths of transmission circuits and location of substations at many different positions with respect to the generating equipment, prohibits the acceptance of any definite point on the system as a reference for constant voltage except the consumers' bus bars. The receiving voltage at primary substations must be varied according to load conditions on the distribution lines, by regulating the generating units, or by using synchronous condensers to boost or buck the voltage as becomes necessary.

A problem now actively confronting the companies in this territory is that of a rural distribution system, constructed as cheaply as possible, yet flexible enough to meet future demands in the most economical manner. This, in some cases, will call for a set of standards for equipment different from any others. The main problem will be that of suitable transformers having multiple ratios for adaptability on possibly as many as two or three different circuit voltages, and for locations close to the source of supply and at the end of the line.

The above comments will serve the purpose of an outline of the feelings and position of the companies in regard to standardization as a general proposition. In particular, the remainder of this paper covers a detailed analysis of the mechanics of adjustment to any proposed standards. The main problems confronting the companies concerned in this paper are those relative to generation and transmission since the bulk of their power is derived from hydroelectric and steam electric stations situated at a considerable distance from load centers. The problem of working out a set of standards for the lower voltage distribution lines can best be handled, it is believed, by the metropolitan companies the generation of which takes place near the load. Because of the diversity in present practises of equipment of this class, any set of standards satisfactory to such companies could probably be adjusted with equal facility to conditions here.

TABLE II

PROPOSED VOLTAGE RATINGS FOR SYSTEMS, GENERATORS, SWITCHING, CONTROL & PROTECTIVE APPARATUS, TRANSFORMERS, ETC.

Systems	Generators & sync. condensers	Ind. motors	Apparatus	Step-up transformers		Step-down transformers	
				Primary	Secondary	Primary	Secondary
	(see A)	(see B)	(see C)	(see D)		(see D)	
							115

161,000			161,000		230,000	220,000	
230,000			230,000				

GENERAL NOTE

Guarantees of efficiency, heating, overload, etc., should be based on the rated voltage of the individual apparatus as shown above. Voltage tests on all equipment should be based on the rated voltage of the circuit on which it is to operate. The rated voltages are in all cases the maximum permissible voltage for continuous operation.

SPECIFIC NOTES

A.—Generators and synchronous condensers should be designed to deliver rated kv-a. output at rated power factor and frequency throughout a range of 5 per cent below and five per cent above rated voltage.

B.—Induction motors should be designed to deliver rated h. p. throughout a range of 10 per cent below and above rated voltage at rated frequency.

C.—Apparatus as here used includes oil circuit breakers, disconnecting switches, current transformers, lightning arresters, insulators, bus bar supports, bushings and fuses; all to be maximum rated. The voltage ratings of potential transformers should be the same as other apparatus with their secondaries rated 115 volts to permit the employment of the now existing even ratios of transformation.

D.—Transformers should be designed and tested for operation on system rated voltages rather than transformer voltage ratings.

a. Step-up transformers should be equipped with the equivalent of three 2½ per cent full capacity taps in the primary winding, two 2½-per cent taps above and one 2½-per cent tap below rated primary voltages.

These taps are necessary to compensate for the inherent regulation of the transformers from no-load to full-load and also to provide sufficient range to make them adaptable to locations remote from, or adjacent to, load centers.

b. Step-down transformers should be equipped with the equivalent of four 2½ per cent full capacity taps below rated voltage in the high-tension winding.

*For rural distribution lines.

III. Authors' Proposal

In the September 1926 N. E. L. A. *Bulletin* there appeared a complete set of voltage standards recom-

mended by the manufacturers.[2] These standards are not applicable in their entirety to the present operations in the Southeast. For the sake of simplicity in future discussion they will be referred to and used as a basis for the author's proposed standards which are shown in Table II.

Criticism of the manufacturers' proposed standards is not intended to be destructive, but rather a sincere attempt to show their applicability to the interconnected companies of the Southeast, and to acquaint those interested in this subject with the existing conditions. Quite naturally, comments are more directly bearing on the properties of the Southeastern Power and Light Company since it is with these properties that the writers are most familiar.

It appears to the writers that the manufacturers' definition of rated voltage is satisfactory, namely: "Rated Circuit Voltage: For the purpose of fixing a value to be used in designing and testing electrical apparatus, the rated voltage of a circuit (or system) is defined as the highest rated voltage of the apparatus supplying it. By 'circuit voltage' is meant the voltage from line to line as distinguished from line to neutral. This voltage rating applies to all parts of the circuit. The actual operating voltage of the circuit may vary from the rated circuit voltage but should not exceed it."

The manufacturers' proposed standards would permit a 5 per cent margin above rated voltage for equipment of one class and strictly forbid the employment of such a margin for other classes. The dividing point has been made between 69,000 volts and 88,000 volts to suit the present ratings, and as stated, to prevent any re-design of equipment above 88,000 volts. Restrictions discriminating between classes of voltage serve only to complicate definitions and destroy uniformity in tests and application.

The system rated voltages in the manufacturers' proposal are, with the exception of the first two (2400 and 4150), multiples of 11.5 up to 69,000 volts and beyond this are multiples of 11.0. If the history of the development of these voltage ratings is traced it will be remembered that practically all systems coming within the range of the tabulation started with maximum operating voltages which were multiples of 11.0. The range of operation to take care of peak load conditions was from maximum operating voltages in multiples of 11.0 at the generating end to voltages in multiples of 10.5 at the receiving end. As the load grew and the lines were extended it was necessary to raise the voltage at the generating end to values as high as 11.5 in order to maintain voltages in multiples of 10.5 at the receiving end. In order to accomplish this, it was necessary to over-excite generators and transformers, or, as has been done in recent years, to purchase transformers having taps to give voltages five per cent above the multiples of 11.0. The increase in potential at the source rather than the decrease at the load end of the line has been necessary and justifiable. Many thousands of transformers have been purchased with ratios, for example, of 110/44 kv. with four 2½ per cent taps below normal, in the primary winding. As loads on the distribution circuits were increased it was necessary to maintain higher than 44 kv. on the secondary by over-exciting the transformers. This was undesirable and recently transformers have been purchased having a ratio of 110/45 kv. with five 3 per cent taps below normal in the primary winding which resulted in better voltage at the distribution substations. The higher voltage transmission lines gradually became loaded so that the potential at some substations dropped as low as 100 kv. and with 110 kv. maintained at the generating plants, and primary substation transformers having four 2½ per cent taps below normal in the primary, and connected on the lowest tap, the secondary voltage could not be maintained at its rated value when carrying peak loads. The evolution was the same as in the case of distribution circuits, namely, raising the potential at the source by means of over-excitation, or by the purchase of step-up transformers having taps to deliver above rated voltages. Thus it will be seen that transmission circuits of the higher voltages have already reached the stage where it is desirable that rated voltages should be multiples of 11.5, as are the distribution voltages, and in fact must be such in order to utilize present equipment. It should be remembered, however, that maximum operating voltages in multiples of 11.5 will not occur at all generating stations, but only at those most remote from the load centers. The reason for this will be evident by referring to Fig. 1. In many instances several hydro plants are located on the same stream. Where these plants are distant from the load centers, separate lines from each of them to the load would be uneconomical and hence they are tapped to a group of circuits of one or more lines, extending from the most remote plant to the load.

During extreme emergencies, such as tornadoes, floods, etc., voltage ratings may be exceeded justifiably in order to maintain service; hence all equipment should have sufficient factors of safety to permit short time operation at five per cent above rated voltage. The operating companies should also realize that such practises, although necessary at times, are encroaching on the factors of safety of the apparatus and must be only for short time operation.

It will be noted that a voltage class of 103,500 has been included in the authors' proposed voltage standards. There are two large companies in this section with an installed transformer capacity of over one and a half million kv-a. falling in this class. To select the next voltage class above or below 103,500 volts would involve excessive costs in the rewinding or replacement

2. See also *Voltage Standardization of A-C. Systems from the Viewpoint of the Electrical Manufacturer*, by F. C. Hanker and H. R. Summerhayes, A. I. E. E. Winter Convention, February, 1927.

of these transformers alone, which probably could not be justified.

IV. Generators and Synchronous Condensers

The rated voltages of generators and synchronous condensers, as listed in the manufacturers' proposal would, in general, be acceptable. At present, generators rated 6600 volts are of necessity being operated over peak load hours at 6900 volts. This probably shortens the life of the machine insulation, but since the circumstance prevails, future design at the suggested voltage will prove advantageous. The necessity for operating generators at five per cent above their rated voltage will only occur during emergency conditions. Synchronous condensers where operated on the tertiary of a three-winding transformer bank throughout the range of full leading and lagging kv-a. must of necessity be designed for rated kv-a. from five per cent below to five per cent above rated voltage.

V. Induction Motors

The ratings of induction motors and customers' equipment should remain the same as stated in the manufacturers' proposal, due to the tremendous amount of apparatus at these voltages now in service, and the remainder of the system modified as necessary to maintain these voltages at the customers' terminals.

VI. Apparatus

The term "apparatus" as used in this section is to be interpreted to include oil circuit breakers, disconnecting switches, current and potential transformers, insulators, bushings, bus-bar supports, lightning arresters and fuses. It would seem logical that the above listed apparatus should have voltage ratings exactly the same as the system voltage ratings. The ratings given in the manufacturers' proposal are merely those of present equipment which are adaptable to their proposed system rated voltages. In some instances these are similar to the system voltage ratings and in others they are not. The reason for variations in present ratings is apparently an attempt of the manufacturer to best fit their equipment to the multiplicity of voltages now in use. In order to accomplish the objective in standardizing voltages, the manufacturers would aid materially by rating their apparatus identically with system voltage ratings. This would tend to eliminate the present practise of gradually increasing circuit voltages.

Reference to the manufacturers' published ratings, particularly those for oil circuit breakers, horn gap and disconnecting switches, will show an appreciable variation in the ratings of apparatus for application on circuits of a given voltage. Closer attention should be given to the design and application of insulation in order to secure more uniformity in dielectric strength and flashover values of the various apparatus connected to circuits of given voltage ratings. A complete discussion of this matter and the factors of safety to be given different types of equipment involves entirely too much space to be more than mentioned in this paper, but unquestionably deserves serious consideration.

If the rated voltage is the maximum continuous operating voltage, lightning arresters should be rated the same as other apparatus. At stations where conditions of dynamic and static over-voltages require special design, the voltage rating should be that of the circuit and the nameplate should indicate that they are suitable for one location only. Present lines of apparatus, other than transformers, can no doubt be redesigned and re-rated where necessary to conform to any reasonable set of standards immediately upon their acceptance, without undue burden to either manufacturer or operating company.

VII. Transformers General

The problems relating to step-up and step-down transformers are by far the most important of the entire subject of standardization. The system rated voltages which the authors have recommended have been made after careful investigation of their adaptability to present operations in this territory; likewise the proposed standards for transformers have been based on present operating experience and while they are not suitable for all operating conditions they are believed practical. Transformers to be entirely interchangeable between stations of the same voltage class would require five per cent more taps than indicated in Table II. It is recognized, however, that incorporation of sufficient taps in standard transformers to fulfill every operating requirement would penalize the standards and make them inconsistent with proper engineering practise. Due to this fact it is inevitable that there will always be a demand for certain classes of transformers to meet special operating conditions. The great majority of this special apparatus will be such as can be used on the standard voltages. Although a difference will be found in the high-tension and low-tension voltage ratings for step-up and step-down transformers, their test voltages should be based on the rated circuit voltage at which the equipment will operate and not on the actual primary or secondary voltage rating. The following comments apply especially to two-winding transformers, but three-winding transformers should come under the same classification of ratings, except that in most cases they will require special design due to short-circuit conditions or reactance requirements between windings when one winding is used for the operation of a synchronous condenser.

The voltage ratings of transmission and distribution transformers must be such that they will dovetail together to form a well balanced system from the generators to the consumer. Fig. 2 illustrates present operating practise and the application of the proposed voltage ratings of generators, step-up and step-down transformers.

Under present conditions with generators over-excited five per cent, it is permissible to take only a seven-per cent voltage drop in the transmission line and eight per cent in the primary distribution circuits. This limitation is due to the fact that: first, the generator voltage rating is the same as the rating of the primary windings of step-up transformers, and second, the voltage ratings of step-up and step-down transformers of transmission and primary distribution circuits are alike.

step-down transformers must be changed, necessitating the rebuilding of a large amount of present installed equipment.

VIII. Step-Up Transformers

Only generating station transformers will be considered in this section since it is believed that step-up transformers used in tying two systems together, or for like uses, will be entirely special and dependent upon their location and the purpose which they serve.

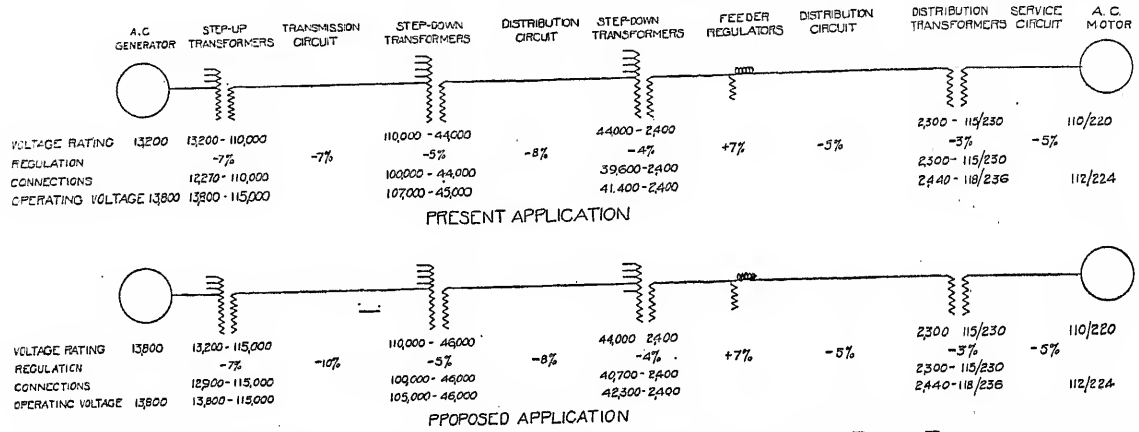

Fig. 2—Present and Proposed Ratings of Generators, and of Step-Up, and Step-Down Transformers, with Illustrations of Representative Applications under Full Load

Recently the Alabama Power Company has purchased step-down transformers rated 110/45 kv. to meet the limitation outlined under Table II and would not hesitate to go a step further to the use of 110/46-kv. transformers, if such a rating is adopted as a standard. In Fig. 2, illustrating the use of the authors' proposed standards, a 10 per cent voltage drop can be allowed in transmission lines and eight per cent in primary distribution circuits without over-exciting the generators. On certain systems in the Southeast it would be easier

Step-up transformers at generating stations in the Southeast will require taps and ratios which will compensate for their inherent regulation and which will be adaptable also for stations located adjacent to, and remote from, the load centers.

A maximum transformer regulation of seven per cent will be assumed in further discussion. This figure should be sufficiently high to include the majority of step-up transformers purchased. One case where higher than seven-per cent regulation may occur is at

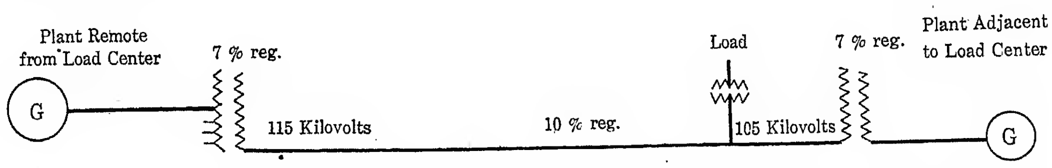

Fig. 3—Diagram Showing Step-Up Transformer

The generators are rated 13.8 kv. The transformers are rated 13. 2/115 kv. and their primaries (low-voltage side) have two 2.5-per cent taps above normal and one 2.5-per cent tap below normal. They have 7 per cent regulation. At full load the generator at the remote plant operates at 13.8 kv. The 12.9-kv. tap is used on the step-up transformer. With 7-per cent drop in the transformer and 10 per cent cut in the line, the voltage at the load is 105 kv. The generator near the load operates at 13.5 kv. and the 13.8-kv. tap is used in its transformer, giving 105 kv. at the load.

to make a transition from present ratings to the standards proposed by the writers, than to meet the standards proposed by the manufacturers because all that is required is an over-excitation of the generators and the operation of step-up transformers at five per cent above rated voltage. The disadvantage of reduced life of insulation of present transformer and generator windings, it is believed, is overbalanced by the operating advantages obtained. If the step-up transformers are operated at a maximum of 110,000 volts, the rating of

seasonal generating plants where during one period of operation the plant is run at full capacity near unity power factor, and a second condition where the plant is carrying rated kv-a. capacity at low power factor, using the generators for voltage boosting.

Fig. 3 is included to indicate the ratios and taps required for step-up transformers on a basis of seven-per cent transformer regulation and 10 per cent maximum line drop. The voltage taps as shown in Fig. 3 will not only compensate for the transformer regulation,

but are suitable for plants located at different points with respect to the load and for seasonal operation.

IX. Step-Down Transformers

Step-down transformers should have ratings and voltage taps for service in locations adjacent to, and remote from, the generating plants and to compensate for their inherent regulation. Step-down transformers will of necessity be shifted from one point on the system to another due to load growth, and should therefore be more flexible than step-up transformers which are rarely moved. The ratings which the writers have recommended will be found to vary from the manufacturers' recommendations only in so far as the changes which have been suggested in the system rated voltages. A maximum regulation of five per cent for step-down transformers has been assumed and this value will seldom be exceeded. The equivalent of four 2½ per cent taps as proposed, while not being sufficient to include all operating requirements, should include a large majority of the transformers purchased.

X. Transformers for Rural Distribution System

Although the problem of rural distribution is comparatively new, experience to date indicates that the most economical circuit voltage for rural lines is 7200/12,470 Y.

The manufacturers' publications state that transformers for this voltage class are given a test from high-voltage winding to low-voltage winding and core of 25,940 volts (2 × 12,470) plus 1000 volts. On the basis of the proposed definition of "Rated Circuit Voltage," apparatus for rural distribution lines should be rated 7200/12,470 Y, and has been so listed in Table II. The advantage of this rating is that it is a multiple of 2400/4,150 Y, making it possible to use multiple windings on the secondaries of power transformers supplying distribution circuits which can be connected in parallel for 2400/4150 Y or in series for 7200/12,470 Y. This also allows a four-per cent voltage differential between supply transformers and customer's transformers. As the latter have a voltage ratio of 6900/11,950 Y to 115/230, the maintenance of 7200 volts at the supply end makes it possible to maintain rated secondary voltage on the customer's premises without the use of excessive taps on the primary windings of the step-down transformers.

XI. Conclusion

1. The writers have suggested modifications of the manufacturers' proposed standards to make them more adaptable to the interconnected systems of the Southeast. These changes consist of:

a. Addition of 103,500-volt class,

b. Uniform voltage ratings, multiples of 11.5 throughout,

c. Changes in apparatus ratings to make them identical with system voltage ratings,

d. Providing equivalent of one 2½ per cent full capacity voltage tap below normal, and equivalent of two 2½ per cent full capacity taps above normal in the primary winding of step-up transformers to take care of transformer regulation in excess of five per cent, and location of transformers adjacent to, or remote from, load centers,

e. Addition of 7200/12,470 Y voltage class for rural distribution systems.

2. The interconnected power companies in the Southeast are in accord with the proposition of standardization and it is believed that these proposed standards in general would be practicable and acceptable to the majority of operating companies in this section.

XII. Appendix

The appendix will be used for a detailed discussion of the reasons why some of the authors' proposed standards differ from those recommended by the manufacturers, and also to bring attention to instances where special equipment will be required.

A. An analysis of operating reports of companies in the Southeast would indicate many systems operating considerably above rated voltages, and with excessive voltage drop. For example, 110,000-volt systems during peak conditions will be found with voltages as high as 118,000 volts at the remote generating plants and as low as 98,000 volts at remote substations. There are reasons for this, some of which are probably justifiable and others which are not. Needless to say, a 20 per cent voltage drop on any system should not be tolerated except during emergencies, because voltages of 15 and 20 per cent above ratings of equipment not only shorten the life of insulation but encroach on the factors of safety.

In the standards proposed herein a 10 per cent voltage drop on transmission circuits has been assumed as a maximum. This value will be justifiably exceeded in at least one instance in the Southeast. The particular situation is one in which the load center is distant from the source of supply. During the peak hours of the day the load is carried from one set of plants 100 mi. distant, and the remainder of the time it is fed from a different source located some 60 mi. distant. Thus it will be evident that the yearly load factor of the transmission circuits is very low; hence a voltage drop of 15 per cent on these lines, when carrying peak loads, will be found economical. The maximum transmission losses at peak load in this illustration are but 9.8 per cent which, it will be admitted, are not beyond economic limits. The annual losses are approximately 3.0 per cent of the total energy transmitted.

To correct this condition to come within a 10 per cent voltage drop would necessitate one of two things, either the construction of an additional transmission line at a cost of not less than $750,000, or the installation of a $200,000 synchronous condenser station. With

a new transmission circuit, the peak load line losses are reduced to 4.5 per cent and the yearly losses reduced to 1.5 per cent; capitalizing the difference in annual losses based on the power transmitted at 10 per cent would only justify the expenditure of $315,000, hence the line is uneconomical. A synchronous condenser likewise cannot be justified since the transmission losses remain practically the same and the condenser has only corrected voltage conditions.

With a 15 per cent line drop, the standard transformers cannot be used at the remote substations, and units having the equivalent of 15 per cent taps below normal in the primary winding, will be required at an estimated increase in price above standard transformers of from three to five per cent. These transformers are satisfactory, however, for operation at any point on the circuit, and proposed standards have not been penalized by the necessity of these special transformers to fit operating conditions.

B. It is very probable that some of the utilities having a large amount of what may be termed off-standard apparatus in service will be unable to justify a change to meet standards. This is especially true where to abide by the standards would mean lowering present circuit voltages. By reducing operating voltages, the power transmitted over present equipment would be reduced, of course, and the power limit of lines would be decreased. The problem of stability had not been given serious consideration until some few years ago, but as transmission distances have increased and lines become more heavily loaded these problems have been encountered and it is known that lowering the circuit voltage will decrease the static and transient power limits of a line.

A specific example where the reduction of circuit voltages from those recommended by the writers would bring considerable hardship is on the Alabama Power Company's system if it were necessary to reduce the operating voltage on transmission lines from a maximum of 115,000 volts down to a maximum of 110,000 volts. The generating plants with the exception of one steam plant are all remote from the load centers of Birmingham, Bessemer, and Anniston. The high-tension voltage at these load centers is, as would be expected, the lowest on the system, and at present varies between 105,000 and 108,000 volts. To reduce this voltage five per cent, as would be necessary were the maximum operating voltage 110,000 instead of 115,000, would require the installation of complete new transformers at these substations. Present transformers have taps as low as 100,025 volts which with 100,000 volts impressed would not give normal voltage on the secondary when operating at full load; thus the voltage must be maintained at approximately 105,000 volts. Tl total transformer capacity installed at these thr substations is 140,000 kv-a. and even granting th these transformers could be rebuilt to deliver rat secondary voltage with 100,000 volts impressed on t primary, which we seriously doubt, without reduci their rating, the expense involved would be unjustifie These stations are at present heavily loaded and different secondary voltages so that at least two cor plete new banks of transformers would be requir were it possible to rebuild the present units.

Aside from the difficulties involved with transforme if the circuit voltage were to be reduced, such a pr cedure would involve the immediate construction some 150 mi. of 110-kv. lines at a cost of not less th $1,500,000, which would hardly be justifiable.

This is only one specific case where the necessity reducing operating voltages from those recommend would entail considerable hardship; there are seve other such examples which could be cited. The on justification for such expenditures would be in the eve of the acceptance of 110,000 volts as standard, requiri those companies operating at 115,000 volts to purcha all equipment of the next higher voltage class, but do not believe that any standards are intended to pen ize present operating conditions where there is such prevalence of equipment now in service which could r be operated on the manufacturers' proposed standar

If to be in complete accord with any standar involves increasing the circuit voltage, a careful analy of conditions must be made. If spacings, insulati corona limit and other electrical factors are satisfact with increased voltage, the number of customer a other step-down substations must also be consider The cost of relocation, retiring or rebuilding prese transformers must be balanced against the increas carrying capacity of the line at the higher voltage, a decreased losses; also the cost of future apparatus w standard ratings balanced against the cost of off-star ard transformers. The increases in costs of spec transformers above the price for standard units v have to be given by the manufacturers. It is believ that on lines containing few substations it will be fou practical to gradually work toward standard voltag On other circuits containing numerous substations a customers, and where alterations in station layo would be necessary to operate on a higher circ voltage, such changes may not be feasible. Th questions will require careful study for each differ proposition and hence no definite conclusions can made.

Discussion

For discussion of this paper see page 205.

Suggested Transformer Voltage Standards
Their Relationship to Pacific Coast Practise

Committee Report[1]

H. H. MINOR, Chairman

Synopsis. Explanation of authorship and basis of paper. General discussion of the proposed system voltage standards and the principles underlying them. Listing of transformer voltages and kv-a. connected now in use by P. C. E. A. Companies. Detailed discussion of changes in proposed standards to bring them into conformity with Pacific Coast practise. Summary and conclusion.

THIS paper is presented by the Subcommittee on Transformer Standardization of the Electrical Apparatus and Overhead Systems Committees of the Pacific Coast Electrical Association as the result of a study of transformer ratios made last year and a further investigation carried on during the past few months. It is felt that it will be of interest as part of a general discussion of the subject, system voltage standardization, as it is a composite of the views of representatives of the several Member Companies of the P. C. E. A.

The work last year was carried on by means of questionnaires and by discussion at joint meetings of the two parent committees. The table of "Proposed Voltage Ratings For Systems" presented to the National Electric Light Association by a special committee appointed by the National Apparatus Committee to study data collected by that body was discussed, in so far as it applied to transformers, at some length. This year a survey has been made of the voltage ratings and kv-a. capacity of transformers in use by P. C. E. A. Companies. Further discussion of possible new standards and the probable application of those suggested to Pacific Coast conditions was invited. The following is an attempt to present an analysis of the data collected and to present an outline of the opinions of the P. C. E. A. members that have come to the committee.

The general view is that there is need of revision of the present transformer standards with respect to voltage rating. The five principles upon which such revision should be based, as set forth in the Memorandum of the Special N. E. L. A. Committee which was published in the September 1926 issue of the N. E. L. A. *Bulletin*, are excellent.[2] Of these, principle *B* which reads: "The voltage selected must closely resemble those now in use to permit a reasonable degree of interchange ability of old and new apparatus" is of particular importance. It will probably result that this is the vital point to be considered in any attempt at revision of the standards.

Principle *C*, which states that the changes involved must not necessitate too great an expense in the development of new apparatus, is also of extreme importance. This expense, however, should be the expense to the user of the apparatus and not simply the cost of development and manufacture. It should include the probable cost to the user because of the fact that principle *B* is not adhered to, sufficiently. Most of the present-day systems for the transmission and distribution of electrical energy are so greatly involved through interconnection on their own systems and with other systems that the voltages in use are fixed within rather narrow limits. That present standard transformers do not lend themselves to use on many of these systems without operating them at considerable variance with their rated voltages and those upon which tests and guarantees are based, is very true. This has naturally resulted in the purchase of a great amount of "special" or "off-standard" equipment.

To be successful, a new set of transformer standards must result in a decrease in the percentage of such specially designed transformers purchased. This result must not be obtained, however, by the inclusion in the standards of a great number of new designs.

Adherence to principle *B* will result in a great reduction in the special transformers but principle *C* will have to receive careful consideration so that the ultimate cost to the industry as a whole will be lessened. Thus the task before those to whom is delegated the fixing of standard voltages for systems is one of making such compromise as is necessary between an ideal or theoreti-

cal standard and the voltage ratings of equipment now in use in order to arrive at a result that will be most satisfactory. That this is no easy task is evidenced by the study made by the N. E. L. A. Special Committee.

The proposed set of standard voltages and the explanatory notes with them are a wonderful improvement in many ways over the present standards. It may be the best possible compromise to which reference is made above. Certainly very careful thought has been given to its preparation, that the weaknesses of the present system of voltages shall be largely eliminated. The transformers and their taps listed will fit nicely into the somewhat ideal simple system used as an illustration in the Memorandum of the Special N. E. L. A. Committee. That such transformers would fit as well into existing systems may be open to question. In the West, where transmission distances are long, the full load drops encountered in the lines are considerably greater than the limits set in this example. The result is that in many cases step-down transformers are purchased with a much greater range of taps than the proposal allows in order to arrive at flexibility in the use of these transformers over a large system, or variations in their voltage ratings are specified to conform with existing drop conditions.

The accompanying tabulation gives an idea of the great variety of voltages and ratios in use by the P. C. E. A. Companies. Also is listed in part the kv-a. connected of transformers of the different classes shown. While this is not a complete listing, due to lack of information from a few of the Companies, it is felt that it presents a fair picture of the transformer situation on the Pacific Coast with respect to the possibility of arriving at a new set of standards that will fit into existing conditions.

A study of this tabulation shows that in the lower voltage classes, which include the great number of distribution transformers supplying utilization voltages, approximate conformity with the proposed standard exists. There are some changes, however, that seem advisable in view of present practise. In the higher voltage classes there is not such close conformity to the proposed ratings. The very great variety of voltages used is due in part to the above practise of specifying special transformers for use at different points on systems. For the most part, also, the larger systems have been built up by a gathering together of many small systems and interconnecting them by means of transmission lines. Each of these smaller companies had their own particular voltages and they were usually continued by the use of more or less "special transformers." This also has contributed to the great variety of transformer ratings.

The use of 2300-volt, delta-connected systems of distribution, supplying 110 to 115 volts to the consumer, has been the original set-up of most systems. As load

TABLE OF TRANSFORMER VOLTAGES IN USE AND KV-A. IN TRANSFORMERS CONNECTED TO LINES OF PART OF P. C. E. A. COMPANIES

Nearest voltage class	Primary voltages (Full winding)	Secondary voltages (Full winding)	Kv-a. connected
2,400	2000 to 2900 volts (2300 predominant)	110 to 850 volts (115-230 predominant)	1,055,200
4,150	3810 to 4800 volts (4000 predominant)	110 to 2300 volts (115-230 predominant)	23,721
6,900	6000 to 7900 volts (6900 predominant)	110 to 2300 volts (115-230 predominant)	469,753
11,500	10,000 to 12,500 volts (11,500 predominant)	110 to 2300 volts (115-230 predominant)	625,210
13,800	13,200 to 14,400 volts 15,000 to 18,000 volts	110 to 850 volts 110 to 2400/4150 Y	9,400 421,000
23,000	20,000 to 26,400 volts 20,000/34,600 Y and 22,000/39,000 Y.	110 to 6900 volts 2200 and 2300 volts	46,706 10,087
34,500	29,705 to 36,415 volts (Connected Y on 66-kv. systems)	110 to 4150 volts 6900/11,950 Y 7500/13,000 Y 11,500 volts 13,200 volts 17,000 volts 22,000 volts	257,266 91,075 44,500 13,500 72,110 3,000 18,667
34,500	33,000 volts (Connected delta)	2400-11,500 volts	20,000
34,500	38,100 to 41,600 volts (Connected Y on 66-kv. systems)	110 to 4150 volts 6900/11,950 Y 7200/12,500 Y 7500/1300 Y 11,500 volts 16,500-11,500 volts 22,000 volts 2400-11,500 and 16,500-33,000 volts	139,092 39,825 200,000 8,350 187,000 323,000 8,250 580,000
69,000	50,000 to 76,200 volts (Connected Y on 110-kv. systems)	110 to 4150 volts 6900/11,950 Y 7200/12,500 Y 7500/1300 Y 11,500 volts 13,200 volts 17,000 to 17,500 volts 31,215/54,000 Y 34,640/60,000 Y 45,800/79,300 Y	72,388 138,333 12,000 112,833 181,817 164,167 9,900 26,667 135,500 185,000
69,000	50,000 to 66,000 volts (Delta connected)	110 to 4150 volts 6900/11,950 Y. 11,500-16,500 volts 20,000/34,600 Y 22,000-11,000 volts 36,000 volts 2400-11,500 and 16,500-33,000	37,800 10,750 121,000 5,000 9,000 900 95,000

110,000	110,000 volts (Delta connected)	9500/16,450 Y	37,500
132,000	115,470 to 127,000 volts (Connected Y on 220-kv. systems)	11,500 volts 63,500 volts 66,000 volts 72,000 volts	206,739 166,667 369,000 315,000
154,000	150,000 volts 154,000-115,000 volts	66,000-16,500 volts 11,000	305,000 80,000

density increased it became necessary to provide greater capacity to existing lines. The logical set-up and the one taken by most of the Companies was to use 2300 volts connected Y or the so-called 4000-volt system. In many cases the lines were made three-phase, four-wire, the 2300-volt class transformers being connected Y-delta for three-phase service and from phase wire to neutral for single-phase service. As the territory covered grew and longer feeders became necessary, it was found best economy to discontinue stringing the neutral wire and make use of a special 4000- to 115/230-volt transformer for single-phase use on these lines, still employing three 2300-volt transformers connected Y-delta for three-phase service. This practise has been and is being extended rapidly. One manufacturer has catalogued a 4000-volt distribution transformer. It would seem advisable to include such a transformer in the proposed standards. Its rating, to conform with the Y voltage of the 2300-volt transformer, should be 3980 to 115/230, etc., for step-down transformers.

The next higher voltage class of transformers in use is the 6900-volt. As shown by the accompanying tabulation, there are a great many of this class in use on the Pacific Coast. There are, however, very few 6900-volt delta systems or lines. The almost universal practise is to use these transformers connected Y-delta on 11,500-volt systems, just as the 2300-volt class is used on 4000-volt systems. The present standards recognize this use by making the rating for distribution transformers of this class 6900/11950 Y to 115/230, etc

There are also in use many 11,500-volt class transformers on these same systems, either connected delta-delta for three-phase service or used separately for single-phase loads. There is, however, a discrepancy between the ratios of these transformers and the 6900-volt class in the present standards. The relationship between these two classes should be as 1.73 is to 1 instead of as 1.67 is to 1, which is present practise. The practical result has been that the 6900-volt class is connected on the 6585-volt tap and the 11,500-volt class on full winding to more nearly approach the proper secondary voltage when both classes are connected to the same line. This, in effect, cuts down the available taps on the 6900-volt transformer and the user is paying for more than he needs.

In the proposed standards the actual ratios of these two classes are changed. The step-down proposal is respectively for the 11,500-volt system and the 6900-volt system, 11,000 to 115/230, etc., and 6600 to 115/230, etc. The relationship between them is still as before: 1.67 to 1. No provision is made in the proposed standard, however, for Y-operation of the 6900-volt class transformer. To conform as nearly as possible with the proposed standards and also with the Pacific Coast practise, it will be advisable to make the proposed standard for these two classes substantially as below:

System	Step-up Primary	Transformer Secondary	Step-down Primary	Transformer Secondary
6,900	6,600	6,900	6,600/11,430 Y	6,900
11,950	11,430	11,950	11,430	11,950

This rating of the step-down, 6900-volt class transformer will require it to be tested for 11,950 volts under the recommendation of the Special N. E. L. A. Committee that high potential tests be based on "rated circuit voltage" of the system of which the apparatus forms a part. That this is correct for such transformers connected Y is undoubtedly true. Should there be sufficient use of 6900-volt transformers on 6900-volt circuits to warrant it, it may be advisable to include both the above suggestion and the 6900-volt step-down transformer for use on 6900-volt delta lines. This is not the case on the Pacific Coast as practically all of the 469,783 kv-a. listed in the accompanying table are used on 11,500-volt systems.

In the proposal of the N. E. L. A. Special Committee, the following recommendation is made in "Note F" accompanying the proposed Table of Voltages:

"When possible, 11,500-volt systems should be discouraged in favor of 13,800-volt ones."

On the Pacific Coast this suggestion is not at all possible. The practise, mentioned above, of using both 6900- and 11,500-volt class transformers so universally on 11,500-volt systems cannot be changed without immense cost. To change to 13,800 volts would necessitate the replacement of more than 1,000,000 kv-a. in 6900- and 11,500-volt distribution transformers and almost as much capacity in station transformers serving them. It is the unanimous opinion of the P. C. E. A. membership that the 11,500-volt system should be retained with such changes as are necessary to bring it into conformity with the 6900-volt class step-down transformers, connected Y on such systems.

The failure to include a 6900-volt class of transformer for Y operation in the proposed table is really only a special case of a general condition. The very great use of Y-connected transformer banks for both step-up and step-down purposes seems to point to the advisability of including such transformers in a new set of standards. That this use of transformers is large on the Pacific Coast is shown by the accompanying table. Of transformers above the 13,800-volt class there were reported approximately 4,000,000 kv-a. connected Y and about 1,000,000 kv-a. connected delta. The proposal of the N. E. L. A. Committee only includes transformer voltages for use connected delta, with the single exception of the 2300/3980 Y for step-down and 2400/4150 Y for step-up high voltage ratings. That inclusion of transformers for Y-connection for the various system voltages chosen will approximately

double the number of transformers in the standards, is evident, but it will not greatly increase the number of designs necessary and should not increase the cost of either class. If the proposed standards were to be adopted, those companies using Y-connected transformers would be forced to buy "special equipment" and the designs, patterns, etc., would still have to be made.

The "General Note" accompanying the Table of Proposed Voltage Ratings referring to guarantees of efficiency, heating, overload, etc., and over-voltage tests has caused some comment. It is felt that this note is correct with respect to over-voltage tests of primaries of step-down transformers being based on five per cent over rated primary voltage. This is necessary to care for the over-excitation of the transformer necessary to overcome transformer regulation drop. The same provision, however, would seem advisable for the primary or low voltage winding of step-up transformers. With these it is also necessary to over-excite approximately five per cent in order to supply rated secondary voltage at full load, due to transformer regulation. It would seem that this same result would be obtained, however, if the suggestion, mentioned before, that all apparatus have high potential tests based on "rated circuit voltage" of the system of which the apparatus forms a part, were adopted.

"Special Note E" states that transformers should be designed to operate during emergencies at five per cent above rated voltage, the over-voltage being obtained by over-excitation. Comment has been made that this statement is very indefinite. The question is asked as to just what constitutes such an emergency and how long such an emergency might be allowed to exist. In the Memorandum of the Special N. E. L. A. Committee the loss of one or more of a parallel group of transmission lines, causing abnormal drops between sources of generation and utilization, is cited as an emergency. One can well imagine such a condition lasting for many hours or even days when the lines are in mountainous and inaccessible regions. Under such "emergency" operation the transformer would be subject to the same conditions as would obtain for continuous operation in this over-excited condition. Another emergency that is often encountered on almost all systems is the sudden failure of apparatus or lines that will cause a large block of load to be disconnected from a long transmission system. The result is a very decided rise in voltage at points distant from the source of energy due to the decrease of line drop and transformer regulation.

Referring to the Memorandum of the Special N. E. L. A. Committee and particularly to Fig. 2A therein, let it be assumed that this represents part of a system at full load served from a 13,800-volt and 2400-volt distribution system. In order to approximate probable practical conditions let it also be assumed that there are four such 69-kv. radical feeders from the 132-kv. line, each carrying 25 per cent of its load. If, then, a fault should occur which would open up the 13,800 feeder switches and drop their load, the five per cent regulation drop of the 66,000- to 13,000-volt transformers would be eliminated as would the 4.5-kv. drop in the 69-kv. line and 25 per cent of the line drop and transformer regulation of the 132-kv. line and the 126,000- to 69,000-volt transformation respectively. This would result in approximately 18 per cent over-excitation of the 66,000- to 13,200-volt transformer. Thus this emergency, which would of course be of very short duration, would cause very much over the five per cent set up by "Note E." It is suggested that a more exact statement of the meaning of "emergencies" should be included in these notes.

As stated above, the long transmission distances in the West make it advisable to allow quite large line drops at full load, and this condition has made some of the companies specify quite a range of taps for their step-down transformers. The following is from one of the larger P. C. E. A. companies:

"While it may be possible in the eastern part of the country with concentrated loads in relatively restricted areas to keep transmission line drops within the limits indicated by the discussion of the proposed standards and consequently to maintain the transmission system voltage level with only four 2½ per cent taps in step-down transformers, we do not consider this economically practicable under the conditions prevalent on this coast. Our system, for instance, is spread over a veritable empire, with widely scattered power sources and load centers, and we find it necessary to provide taps for about 17½ per cent, particularly for transformers connected to the transmission systems. For instance, our present practise for transformers connected to our so-called 60-kv. system provides for two 5 per cent taps and one 7½ per cent tap, enabling these transformers to be used interchangeably on any part of the system. We therefore feel that more than 10 per cent in taps should be provided by these standards, either in 2½ per cent or larger steps as may be found necessary." Other companies operating over extensive territories find the same conditions confronting them and the practise of employing a greater than 10 per cent range in taps is quite common. Thus the "Special Note E (b)" might also be given more thought.

To summarize the foregoing briefly, Pacific Coast practise in the use of transformers points to the advisability of some change from the present standards. The proposed standards are a great improvement over the old and the principles upon which they are based are sound. There is need of the inclusion of a 3980-volt step-down distribution transformer and of a change in the 6900-volt and 11,500-volt class to bring them into conformity for operation on the same 11,500-volt lines. There is a distinct need of the standards including transformers rated for Y-connection as well as

delta connections on standard systems. The "General Note" referring to over-voltage tests could be clarified as could the "Special Note E" referring to emergency operation. More study of the advisable range of taps on step-down transformers seems advisable. "Special Note F" suggesting the elimination of 11,500-volt systems is not at all in keeping with Pacific Coast practise.

In conclusion, it might be repeated that the task before those responsible for the formation of a set of voltage standards is a most difficult one. It must be a compromise between the ideal and the practical. Its result must be an economic gain to the industry as a whole.

Discussion

For discussion of this paper see page 205.

Voltage Standardization

BY A. HUBER-RUF[1]

Non-Member

Synopsis.*—A review of the points of view which in general influence standardization of voltages and a number of proposals of certain standards are given in this paper. The discussion pertains to classes of voltages, three-phase systems, d-c. systems, and nominal voltages. A plea is made for the use of the ratio of $1/\sqrt{3}$ for working voltages.*

I. General

THE standardization of voltages forms the most important basis for the economic manufacture of electrical machinery and apparatus, and for the installation of electrical plants.

In recognition of this fact, the electrotechnical bodies in various countries have drawn up standards, and the International Electrotechnical Commission has now undertaken the task of bringing into line the various standards set up in different countries so as to provide a better international basis for the manufacture of electrical plants, and to facilitate the exchange of energy between neighboring countries.

This report contains only a brief review of the points of view which, generally speaking, influenced the standardization of voltages, and gives a short summary of the results of this standardization.

A few remarks are made at the end concerning American practise so far as the writer of this report was able to obtain information on it on the occasion of the I. E. C. Conference in New York in April 1926 and from various other sources.

The following were the principal deciding factors in the selection of standard voltages:

1. Consideration of the voltages most used in the countries concerned,
2. Consideration of the voltages standardized in neighboring countries,
3. The fixing of as few voltages as possible, at suitable intervals.

The consideration of the three points mentioned presented some difficulties and the solutions proposed are consequently the results of compromise.

Exhaustive inquiries were made in various countries in order to settle the first question, concerning the extent to which the different voltages were employed. The importance of the various voltages, considered from the point of view of connected load in kilowatts, and the extent of the transmission plant was recorded graphically.

Fig. 1 gives an example of such a graphic record drawn up for Switzerland in 1919 for lighting and power systems.

Tables and graphical records were also made for the

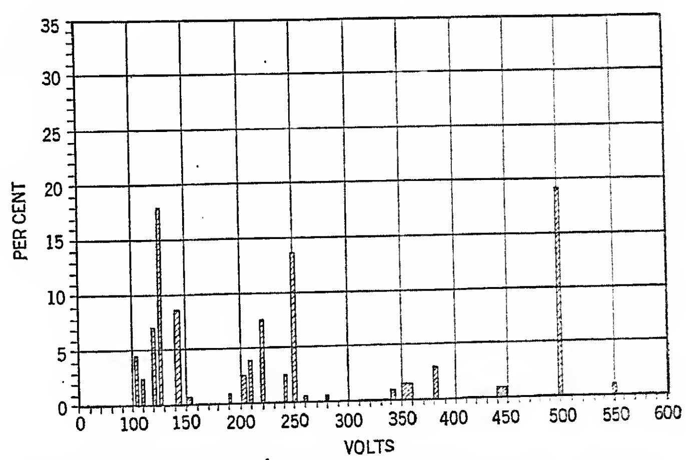

Fig. 1—Frequency of Occurrence of Nominal Voltages in Lighting and Power Systems in Switzerland (1919). The Vertical Lines or Areas Represent the Loads Connected to the Corresponding Voltages in Per Cent of the Total Load Connected to the System in Question

settlement of the second question, concerning standardized voltages in different countries.

Fig. 2 contains such a record for three-phase voltages in various countries.

The third point, "The fixing of as few voltages as possible, at suitable intervals," offered special difficulties.

It was generally recognized to be advantageous for three-phase working that the voltages should bear to one another the ratio $1:\sqrt{3}$ on account of the possibility

1. Brown Boveri Company, Switzerland.

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

of changing over the windings of machines and transformers from star to delta, and the increased possibility of utilization of material resulting therefrom.

Voltages have hitherto been standardized, however, mainly with the ratio 1:2, having regard, obviously, to the series-parallel connection of d-c. or single-phase a-c. machinery.

Series-parallel connection is also possible with three-phase windings but it presents considerable disadvantages as compared with delta-star connection. This point will be brought forward again later on as it is of great importance.

II. Classes of Voltages

In this report, distinction will be made between the following classes:

Class A, up to 99 volts,
Class B, 100 to 990 volts,
Class C, 1000 to 29,000 volts,
Class D, 30,000 to 100,000 volts,
Class E, over 100,000 volts.

Further particulars concerning the standardization of d-c. and three-phase voltages are given in the following, three-phase voltages being considered first as being more important as regards generation, distribution, and utilization of electrical energy.

III. Standard for Three-Phase Systems

Class A, up to 99 Volts. This class is of importance mainly for direct current and single-phase alternating current. There are already several standards existing

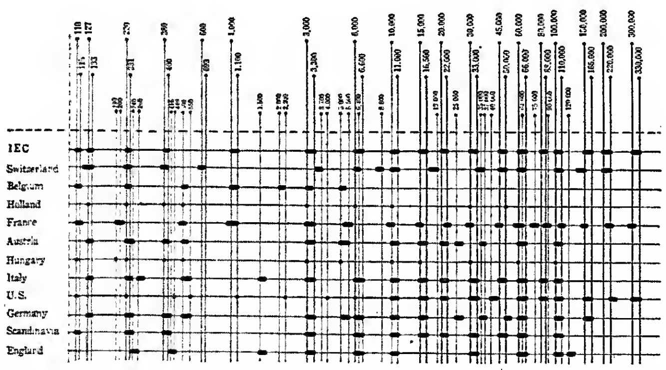

Fig. 2—Voltages for Three-Phase Systems. Comparison of the Standards of Various Countries

in various countries. Hitherto the voltages falling within this class have not been dealt with by the I. E. C. They are of chief importance for the lighting of electric vehicles, etc., for telegraphy, and for electro-therapeutics.

Class B, 100 Volts to 990 Volts. This is the most important class as it comprises house installations and the majority of apparatus utilizing electrical energy.

One hundred ten volts was used at first for lighting and power. When the load and the length of lines increased, the distribution voltage was raised successively and separate mains for higher voltages were frequently installed in towns for supplying electricity for power purpose. In many places this has led to complicated installations.

It has now been the practise for many years to supply energy for lighting, power, and heating, as far as possible from the same mains. Experience has shown that in this case the three-phase, four-wire system presents the most economic solution. For lighting and for small heating apparatus, about 220 volts between the phase leads and neutral is used while about 380 volts between star-connected phase leads is used for motors and larger apparatus.

Higher voltages are also suitable for power purposes, but lighting voltages much above 220 volts, which would result from the use of higher voltages for power in the same mains, are not to be recommended at present owing to the impossibility of manufacturing satisfactory lamps.

Two hundred twenty volts was also selected for three-phase because this voltage was widely used in d-c. and single-phase a-c. systems; lamps and small apparatus for domestic and industrial purposes can therefore be used for all systems, an important feature for the economic manufacture and use of apparatus of this nature.

In addition to 220–380 volts, it is advantageous, from the point of view of existing plants and special conditions, to fix two other standard voltages in Class B, one above and one below in the ratio $1:\sqrt{3}$, namely, about 127 and 660 volts. By changing over star-delta, motors and transformers can thus be used for two adjacent voltages. See Fig. 3.

The ratio 1:2 between adjacent voltages would be very desirable for direct current. Series-parallel connection for three-phase motors, however, necessitates subdivision of the windings and bringing *nine leads* out of the stator frame when the ratio 1:2 is used, whereas for changing over from star to delta, only the *six ends* of the three phases need be led out.

In European practise, motors are provided with terminal plates having six terminals corresponding to the beginnings and ends of the three phases. The change from delta to star can then be effected simply by changing over three connecting links on the outside terminal plate. There usually is not sufficient space on small and medium sized motors to accommodate nine terminals for changing over from series to parallel.

Changing over transformer windings from star to delta is also simpler than using series-parallel connections. Furthermore, three-phase motors and transformers are more reliable in operation when arranged for star-delta connection than when arranged for series-parallel connections, since the latter requires more internal connections and therefore offers more sources of trouble.

The International Electrotechnical Commission took these considerations into account by deciding on the standard voltages for Group II. The voltages stand-

ardized are 127 220 380 volts and also 110 190 volts. In addition to these 115 200 volts and 133 230 400 volts were designated as standard, but with the reservation that each country must decide upon either one or the other series. The most recommendable voltages, however, are 220 380 (Three-phase, four-wire system with 220 volts between phases and neutral for light and 380 volts between phases for power).

Class C, 1000 Volts to 29,000 Volts. From the comparison of the standards of various countries, (Fig. 2,) it is evident that the I. E. C. voltages, *viz.*, 3000, 6000, 10,000, 15,000, and 20,000 volts are standard in most countries, or at all events there are only relatively slight variations.

In the connection it should be noted that in each

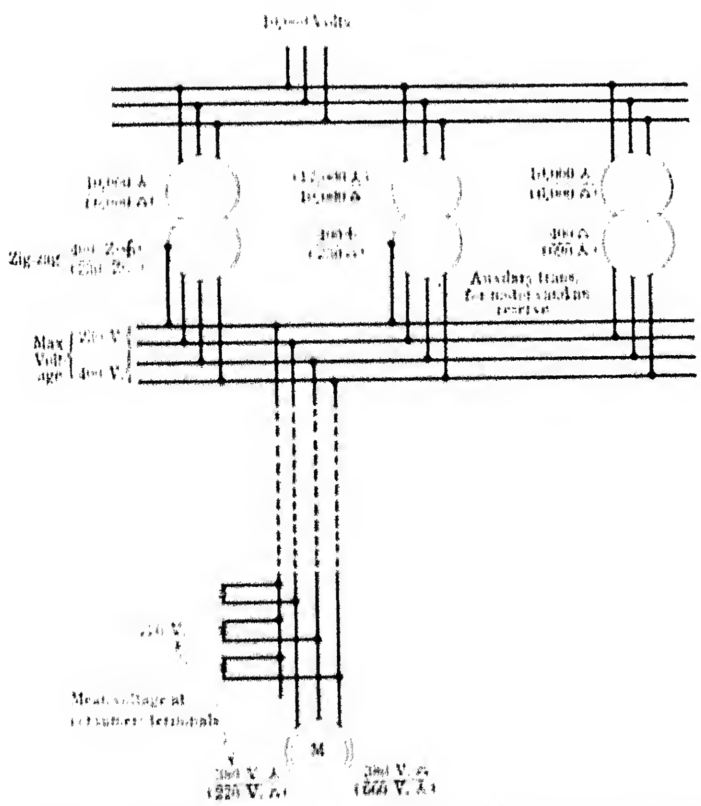

FIG. 3. THREE-PHASE DISTRIBUTION FOR LIGHT AND POWER MEAN VOLTAGE AT CONSUMERS' TERMINALS. (PRIMARY TERMINALS OF TRANSFORMERS)

individual distribution system, generally only one or another of these voltages is used.

To bring about a subsequent reduction in the comparatively large number of steps, the voltages in heavy type were specified as preferred standard voltages.

The following proposal, which had a similar object in view, was submitted to the I. E. C. by the Swiss Committee. In order to allow an increased range of application for this class of voltages by means of the star-delta change-over on machines and transformers, and at the same time to omit one step, it was proposed to alter the voltages 3000 and 6000 to some small extent and to bring together in one step the voltages 15,000-20,000. The resulting series was 3300, 5800, 10,000 and 17,300. Unfortunately this proposal (Appendix I) was not accepted at the conference in New York. The change would not have altered the size of machines, transformers, apparatus, and types of insulators, but the windings would have had to be altered slightly. The result of the alterations would have been a considerable simplification, however, and for this reason the question will be brought up again when it comes to standardizing windings and transformer taps.

Class D, 30,000 Volts to 100,000 Volts. The voltages of this class accepted as standard by the I. E. C. were the widely used values of 30,000, 45,000, 60,000, 80,000, and 100,000 volts, those in heavy type being preferred voltages.

The Swiss Committee also placed a proposal for this class (Appendix I) before the I. E. C., suggesting that the pressures of 30,000 and 60,000 volts should be changed to 33,000 and 58,000 volts so as to ensure the possibility of star-delta connection between these pressures and between 58,000 and 100,000 volts.

Considerations of the present state of affairs and doubts as to the utility of the proposal regarding these high voltages led to this proposal also being rejected by the I. E. C.

It was asserted in particular that it would not be economical to use, for example, transformers insulated for 100,000 volts in 60,000-volt installations. This was not intended for general practise, however. It should be made possible, however, for reserve transformers or even normal transformers, to be used in emergency cases in systems of the next lower voltage by changing over from star to delta.

In this connection an actual case should be mentioned which came to the knowledge of the writer of this report, after the Conference in New York. In the Queenston Power Station at Niagara, transformer units each comprising three single-phase transformers with a total capacity of about 50,000 kw. are changed over from 120,000 volts to about 60,000 volts with disconnecting switches, by means of the star-delta connection. The correct voltage is obtained by regulation on the generators. Although the voltages are approximately in the ratio 1:2, use was not made of the series-parallel connection of the windings, but of star-delta change-over instead; this in spite of the disadvantage that the voltage of the generators has to be regulated to a considerable extent.

Transformers of Class D usually have low-voltage windings belonging to Class C. If the change-over could be effected in both classes, the advantages, of course, would be correspondingly greater, as indicated in Fig. 3.

Class E, Over 100,000 Volts. The I. E. C. has decided on 150,000, 200,000 and 300,000 volts as standard voltages above 100,000 volts.

These voltages bear to each other and to 100,000 volts the ratio 1:2. It was assumed that it would be general

practise in such plants to use a combination of three single-phase transformers instead of one three-core transformer, so that if necessary, series-parallel connection would be used with some advantage. Three-core transformers are also designed, however, for pressures over 100,000 volts. The example of the Queenston Plant shows that for groups of three single-phase transformers, also, the star-delta change-over connection is preferable to series-parallel connection, particularly so because it is frequently necessary to change over relatively quickly outside the transformer, and for this purpose single-phase transformers must each be provided with four high-voltage terminals for series-parallel connection.

It is often the practise in high-voltage and extra high-voltage plants to use lower transmission voltages when starting operation and during the first period of operation. This is done on the one hand to test the plant more carefully and on the other hand because the load demand at first usually is not equal to its subsequent maximum.

These considerations, too, indicate that the possibility of a simple change-over to a lower voltage is desirable with transformers, and that wherever possible the lower voltage should also be a standard voltage.

IV. Standard Voltages for D-C. Systems

Class A, Up to 99 Volts. The fields of application are the same as mentioned in paragraph III A. The d-c. voltages also of class A have not yet been dealt with by the I. E. C.

Class B, 100 Volts to 1000 Volts. The more extensive d-c. systems are to be found in towns. New d-c. systems, however, are no longer installed on a larger scale for lighting and power as the economic advantages of three-phase, four-wire distribution are very considerable. A certain relationship, *i. e.,* common voltages for d-c. and three-phase systems, is very advantageous, however.

It might have been possible to obtain this relationship at 110 volts, but this was considered too low for lighting and domestic apparatus generally on account of the large cross-sections of conductor necessary. The fact that 110-volt lamps are more reliable than, for example, lamps for 220 volts, was not of such importance because the manufacture of lamps will be improved. The pressure derived from 110 volts between phase leads and neutral, *i. e.,* 190 volts for power mains, is, generally speaking, also too low.

In addition to 100 and 220 volts, 440 volts is also widely used in d-c. systems, and various combinations of 110 and 220 volts, namely 2×110, 4×110, and 2×220 volts, were accepted as standards by the I. E. C.

The I. E. C. has also designated as standard the pressures 115, 230, and 460 volts, but with the reservation that each country must decide upon either one or another series.

Higher voltages in this class and voltages in the next classes are used principally for electric traction which for the time being is not being taken into consideration.

V. Nominal Voltages, Voltages at Consumers' Terminals, Maximum Voltages and Test Voltages

According to the standards in some countries the mean voltages at consumers' terminals are taken as nominal voltages for class B, while for classes C and D the maximum voltages at the generators and secondary terminals of transformers were fixed as nominal voltages. In favor of the second ruling, it is maintained that the calculation of the test voltage for a plant should be based on the nominal voltage and that the highest voltage normally occurring should be used as a basis for the calculation of the test voltage.

This consideration is correct as far as it goes. It is also easily possible, however, to base the calculation of the test voltage on the mean nominal voltage at con-consumers' terminals, provided allowance is made for the difference between this and the maximum allowable voltage in the system in question. According to various standards and also according to the I. E. C., this difference amounts to about 10 per cent for class C and the higher classes of voltage.

The question as to which voltage in a plant is to be taken as the nominal voltage is thus of secondary importance as far as the reliability of material is concerned. The most important point is that the same voltage shall be used throughout as a basis, and that the same safety factors and factors for calculation of test voltage be employed by the different countries.

The opinion in Switzerland is prevailing that the formula given by the I. E. C. in Publication 34 for medium sized machines and transformers, *viz.,* test voltage $= 2E + 1000$, is sufficient for testing the insulation of windings, *i. e.,* when a solid or liquid insulation material is in question, thus including also large machines and transformers. A test voltage of $2E + 10{,}000$ is proposed for insulators where air is the dielectric medium. In other countries there is a question of increasing the factors to some extent. As this does not directly affect the standardization of voltages, further details will not be dealt with here.

The fixing of the *mean voltage at consumers' terminals* as nominal voltage was very strongly advocated in France on the grounds that this voltage usually figures in contracts for the supply of electricity and should therefore be considered as the nominal voltage. The I. E. C. accepted this proposal. This solution has the advantage that the nominal voltage of all classes is referred to the same point in the system, *i. e.,* to the mean voltages at the consumers' terminals (lamps, motors, and primary terminals of transformers).

This point is not made sufficiently clear in various regulations, including those of the Electric Power Club. The next section of the report will deal with this subject more fully. The decisions of the I. E. C. relative to

the question and the table of accepted nominal voltages are given in Appendixes II and IIA.

Figs. 3 and 4 show diagrams of connections for three-phase installations. These give the maximum voltages at the generators and secondary terminals of transformers, and also the mean nominal voltages at the lamps, motors and primary terminals of transformers, for net-work of nominally 220–380, 10,000 and 100,000 volts.

Fig. 3 also indicates various possibilities of changing over on the primary and secondary sides of transformers and motors.

VI. Remarks on American Practise

The relations between Europe and America in the field of electrical engineering have always been relatively close. In the conferences of the I. E. C., and when drawing up standards for various countries in Europe, endeavors have been made to give due regard to American practise, also.

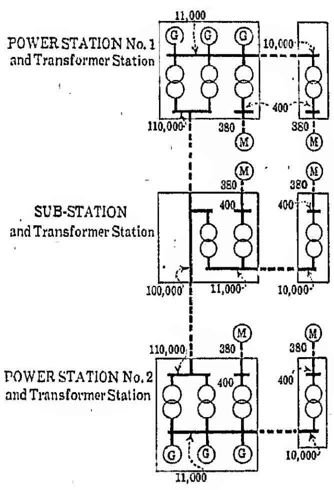

Fig. 4—Distribution of Voltage. Limiting Values

The following case is assumed: Two power stations operating in parallel. Generators for 11,000 volts at full load, one in each station connected to 11,000/400-volt transformer for direct distribution in the immediate vicinity; 380 volts at motor. One 11,000-volt outgoing feeder to a transformer station for supplying another district; as before, transformation ratio 11,000/400 volts and 380 volts at motor.

There are also 11,000/110,000-volt transformers in each power station supplying a substation situated about half way between them, containing 100,000/11,000-volt transformers. Energy is distributed from the substation by means of 11,000/400-volt transformers. There is also an 11,000-volt outgoing feeder for supplying a transformer station at 10,000 volts in another district. This station also transforms down from 10,000 to 400 volts for a pressure of 380 volts at motor terminals (220 volts for lightning).

The Conference in New York in April, 1926 made possible a still closer cooperation between electrical engineers in America and Europe. Earlier discussions of the I. E. C. led to the opinion that American practise regarding standard voltages shows many points of similarity to European practise. In particular, the view was held that the American standard voltages, 6600, 11,000, 22,000, 33,000, 66,000, 88,000, 110,000, and 220,000, represented the maximum voltages of the systems in question, in which 6000, 10,000, 20,000, 30,000, 60,000, 100,000, and 200,000 respectively were the mean voltages at the end of the lines, *i. e.*, at the primary terminals of the step-down transformers. It was thus supposed that the American standards agreed with the European standards, as these give as nominal voltages the same values, 6000, 10,000, 20,000, 30,000, 60,000, 80,000, 100,000, and 200,000 volts, at the consumers' terminals and at the primary terminals of transformers, these values being about 10 per cent lower than the maximal voltages. The difference of about 10 per cent between the mean nominal voltages and the maximum voltages on one and the same system was accepted as I. E. C. standard.

The view that the voltages, 6600 volts, etc., are an American standard maximum is confirmed apparently by some standards of the Electric Power Club. On page 185, for example, taps of five per cent (6270 volts) and 10 per cent (5940 volts) are quoted for 6600-volt transformers. This would obviously indicate that at the consumers' end of a line, *i. e.*, in this case at the primary terminals of the transformer, the pressure is about 5940 or 6000 volts according to the load and the length of the line. This would correspond exactly to the nominal voltage or mean voltage at consumers' terminals accepted by the I. E. C.

The low-tension voltage quoted by the Electric Power Club as standard for 6600-volt transformers is 220–440 volts. This appears not to agree with other standards defined by the Electric Power Club. On page 129, 220–440 volts are quoted, amongst others, as standards for motors. Lamps and other apparatus are also constructed for 220 volts. Such apparatus, however, is very seldom installed immediately near the transformer terminals, but some length of network is usually necessary, involving a voltage drop which must be taken into consideration. This drop for low voltage is assumed to be about five per cent on an average. The mean voltage at the secondary terminals of the transformer should therefore be raised by this amount. Thus, if motors are wound for 220–440 volts, the voltage at the secondary terminals of the transformers should be about 230–460 at full load. With this correction, the transformers would correspond to the I. E. C. standards. The latter standards do not yet contain data for increased voltages at the transformer secondary terminals for the low voltages but this question is to be settled at the next meeting.

The above remarks concerning the transformers for 6600 volts as defined by the Electric Power Club apply similarly to the transformers of other standard voltages, *i. e.*, 11,000 volts, 22,000 volts, etc.

VII. Concluding Remarks

The foregoing report emphasizes intentionally the importance of the *three-phase current* for the distribution of energy for lighting and power, as the standardization of voltage is influenced thereby.

The report also deals very fully with the question of star-delta change-over of machine and transformer windings, for the following reasons: In standardizing,

great importance is rightly attached to voltages used hitherto. In addition to this, there is, however, the not less important question of adapting the standardized voltages to three-phase current, to be considered. If it is asserted that the change-over from star to delta is relatively seldom used at medium and high voltages and that it will not therefore be of great importance, it should be remarked that up until now it was not possible to make use of this change-over with many of the voltage used hitherto, as the resulting voltages are not standard. It is nevertheless frequently pointed out that the pressures 3, 6, 10 kv., and 30, 60, 100 kv. allow the change-over to a large extent. The approximation, however, especially at 3–6 and 30–60 kv., is not sufficiently close. Swiss electrical engineers are of the opinion that a closer agreement between the values would be of great advantage to manufacturers and electric supply companies.

These remarks should in no way lessen the importance of the fact that the I. E. C. has succeeded in fixing standard voltages to which all concerned are agreed. These voltages also form a basis for considerable simplification, as compared with conditions hitherto prevailing.

Appendix I

INTERNATIONAL ELECTROTECHNICAL COMMISSION

PROPOSALS OF THE SWISS COMMITTEE REGARDING STANDARD VOLTAGES FOR THREE-PHASE CURRENTS

A. Proposal. At the meeting held on the 21st April, 1925, at the Hague, it was decided to submit to the National Committees the following proposal of the Swiss delegate, M. A. Huber-Ruf, in regard to the standardization of high pressures. This proposal was inadvertently omitted from the Minutes R. M. 22.

The three-phase pressures proposed by the Advisory Committee on Standard Pressures, which bear to each other an approximate ratio of $1:\sqrt{3}$, should be modified and fixed as shown below, in order to make star-delta interconnection possible.

Two series should be formed, one starting from 10,000 volts and the other from 100,000 volts, as follows:

1st series..... 3300 5800 10000 17300
2nd series.... 33000 58000 100000

It is recommended that the pressures of 3000, 6000, and 15,000–20000 volts should be replaced by the pressures of the first series above, and pressures of 30,000 and 60,000 volts by those of the second series, in all new installations or when important additions or modifications are made to existing installations.

B. Explanation of the Reasons for the Proposal. The rational manufacture in series of three-phase machines and transformers requires above all the use of standard pressures interrelated by the ratio $1:\sqrt{3}$. This scale is the only one in which a standard pressure is obtained when the change from star coupling to delta coupling, or vice versa, is made.

The foregoing proposal satisfies this requirement for the *most commonly used* pressures and will also make it possible to establish in the future a standard series of high three-phase pressures as rational as that which has been fixed for low three-phase pressures on the basis of the ratio $1:\sqrt{3}$.

Appendix II

STANDARD VOLTAGES, R. M. 42

A. DECISIONS OF THE NEW YORK CONFERENCE OF I. E. C., 1926

1. Voltages, Class A.

TABLE I

Series	Voltage at Consumers' Terminals		
		Alternating Current	
	Direct Current	Single-phase	Three-phase
I	1 × 110	1 × 110	110
	2 × 110	2 × 110	127
	4 × 110	1 × 220	220
	1 × 220		
	2 × 220		
	1 × 440		
II	1 × 115	1 × 115	115
	2 × 115	2 × 115	133
	4 × 115	1 × 230	230
	1 × 230		
	2 × 230		
	1 × 460		

a. Each country must decide either on Series I or Series II.
b. The values given for three-phase are the voltages between line and neutral. The voltages between phase leads corresponding to the given values between line and neutral must also be considered as standard values, *e. g.*, 380 volts. (This note will be added to the table drawn up by the I. E. C.)

2. Voltages, Class B.

a. THREE-PHASE VOLTAGES
TABLE II

Nominal I. E. C. Voltages Mean Value at Consumers' Terminals	Maximum Voltages
1,000	1,100
3,000	3,300
6,000	**6,600**
10,000	11,000
15,000	**16,500**
20,000	22,000
30,000	**33,000**
45,000	50,000
60,000	**66,000**
80,000	88,000
100,000	**110,000**
150,000	165,000
200,000	**220,000**
300,000	330,000

b. Definition of "nominal high voltage:" The nominal high voltage shall be the mean voltage at the consumers' terminals and shall be called nominal I. E. C. voltage of the network of that voltage range.
c. The maximum voltages at the generators and secondary terminals of transformers shall be considered to be about 10 per cent higher than the mean voltages at the consumers' terminals. The values are included in the above table.
d. The maximum and minimum values of the voltages according to paragraph I, and the variations occurring under working conditions, should be considered at a later date.
e. Preferred nominal voltages. The voltages which are in heavy type are preferred high voltages.

Discussion

PAPERS ON VOLTAGE STANDARDS

(Summerhayes and Hanker, Aggeringer, Silver and Harding, Gear, Scholz, Ehrhardt and Jones, Minor, . Huber-Ruf)

New York, N. Y., February 9, 1927

B. G. Jamieson: This discussion was organized for the purpose of presenting this voltage question in such a broad light that it may arouse a unity of purpose and a spirit of compromise so that following this presentation there may be substantial progress towards either a settlement of the question or a definite statement that perhaps we are too far apart ever to settle it.

A few references may be made to previous work. This subject was recognized as preeminently important by the Electrical Apparatus Committee of the N. E. L. A. about 1921 and 1922, with particular reference to one of its several aspects, namely transformers. As a result the 1922 standard of the Electrical Apparatus Committee for the transformers was compiled and approved.

In 1924 the manufacturers began to complain that less than 50 per cent of the power transformers were being ordered in accordance with these standards, and an investigation by the Transformer Committee of the N. E. L. A. revealed that not only was a revision of the 1922 transformer standards necessary but that any such revision should take into account the whole system from the generator to the consuming devices.

In 1926 the International Electro-Technical Commission held a meeting in New York, at which time standard system voltages was a major topic in the program, and it became evident that the United States was unable to present anything like a nationally endorsed schedule of system voltages. The recognition of this dilemma brought about a serious committee activity which has crystallized into this symposium.

As I said in the beginning, it is but an expression of a very earnest endeavor to bring about some unity of sentiment on this subject.

President Chesney in his address[1] on February 7 stressed the topic of standardization and the Institute's obligation in this work. In the appreciative responses to his appeal, a suggestion was offered, and that particular suggestion seemed to me to be particularly worth our consideration. The substance of it was that we accomplish our ends (meaning the greater efficiency in our work of attempts at so-called standardization) by a somewhat diminished stressing of that term. That is to say, instead of stressing the word "standard," let's see if we can't use some other word perhaps that will help in bringing about what we desire.

If, for example, we can convey to engineers that what we really are seeking is not in the nature of the absolute which the word "standard" always suggests nor of that fixed character, nor a futile academic ideal, but the ideal that engineers as economists all really appreciate, namely, that we ought to unify and thereby simplify our practise, perhaps this avowed concession to contemporaneous practise and, of course, fixed capital, will attract and soften some of the irreconcilable elements now preventing the desired unification. Operating practise will change with the development of the art, but we should, of course, maintain its orderly direction.

M. D. Cooper: Since the focal point of all endeavor along lines of voltage standardization is the ultimate service voltage, it may be interesting to review briefly the development of the present program of standardization in reference to lighting voltages and incandescent lamp demand.

The original Edison central stations practically all operated at 110 volts. The inherent spread in voltage encountered in the manufacture of carbon lamps induced a corresponding spread in voltage on the part of central station lighting companies so that in the early years of the century lamps were supplied in a large number of voltages between 100 and 130 volts. After the advent of the drawn-wire tungsten filament, the spread in voltage in lamp manufacture ceased. The outstanding voltages of greatest demand were 110, 115, and 120 volts, wherefore the lamp manufacturers started a movement to centralize the lamp demand on these three voltages.

The original 110 volts continued to be the favorite voltage until 1919, when the percentage of demand at this voltage was exceeded by that at 115 volts.

In 1923 the National Electric Light Association put forth the recommendations in reference to standardization of service voltage as quoted in the paper by Messrs. Hanker and Summerhayes.[2]

The percentage of total lamp demand at 115 volts has risen continuously, and for 1926 stands at 47 per cent. For the last seven years there has been a steady decrease in the demand for

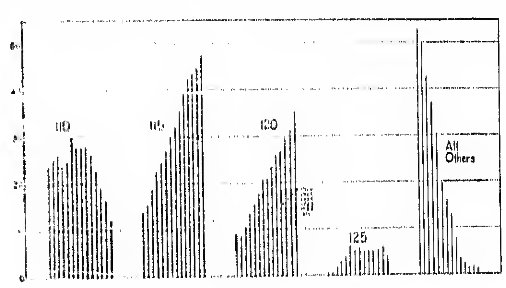

Fig. 1

110-volt lamps. This decrease has been accelerated in recent years by the increasing favor of the 3-phase, 4-wire network, which gives an undesirably low-power voltage when operated at 110 volts for lighting. In 1926 the demand for 110-volt lamps was only 12 per cent of the total.

There will always be a theoretical advantage in operation at 120 volts in preference to 115 volts. With growing load, however, it will be increasingly difficult to work line apparatus at sufficiently high voltages to maintain 120-volt service at peak load.

With the added impetus which will be given to operation of the new network system at 115/200 volts by the probable standardization of a line of 200-volt motors in the near future, we can anticipate an increase in percentage of the total demand at 115 volts at the expense of all other voltages.

It is often difficult to place any cash value upon any one particular step in a program of standardization. If we go back far enough in the history of the art, however, and draw a comparative picture between conditions then and now, we cannot fail to see the great advantage of standardization. For example, in the year 1900 standardization was just beginning to be felt in the matter of incandescent lamps. At that time there were 5 principal sizes of lamps ranging from 2 to 32 candle power and in most of these types there were available 4 types of filament construction, 3 different efficiencies of lamp, 3 different finishes of bulbs, 30 different voltages and 13 different bases. Multiplying all these factors together we find that there were more than 50,000 types of lamps in current demand. At the present time, with much greater range of size, *viz*,—10 to 1000 watts— with one standard efficiency, base, filament construction and bulb for every size of lamp— one type of bulb finish for the majority of the sizes—and only 3 voltages, the number of lamp types for general lighting has decreased from 50,000 to 54. The completion of the

1. *Electrical Standardization*, address by C. C. Chesney, A. I. E. E. Journal, March, 1927, page following p. 214.

2. *Voltage Standardization of A-C. Systems* by F. C. Hanker and H. R. Summerhayes, A. I. E. E. Journal, May, 1927, p. 438.

voltage standardization as recommended by the National Electric Light Association will still further reduce this number of types to only 18.

The writer had occasion to see what standardization means in ordinary business on a recent European trip. In Vienna there was a lamp manufacturer who maintained a factory stock of about 3,000,000 lamps. The biggest single item (lamps of the same description) in this stock was one of 3000 lamps. This condition resulted from a lack of standardization with its resultant complication in requirements of different voltages, style of lamp, bulb finish, bases, etc. In a factory stock in this country of approximately the same total size the largest single item was 40-watt, 115-volt lamps of which there were 198,000, or about 70 times as great a stock of the most popular item as could be maintained under the European conditions of non-standardization. The greater availability of the product under conditions of standardization makes, for much more convenient commercial service as well as greatly decreased cost of warehousing, less investment in stocks, less delay, duplication of shipments, etc.

No one needs to speak to the electrical industry in this country on the advantages to be gained by standardization, and I draw this parallel to emphasize more fully the advantages that can accrue to us by a thorough standardization from the lamp back to the generator.

C. E. Skinner: It seems to be well established that we need national industrial standardization. In the electrical field, there has been considerable effort, particularly through the work of the I. E. C. to bring about international standardization, especially with regard to fundamentals, such as the basis of rating. This effort has been continued for a number of years and further progress was made at the meeting of the I. E. C. in New York, April 1926, where this general question of voltage standards was considered.

Unfortunately, international accord seems difficult, due to the fact that in Europe they have been inclined to use the even thousands, while we in America have in general adopted voltages which are multiples of eleven. The lack of voltage standards is responsible for much of the confusion and non-standardization in international electrical trade. For example, a manufacturer of incandescent lamps doing a truly international business, is forced to manufacture something over 70,000 sizes, types and varieties. This makes mass production, as we understand it, impossible.

International standardization is of importance to everyone having anything to do with international trade and in trying to arrive at national standards we should continuously keep in mind the desirability of international accord wherever this may be at all possible.

A. H. Kehoe: I assume it to be generally accepted that the "mean lamp voltage" is the proper basis to use in any standardization of voltages. Some of the papers fail to indicate that standardization has not been rigorously adopted but is still on a tentative basis with three recognized lamp voltages, namely, 110, 115, and 120 volts. It appears that the immediate practical result to be sought is simplification or unification of practise, rather than hard and fast standardization which is likely to be too narrow to be suitable for future requirements. Last year's *Electrical World* statistics recorded over 50 per cent of the residential customer being supplied with 110 volts. Data presented today indicate 120-volt lamp use to be 35 per cent of this class of lamp. With these conditions existing it appears evident that simplification, particularly of the lower voltages, may be possible, but standardization of voltages or equipment unless broad enough to cover such conditions would be standardization in name only, similar to former cases mentioned in the papers.

I differ with statements in certain of the papers which indicate that adopted standards are endowed with properties whereby it becomes a moral duty to adopt them. It is recognized that contractual obligations, in the absence of other specifications, are controlled by existing standards, and the responsibility for the operation of apparatus outside of standards when not covered by specifications places a responsibility on the operator which would not otherwise be present. In practise, probably most of the departures are covered by specification, and I hold the real concern should be for the blind follower of standards regardless of their value for his conditions. For instance, consider the systems equipped with the present standard transformer—this group of papers indicates how inadequate they are for proper operating conditions. I disagree with the statement in the Hanker-Summerhayes paper that "The design of electrical systems contemplating the use of apparatus under conditions more severe than sanctioned by the A. I. E. E. standards should be discouraged." In certain instances, equipment is (and, in my opinion, should be) purchased with insulation in excess of the values which are standard at present, and if conditions warrant the use of apparatus with less than standard values, I see no moral reason why it should not be done. To discourage such action is merely to retard progress temporarily. When variations from standards become of economic importance, changes in standards should be considered. These cases do not have the hazards of a steam boiler, and are not incorporated in the safety requirements of the industry.

It appears possible to me for present conditions to be covered by modifying minor details of the proposals made in the different papers so that a large percentage in the industry can adopt a unified practise. To do this it will be necessary to recognize that we have three "lamp base" voltages, that important economic results are to be obtained by unification, and that the standards are very likely to require changes from time to time as developments in the art change the economics of the situation. If the first step is comprehensive, further simplification at a later date will doubtless be possible. What the future simplification is likely to be should be indicated only in a general way so that future progress will not be delayed if new conditions require changes from what is indicated at present.

W. F. Dawson: This standardization of voltages means much to all of us, but it appears that in starting out for standardization, existing practise has been ignored.

It is now proposed to make standard voltages 5 per cent higher than heretofore and to permit an operating leeway between plus 5 per cent or minus 5 per cent. Previously the plus or minus margin of 5 per cent was permissible but with the understanding that standard temperature guarantees did not apply; in other words, the departure from standard voltage was assumed to be an overload condition. Now apparently, it is proposed that in addition to raising the standard voltages 5 per cent, we are also to guarantee standard temperatures with 5 per cent margin, which is equivalent to raising the voltage standard 10 per cent. Many operators have come to consider dynamo-electric machinery as capable of overloads and special operating conditions much beyond the specifications. They found apparatus rather generously rated, but overlooked the fact that competition has been gradually driving manufacturers to adjust ratings more nearly in accordance with performance ability.

We are prepared to meet these new proposals, but venture the hope that one year, or five years from now, we shall not be confronted with another new "standardization" which will not be standardization, but actually "destandardization."

Many of the smaller turbine alternators are built in advance on stock orders and when special requirements are insisted upon, it means that these standardized and stock machines cannot be utilized. Special requirements mean that machines must be built to order, and involve special development which adds greatly to the cost. The time required for building the apparatus is also increased substantially.

J. H. Foote: Perhaps it is all right to standardize the voltages on the basis of utilization voltage. But we don't want to forget that the correct basis for apparatus design is not the utilization voltage or multiples thereof. In my opinion, the correct basis is the maximum voltage to which the apparatus will be subjected under the maximum load.

For instance, we may say that the correct utilization voltage is 115 volts in terms of a distribution system with 20-to-1 ratio transformers. We can say that the nominal for the distribution voltage is 2300 volts. That is fine, but don't buy 2300-volt generators and don't buy 2300-volt secondary transformers to feed a 2300-volt system, or you are in just the same trouble that you are in now.

That is what caused all this trouble—a generator which has a voltage rating and which was designed to supply that voltage at full load. That means that the generator will probably be a 2500-volt generator. The paper of Messrs. Silver and Harding bring that our very nicely.

Their paper seems to recognize the actual voltage situation more than the other papers in that they figure out what the voltage should be, but apparently have not the courage to say that voltage is impossible and, therefore, they will change the transformer ratio. To jump from the 2300-volt class to the 6600-volt class, a 6600-volt system is just three times a 2200-volt system. Therefore on the same basis on which we say a 2500-volt generator would be needed for a 2300-volt system, a 7500-volt generator would be needed for a 6600-volt system.

Just double that and you have instead of a 13,200-volt generator a 15,000-volt generator.

You say, "That is impossible." Well, it is done. Much 13,200-volt equipment is now operating under full-load conditions at potentials largely in excess of 14,000 volts, and the only reason they don't operate at 15,000 volts is that the machines would probably burn up if operated at that voltage at full load—and some of them do burn up once in a while. The temperatures run to excessive degrees, and the operators change the ratio of their distribution transformers from the 120-to-1 ratio, to a lower ratio by dropping down on the 5 per cent tap.

That means that in place of using the taps in our transformers for line regulation or for transformer regulation, we have to use that range because of the inability of the generator to produce adequate voltage.

Now that is the fundamental picture that comes to me when I think of this transformer standardization. I always have to think of the starting from the utilization voltage. Most of us are led astray in these profiles by starting at the generating end of the transmission system. We should start with the motor and the lamp and see what the voltage must be to supply their requirements adequately.

Now there are some more complications that make the present situation, I believe, besides this tenacious hold on the 11-multiple and the like. One is that most of us are using standard distribution transformers which are of straight ratio. Five or six years ago the Transformer Committee changed the ratio of the transformer stepping down to primary voltages from standard to a little off standard at that time. For instance, they changed from 13,200/2200 volts, which was the former standard, to 13,200/2300 volts, giving us 100 volts boost and helping out the situation somewhat.

Now we have all those transformers and we have the present generators and we have a situation. The solution that we must arrive at is something which will utilize as much of this equipment as possible, and I do not think that the solutions as proposed generally take adequate care of that situation.

There is another reason for our difficulty. We have without thought for many years brought transformers with either four 2½ per cent taps, or two 5 per cent taps, because it was standard and because the manufacturers found it convenient to limit the tap range to 10 per cent. Ten per cent has been shown in any number of transmission systems to be an inadequate range.

This is brought out in one or two of the papers, and most of us who operate systems involving ups and downs and transmission distances know that 10 per cent is not enough. The remainder of the required range is taken out by over-voltage apparatus.

We have found in the systems I am connected with, that a tap range of 16 to 17 per cent seems to be indicated as necessary in an interconnected system for transmission transformers. That does not mean distribution transformers. It is our opinion that distribution transformers should be without taps; that is, the generator voltage is adequate, and straight-ratio transformers and proper feed regulators are used, but there is no necessity for taps in a straight distribution transformer.

Another difficulty is that due to following present standards we have been using not only generator voltages but also transformer secondary voltages, which are too low to supply adequate voltage to the distribution systems.

Perhaps the last difficulty, which has not been really brought out in this meeting, is that in the years that have passed, people have adopted two different schemes of raising the voltage on their system. One is to use multiples of two. For instance, a man who had a 6600-volt system, some day when he needed it doubled his voltage, and then he had 13,200. The other man bought the 6600-volt transformer, and instead of doubling his voltage he *y*-connected it and got 11,400 or thereabouts.

Then a third man adopted 11,000 volts as his voltage. And so there are at least three voltages all in the same range and we wonder why they aren't the same.

Any new standard which we may adopt, which will displace those three lines of transformers or unify them must have a sufficient range of taps so that it will take care of the situation adequately and in following these proposed standards, limiting the taps to 10 per cent or so, that is impossible of solution.

In the solutions which are offered, I note a dread to change the name of the voltage. Instead of that we change the ratio of the transformer. I seriously question that we should do that. Transformers are rather flexible. We have thousands of them already installed and in supplying the new standard transformers to operate on the same system they must, of course, have approximately the same ratio. I think that, that has been brought out by Mr. Kehoe in his discussion.

There is another matter that seems to complicate the situation. That is, that all the new standards are proposed to be nominally rated. This was started four or five years ago and is a reversion to the old standard of rating at the receiving end and applying certain factors to take care of the drops and the like. It gets us into trouble.

For instance, take the 132,000-volt class of transformers. A voltage of 132,000 is largely a nominal voltage and means absolutely nothing. If a man buys a 132,000-volt transformer, we would not know what he was talking about unless he specified whether it would have one 5 per cent tap, or two 5 per cent taps in an extended winding supposedly to hold voltage under load.

That would mean that the extreme ratio of the transformer would give a no-load voltage of about 145,000 volts. If we rate that a maximum-rate transformer it would be a 145,000-volt transformer, and according to the present A. I. E. E. standards would be subject to a considerably higher test than a 132,000-volt transformer.

Therefore the proponent of the nominal rating says that it is to our advantage to rate apparatus nominally and supply over-voltage specifications in order that the A. I. E. E. test be not increased and, therefore, the expense of the equipment.

I think that that is a subterfuge. If the A. I. E. E. test at 132,000 volts is adequate for a transformer with a top-tap ratio giving 140,000 volts, then the thing to do is to change the

standards. Instead of making them twice normal plus 1000, make them 1.9 normal plus 1000 or anything else. But why try to fool ourselves about this situation?

Another difficulty is that by nominally rating equipment, the manufacturer rates his insulated apparatus, such as the lightning arresters and oil circuit breakers and other apparatus, at that nominal rating. This means that any engineer who is desirous that the apparatus be adequate as regards test voltage must go into the next class if he is honest with himself and specifies a transformer at the maximum rating.

It seems to me that such apparatus should have the division point half-way between one class and the other class. This is particularly true of lightning arresters, because the performance of the arrester is absolutely dependent upon the actual voltage. Rating a lightning arrester at a maximum of 138,000 volts and a minimum of 126,000 or something like that, which is established practise, means that a system having 140,000 volts must either have special apparatus, or else must go into the next class which is 154,000.

If the division point between the 132,000 volts and the 154,000 volts were made at something around 147,000 volts just about half-way between, then the range of apparatus would fit the standard more adequately.

As I see it, the result, if we go ahead on any such basis as has been proposed, namely to change the distribution transformer ratios in order to keep the names correct, not a present standard and a present special, but a new standard, an old standard, and a present special. We are going to have three sets of transformers in a few years instead of two, and I should like to emphasize that in my opinion any new standard must be decidedly broader in scope than anything that has been offered yet, in order that it may not only include the present standard of transformers, but may also absorb as many of these present specials as possible.

This circuit-voltage rating is something I should like to mention. This A. I. E. E. definition, I believe, should be clarified, the definitions for the purpose of fixing a value to be used in designing and testing electrical apparatus. The rated voltage is defined as the highest rated voltage of the apparatus. That means that if you rate a machine at anything less than maximum voltage that is the rated voltage. That keeps the test down and cheapens the apparatus without changing the test definition, but the A. I. E. E. says, "This voltage rating applies to all parts of the circuit. The actual operating voltage may vary from the rated circuit voltage but should not exceed it."

We are proposing in these new standards to exceed the voltage. If that is all right, the A. I. E. E. rule should be changed. I think the A. I. E. E. rule is all right except that it should say, "It must not exceed it," instead of "should." I think we should bring the ratings of our systems up to what they really are.

To summarize the situation, as I see it: Adequate standards must be technically correct, or else engineers who really think they have worked out the solution adequately will continue as they are at present to buy so-called special apparatus. These new standards must include as much as possible of the present special standard apparatus. They must be based upon premises which will avoid the mistakes of the past, and I think the present standards are merely trying to make standard equipment which has been proved to be inadequate in the past.

They must recognize transformers as ratio machines only, with a certain maximum voltage rating. They must have an adequate tap range, which inter-connected systems find is at least 15 per cent, although full capacity is not necessarily required above 10 per cent.

Generators particularly must be rated at maximum voltage in order that injurious heating will not be experienced. Transformers should be rated at maximum voltage in order to clarify the situation and work in accordance with the present A. I. E. E. installation standards.

Finally, the general apparatus names should be such as to place the nominal rating of the apparatus midway between the maximum and minimum ratings of the new standard itself.

F. L. Hunt: It is not difficult to pick out details in the various papers which have been presented with which we disagree, but I believe, if possible, this discussion should be confined to the general features of the question before us.

I am willing to express my opinion as to one of the general points under discussion, and that is that we should base our standardization on the idea that power will flow in two directions on most of our important circuits. In general terms, I like the idea that Mr. Argersinger has proposed.

H. C. Sutton: In my opinion, generators should be designed to deliver full rated output throughout a range of 10 per cent above or below rated voltage. The manufacturers' proposal of 5 per cent voltage range does not give sufficient flexibility for operation.

There is one other point that I particularly want to stress, and that is, the difficulty due to the present rating of apparatus for voltages above 66 kv. For instance, step-down transformers have a voltage rating in multiples of 11.5 up to 69,000 volts. This same rate should apply for the higher voltage ratings. There is no logical reason for changing the multiple to 11 when the figure of 6900 volts is exceeded.

N. B. Ames: It seems to me that we have overlooked the main point in this proposition entirely. After all, is it a matter of the particular voltage to use or is it a matter of regulation? That seems to me to be the answer to the question. There are two very practical theories in conflict here, of course, (1) whether we shall have excessive reactance in our transformers and generators producing poor regulation and ample protection, or (2) whether we shall reduce this reactance and get better regulation and depend upon our protective devices to give us the protection.

Eugene Vinet: To my mind the essential thing to decide as a first step is what planes or levels of voltages we want to take as standards. That is to say, do we want to take, say, 33,000 volts as a standard or do we want to take 44,000 volts? Whether it is 33,600 or 31,500, etc., is only a matter of fluctuation or regulation as a result of the usual operation. What we have to decide are the planes of voltages that we want to use.

One thing which strikes me in these proposed voltages is that there are too many of them. The purpose of standardization is to reduce to a minimum. My feeling is that we should suggest only approximately 7 or 8 voltages. I speak from personal experience with the organization with which I am connected. Some two years ago we felt that there was a necessity for a standardization of voltages, as, owing to the growth of loads, a good many of the transformers became obsolete, and when we wanted to do some interchanging of transformers we were hindered because the voltages were too varied. We found on a survey of our conditions that we had 21 different voltages.

We have standardized on seven, which is a considerable reduction, and have tried to make everything as simple as possible. That was two years ago. Now every one is fairly well agreed that it has simplified matters considerably and has been of very great help in operation and interchangeability of material, not to mention the saving in money.

It seems to me that it might be well to make a definite issue of certain voltages, and debate them and see whether we can agree on them. For instance, some people favor 11,400, others 13,200. In our own case we have standardized on 11,400 volts star. The reason for that is because we have a great many rural lines which are growing all the time. We felt that the thing to be considered first was the distribution in preference to the generation, because we have got to give service and that should be the dictating factor.

In the case of rural distribution, very often the loads did not warrant voltages of 13,200. We can start at 6600 volts very often single-phase; then we make it three-phase, and then as the load grows we star it and get 11,400. That suits our purpose

very nicely. We also standardized on 33,000 volts. It was a question whether we should go up directly to 66,000 volts, but for economical reasons we felt that it was advisable to make a step between 11 kv. and 66 kv. We have situations where we have relatively small towns to reach for service. In scattered communities we may have a town of 5000 people or thereabout to serve. We may have to build 20 or 25 mi. of line to reach that town with smaller places to be served from such a line. It would not be economical to build a 66,000-volt line. We can't build it at 11,000 volts because it won't give the service. Therefore 33 kv. is a very nice intermediate step. That was one reason for our 33 kv. Then we go up to 66 kv. and 132 kv.

The lower voltages are 115, 230, and 460. Then we have 2300 delta or 4000 star. Those are the only standard voltages which we have. We take care of voltage variations by means of taps.

I am mentioning these voltages because they may offer some ground for discussion. We have been very happy with these few voltages so far. I might mention in connection with the 6600 volts 11,400 star that it might be a good thing to go up to 6900 volts or 12,000 volts star. It occurs to me at this time that it might be a way of compromising with the advocates of 13,200 volts. There isn't any doubt that there will have to be compromises.

So far as we are concerned, we feel so much the importance and the benefit of standardization in voltages, that we certainly will do everything we can to cooperate in this movement and help get it over if possible.

E. C. Stone: It seems to me that there are certain fundamental principles brought out in this discussion that we can all well recognize. The first one is that standardization will start at the utilization voltage. We have heard there were three utilization voltages 110, 115, 120. I wonder if it means that we have to start with three different standards and build up.

The second point is that we must recognize the voltage regulation or drop in the transmission system. This varies widely on different systems, being small on some and large on others, but in any event, in the general problem of voltage standardization, the voltage drop in the various parts of the transmission distribution system must be recognized.

That means, I think, fundamentally that the old set-up of 10-to-1 ratios for transformers and multiples of 10-to-1 ratios is no longer acceptable, and we must break away from that system of ratios to something else.

The suggestion that I wish to offer for immediate consideration is that the essential mechanical features of power transformers be standardized. This is done to a considerable extent at the present time but might be carried further. By mechanical features I mean the core, bushings, end frames, tanks, terminal boards, terminal arrangements, number of taps, number and arrangement of outgoing leads. With these elements standardized, the actual number of turns in the winding, the ratios, and the exact location of taps in the winding might be left as the lowest-cost flexible link in the transmission system, to be worked out to meet to best advantage the local conditions which are peculiar to any particular system. It hardly seems reasonable to install on the system which has very low voltage drops, transformers which are designed with perhaps 15 per cent and 20 per cent full-capacity taps, to meet conditions on systems having long overhead transmission and correspondingly high-voltage drops.

B. G. Jamieson: Mr. Stone has enumerated some fundamentals that apply particularly to transformers, and there are others applying to transformers which will probably make the wisdom of such standardization apparent, as we find ourselves requiring exciting transformers and series transformers and tap changers and phase shifters and various other auxiliaries, that are now coming to be recognized as necessities with large transformers in the larger and more complex systems.

Of course there are standards to be considered in connection with generators. It is proposed by one of the authors that a simple way to get more flexibility without greater complication is to increase the range of generator voltage. That is something that might be discussed profitably. If, for example, we assume that generators will be built to deliver energy on the busses at 25,000 or 30,000 volts in the near future, perhaps we have more to think about in that connection than we now have when we are generating at pressures below 15,000.

It is quite a simple matter to specify any voltage and get any voltage in a generator so long as you stay below 15,000 volts, but before very long on account of general desirability of a lower current in these large machines, we shall probably see higher-voltage generators, and then it may not be so easy to get the 10 or 15 per cent range suggested by the simple device of varying the voltage.

There are other fundamentals in this problem. There is the general question of means of limiting the necessary voltage range, such as is accomplished in part by the use of synchronous condensers. The Pacific Coast companies are using 17½ or 20 per cent tap ranges partly because the use of the devices really makes it possible for them to keep within that range.

We need to know whether we must allow our systems to respond to this upward urge or trend of voltage that seems to be so evident. We need to know, in order to meet that, on what basis a gradation of steps in system voltages is to be founded. We need to know whether they are to be on a Y-delta basis or on a preferred-number basis or on the basis of approximation of our old standards or what not.

We need to know whether those steps can be met by apparatus having sufficient flexibility without being out of the pale of the standard class, or whether we must allow in our contemplated schemes for a very extended number of steps which will give us a minimum in flexibility requirements of individual apparatus forming part of the system.

We need to know whether or not the problem of high voltage resulting from open circuits is something that can be successfully taken care of.

In connection with the fundamentals of this matter, the Committee has made a survey and has been able to get almost universal assent to the basic acceptance of the principle of utilization voltage as a standard of reference in connection with any standard-voltage system. That point has been, we consider, gained and we hope it won't be upset, though of course if it need be, it will be I presume.

Another point referred to by Mr. Jones, namely the question of rated circuit voltage or, as he put it, the system voltage, was fixed by the Committee and approved by the Institute. Now it would be possible to undo that also, if necessary, but I mention that as another achievement of the Committee so that you will understand that at least two of the fundamentals necessary in consideration of a standard system voltage have been, we think, sufficiently settled so the discussion may proceed on that assumption.

C. E. Skinner: At the meeting of the International Electrotechnical Commission in New York last spring, some of our European friends brought to us the term "voltage zones" and it seems to me that this is a very apt term in connection with certain features of our standardization program. By "voltage zone" is meant a certain range of voltages between which all dielectric tests for apparatus are to be the same. This would be of distinct advantage in allowing manufacturers to stock such parts as outlet bushings and other features of design which have a definite limit due to the dielectric test. In many cases, it would probably be cheaper to take an outlet bushing, for example, from the next zone than to manufacture one for a specific purpose which happened to fall just beyond the particular zone. I would suggest that this question of voltage zones be kept in mind in connection with this standardization proposition, especially with regard to the application of dielectric tests.

R. K. McMaster: An important point is the breaking away from any attempt to have transformers of a single ratio suitable for use on both the 6600- and the 7200/12,470-volt systems. There should be a ratio of 2-to-1 between the voltage ratings of transformers for the 6600- and 13,200-volt systems and a ratio of 3-to-1 for the 2400/4150- and 7200/12,470-volt systems.

In the paper by Messrs. Silver and Harding the recommendation is made that 120 volts be the accepted secondary voltage for transformers of the service class. This is quite a step forward, and also will do much toward the consolidation of the 12,470- and 13,200-volt systems. There is only 6 per cent difference between these two voltages. It would be quite possible to have a tap at about that point, or even to use one of the standard taps for 13,200-volt transformers. In the same paper it is recommended that the voltage ratings of motors for use on 6600- and 13,200-volt volt systems should be reduced. This is a good idea and will go a long way toward avoiding step-by-step increases above these voltages.

One of the disadvantages of the 13,200-volt system is that twice this voltage, namely 26,400, is not standard. Might it not be that the real purpose of standardization would be served by adopting 16,500 volts as a standard voltage, this being half of 33,000 volts?

It is very important to maintain the ratio of 2-to-1 between 66,000 and 132,000 volts and between 69,000 and 138,000 volts, allowing the use of series-parallel transformer connections without complications due to a little lower ratio.

In the paper by Mr. Huber-Ruf voltage ratios based on the star-delta arrangement of motor and transformer connections are advocated. In some cases this is advantageous for motors. It is not, however, advantageous for high-voltage systems; not alone for the reason that there are already at least approximately standard voltages which do not allow for this, but also because of the grounding of the neutral which should be provided for at certain stations necessarily and at others as practicable to provide alternate points of grounding.

Regarding transformer taps in general the percentages of taps should be standardized, rather than the number of taps, so that transformers having a non-standard range of taps will parallel with standard transformers. Simple figures are desirable for tap voltages. An example of this would be the use of 64,500-, 63,000-, 61,500- and 60,000-volt taps for 66,000-volt transformers. There will be a readjustment of parallel operating conditions in any event in connection with standardization of percentages of reactance as well as standardization of voltages.

It is also desirable to give considerable attention from a standardization viewpoint to the phase angle between lines of all voltages, in the higher ranges to facilitate interconnections which are not thought of at the present time, and in the lower ranges to facilitate networks supplied from systems of more than one voltage.

For transformers of all ratios, with the exception of those involving 120 volts and small multiples thereof, it should be recognized that a zero phase angle is permissible, at least under certain conditions. The cases where a 30-deg. angle is desirable or permissible should be standardized so that there will not be more than a minimum possibility of a 30-deg. angle existing between systems of the same voltage in the same vicinity. It is also important to have the 30-deg. angle in the same direction wherever it occurs between systems of any two voltages operating under similar conditions.

Mr. Minor's paper mentions the use of transformers having a ratio suitable for connection directly between the phase wires of 4150-volt systems, permitting the omission of the fourth wire. Such transformers should be used wherever practicable, not only to eliminate the need for running the fourth wire, but also to facilitate the use of the combined light and power system with service voltages of 115 and 199.

P. H. Chase: I should like to ask what the manufacturers consider is the relative influence on transformer cost of standardization of reactance, also of such things as insulation of the neutral lead for full-line potentials as against treating it as a fully grounded neutral lead? On lower-voltage distribution transformers, such as those for subway installation, what is the influence of standardization on the number of phases? There are also certain dimensional and other manufacturing standardization points that, to my mind, must influence cost to a degree commensurate with the influence of voltage, as such.

H. L. Wallau: The point has been raised about reducing the number of voltage standards in use. I think that is something we can all consider. The figure mentioned by one of the previous speakers was a reduction from 21 to 7. I might say that in our own system we are gradually tending to 5, if we consider the 2300-4600 volt class as one. Five might be plenty for most of us. It may not be enough for all of us.

Messrs. Hanker and Summerhayes have enumerated five principles to which any proposed system of voltage standards should conform. These will not be challenged.

Undoubtedly the definition of "rated circuit voltage" will meet with general approval, and it is obvious that equipment should tested in conformity with the maximum line to line voltage to which it may be subjected.

The A. I. E. E. test, for transformers, Rule 6356, is twice line-to-line voltage plus 1000. An exception, Rule 6363 for "Transformers with Graded Insulation" is very vague. The manufacturers' present practise is to test at 2.73 times the voltage from line to ground. What test is proposed for this class of insulation? I quote in part "Such a rule . . . would definitely set the rated voltages of apparatus, their *test voltages* and maximum operating voltage."

If test voltages are to meet Rule 6356 even though induced in the windings must we not sacrifice graded insulation and its resultant economy? Should not the A. I. E. E. Standards Committee provide for a definite test voltage for transformers of this class?

Among low-voltage distribution systems of today are some involving transformers with windings for 2080/4160 and 2300/4600 volts delta. The proposed standards recognize only the 2300-volt class.

Cleveland, Detroit and, I believe, Chicago, have thousands of kilowatts of transformers connected of the above off-standard voltages. Too much is involved to discard these. By building transformers of this general class with coils for series or parallel connection, we establish the 4600-volt standard from the 2300-volt standard and by providing a 10 per cent tap, we can obtain 2070/4140 volts from these, which probably would be acceptable to operators.

For new systems the 11,500-volt standard may be abandoned in favor of the 13,800-volt. For many existing systems it must be maintained and transformers for both 6600 volts and 11,500 volts delta connection are required. The former group has been entirely eliminated.

To me, another grave defect in these proposed standards is the lack of reversibility of power transfer, due to the use of different turn ratios for step-up and step-down transformers. With interconnections growing apace, if full benefit is to be realized from them, power should be able to flow in the direction reverse from normal and the voltage delivered under this condition closely approximate the normal sending voltage.

Mr. Argersinger has most clearly indicated this disadvantage and suggested a remedy. It merits close study. His proposed voltage standards retain the values made familiar to us by long usage and his 5 per cent over-voltage tap automatically brings his system into practical agreement with the manufacturers'. However, he omits the 88- and 154-kv. ratings and adds a 176-kv. rating.

These changes would, I believe, be inadvisable because of considerable mileage in 88- to 90-kv. and of 140- to 154-kv. lines.

Also the 176-kv. standard would necessitate the design of a complete new line of equipment and there is a permissible argument that a project requiring at least 176 kv. should be developed at 220 kv. at the outset.

I am in general agreement with his views which, though differently expressed, result in standards not far different from those proposed, except for an additional 2½ per cent of over-voltage operation suggested and the omission of the emergency limitation. What constitutes an emergency and how long does it last? Mr. Argersinger's proposal is the more clear-cut.

Two taps per winding as suggested by him may not prove enough for certain long transmissions. It should be simple to provide others at a slight increase in cost, when required.

All power transformers should be equipped with externally operated ratio adjusters.

Referring to maximum voltage rated "apparatus," when standards are agreed upon, cannot this apparatus be derated to fit, that is, name plate data changed and equipment left as is?

F. C. Hanker: In considering the subject of voltage standardization an effort has been made to investigate the possibility of developing a practical system of voltages that will meet the needs of a large percentage of electricity supply systems.

There has been a tendency in the discussion to cite certain specific needs that appear of paramount importance for a particular district. Where there is sufficient justification for certain values they should unquestionably be adopted but we should carefully scrutinize these suggestions to be sure that they are not an expedient to care for a temporary condition. We should be sure that they conform to a logical plan.

The Pacific Coast has a condition where they are meeting distribution requirements with transformers arranged for 11,000-volt star connection and 6600-volt delta connection. The decision that we burden the entire industry with costs of a 6600-volt transformer that will be satisfactory for operation on 11,000 volts can only be determined by a survey to see whether the cost is justified. In the lower voltages the difference is not as great as it would be in the higher classes. It is very possible if the demand is sufficient that it would be justified. That same condition exists I feel throughout this standardization. We should study the conditions and where there is justification it should be recognized by being included in a standard line. Obviously it would be agreeable to everyone concerned if standards could be made flexible enough to meet all conditions. Unfortunately this cannot be done without increasing costs and only those that are suitable for general use would be included.

The objection to the star-delta proposal is greater for the higher voltages. For example if you take a transformer suitable for delta connection on 66,000 volts and star connection on 114,000 volts you must of necessity design the insulation for the higher voltage service. This means in the first place that the apparatus will cost from 35 to 40 per cent more for the star-delta combination than would be the case if it was designed for the 66,000-volt service. The design must be satisfactory for insulation to ground and insulation between turns when operated on the higher voltage. This adds to the expense of those transformers that are equipped only for the 66,000-volt service. In addition to higher cost you have a lower performance. In view of these disadvantages it does not seem desirable that the entire capacity of 66,000-volt apparatus should be burdened with the greater expense for the possible benefit to those systems that would use the transformers at the higher voltage.

It is generally recognized that the greatest return from standardization is in those classes where quantity production is a possibility. Every effort should be made to reach an agreement on the lower voltages applying to utilization equipment, distribution transformers, substation transformers, and possibly some of the lower transmission voltages that are generally used.

In the higher voltage classes it may not be possible to secure a general agreement on the requirements. The range that has been suggested by several of the groups varies from 5 per cent proposed by the manufacturers to a maximum of 25 per cent for those cases where reversal of power flow may be necessary. There are undoubtedly cases where a greater range than 5 per cent is necessary. We would suggest that a survey be made to establish the capacity of equipment that would come outside the proposed 5 per cent range. This study could be based on equipment already in service. It is probable that the curve would be somewhat similar to the "use-factor curve" showing the time generating apparatus is required to meet load conditions on a particular system. These curves show that the capacity required to care for the peak loads is in use only a relatively few hours during the year representing a high investment cost for these increments of load. If we establish the capacity of transformers operating at normal voltage and at voltages up to 25 per cent above normal, and determine a corresponding cost for transformers with different voltage ranges, we would then be able to establish the total cost to the industry that would result from the adoption of different zones. At the present time the range is based on opinion. Before a final decision is made it is recommended that a study similar to that proposed would be of value in establishing the most satisfactory range.

On the higher voltage transformers it is not the actual turn ratio that is so important as a standardization of the voltage classes. Such a standardization would minimize the number of designs necessary for the manufacturers and result in a reduction in development costs. With such a standardization the mechanical construction of the core, insulation structure, tanks and terminals could be standardized and advantage taken of this condition.

Ernest Pragst: I should like to comment on these papers and the discussion largely from the point of view of the manufacturer.

A number of years ago, the operators of public utilities and the manufacturers of electrical apparatus undertook to standardize the voltages of apparatus. Out of this work a set of standards finally emerged which were sponsored and issued by the National Electric Light Association.

The fact now seems to make itself apparent that when the standards were adopted, little or no consideration was given to the system as a whole. Each type of apparatus was standardized as to voltage with little or no consideration given to its operation in connection with other types of apparatus. Because of these oversights, we now find ourselves with an inoperative set of standards.

Now, the manufacturer has accepted the standards and has a number of standard lines of generators, transformers and motors. When he attempts to sell this standard apparatus, he discovers that his customer cannot operate it in a system without exceeding the limits for which it has been designed and guaranteed.

The operators of public utilities realized some time ago that the standards as adopted could not be used successfully, so they simply abandoned them. Each has sought his own solution in his own way, with the result that but little uniformity of practise now exists.

After listening to the many diverse opinions expressed I find myself in a quandary when I try to reconcile them. Some might have been led to believe that the manufacturers seeking a new set of standards will be next asking the discarding of present equipment. Nothing like this is contemplated. Moreover, nothing particularly radical is being asked.

In preparing the standards proposed by the manufacturers and presented by Messrs. Summerhayes and Hanker, I am sure every effort was made to depart as little as possible from the present standards. A comparison of the proposed standards with the present standards as issued by the National Electric Light Association will reveal the close similarity between the two. Generator voltages are such that the old can be paralleled with the new; transformer ratios are such that through the use of taps

parallel operation of old with new transformers will usually be possible; motor voltages are to remain the same.

I am convinced that greater benefits will accrue to the operator than to the manufacturer through standardization and that the manufacturers are seeking only a workable set of standards that will meet an appreciable part of the requirements of the operating companies. With such diverse views as now exist (most of which are not without merit) an agreement will be reached only if we can realize the necessity of compromise and practise it to the utmost.

L. L. Elden: It is believed that an analysis of the value and quantities of equipment which have been found unsuited for operation under the voltage standards referred to, will be found to be only a relatively small percentage of the units in service and that such difficulties as have developed in this direction will be largely found in high-tension equipment.

The discussion which I will present is one in which Mr. Oliver of the New England Power Company and the writer have collaborated to some extent to present very briefly some views covering our experience in New England. One of us is operating a system utilizing moderate voltages in supplying a compact area, with interconnections to several adjacent systems. The other is operating an extensive transmission system reaching into five states and utilizing voltages of 66,000 and 110,000. The present transformer standards have been entirely satisfactory to the former, and with the addition of standard feeder regulators, high grade, efficient and reliable service has been maintained.

For the second system existing transformer standards have been found unsatisfactory, and apparatus has been purchased which does not conform to A. I. E. E. standards in order to meet operating requirements. Power-factor correction equipment has been found necessary at several points to insure a proper degree of regulation, with the result that substantially uniform voltage conditions are maintained throughout the system. In passing it may also be said that the voltage standards proposed by the manufacturers would still be unsatisfactory for this system.

In this discussion we have refrained from presenting any table of values, believing that the determination of final values applicable to the entire industry cannot be effected at this time. If broad principles applicable to the situation can be agreed upon, much will have been accomplished.

Any undertaking aiming to standardize voltages is bound to meet with many difficulties in view of the many interests affected. Many of the conditions to be met are not fully appreciated. On this phase of the question we may refer to the proposed basis of standardization outlined in the manufacturers' paper.

An analysis of the hypothetical system shown therein discloses the fact that as between full- and no-load conditions, an overall uncontrolled regulation of about 30 per cent would be developed, an amount which could at best only be divided between the generator and receiver if any load be served from, or near the generating station.

If the system is expanded and becomes an interconnected network with additional generating stations, difficulties immediately develop. For example, a second generating station connected to the 69,000-volt section of the system must experience voltage or reactive-power difficulties with changing load conditions on the main system. It is, of course, granted that the addition of regulating apparatus may obviate some of these difficulties.

The system described is hardly sufficiently comprehensive to illustrate the needs of practical application. Even if such a simple system exists, it may be short-sighted to design it so with no provision for expansion. If transmission systems or lines are interconnected, it is questionable whether a considerable difference of potential can be allowed to exist between any two parts. Probably it would always be found desirable to regulate the voltage very closely by power-factor control. Even if not, a step-down transformer may be installed close (electrically) to a step-up transformer, so close that the voltages at the two points are practically identical, and in this case also the proposed standards become inadequate. Some of these difficulties would be eliminated by the following suggested changes in the proposed transformer standards.

Step-Up Transformers

Adhere to proposed secondary voltage ratings and provide one 5 per cent tap above normal rating to maintain secondary rated voltages under load.

Provide two 5 per cent (each) reduced-voltage full-capacity taps.

Taps should preferably be located in the high-voltage windings (low-voltage taps in large transformers involve difficulties, particularly in regard to ratio-adjuster design on account of high current densities).

Step-Down Transformers

Increase proposed primary voltage ratings 5 per cent (which raises this voltage rating to agree with the rating of step-up transformers at zero regulation).

Provide three 5 per cent (each) reduced-voltage full-capacity taps.

Transformers should be designed to operate under emergency conditions at 5 per cent over-voltage (over-excited). Emergency conditions should be defined as existing a considerable length of time, perhaps several days.

Standardization to be effective must recognize that present-day developments indicate that interconnected systems covering large areas, with many sources of power supply are to be more and more important features of transmission and distribution practise in the near future and that voltage requirements in such systems must be studied from all points of view.

It is believed that standardization of voltages cannot be effective if based upon conditions assumed in any radial system. At least one of the papers has presented the question from the network point of view with favorable results.

Conservation of existing investments is no small portion of the main problem and any new standards must be devised to protect such investments.

Progress, however, has been made and agreement seems quite general upon certain items. Generators and transformers should be capable of operating at least 5 to 10 per cent above rated voltage.

Step-up and step-down transformers should be identical in operating characteristics and be equipped with similar taps ranging from 5 per cent above to 15 per cent below rated voltage. The definition of "rated voltage" is logical and acceptable. Certain other features require further study.

The point at which "system voltages" should be standardized must be agreed upon. European practise recognizes receiver voltage as most desirable. American opinion is divided upon this point, and before national progress can be made, agreement must be reached.

There is much to be said in favor of receiver voltage as it is at receiver locations that constant and normal conditions are expected to prevail. Elsewhere wide variation may exist. A difference of opinion exists between Mr. Oliver and myself on account of the difference in the practise of our respective interests.

Standards should be on same basis throughout the full range of systems and not change from receiver to sending values above 66,000 volts as proposed by the manufacturers.

In connection with test voltages applicable to apparatus specified under rated voltages, it is suggested that apparatus should be reclassified for test purposes. Apparatus including windings, for example transformers, should be tested substantially in accordance with present standards as such apparatus has proved most reliable. Oil switches, disconnecting switches,

lightning arresters, high-tension bushings, etc., should be subjected to higher tests than at present. The many failures which occur in this apparatus justify this recommendation.

Further support to this theory is afforded from the data submitted in papers on surge investigations presented at this convention.

In general it is contended the switch ratings in the higher voltage classes (66,000 and over) are much too close to the operating voltages. The added cost of a higher voltage switch is sometimes considered prohibitive and as cost is too often a controlling element, the factor of safety secured is sometimes insufficient. Studies of dimensional data for switches in adjacent classes frequently show but small differences, which leads to the constructive suggestion that costs to the user might be lower all around if the manufacturers would eliminate certain classes of switches and utilize possibly 5 or 6 classes to cover the entire range of usage.

The following groupings are suggested:

For System Voltages of the Kv. Below	Use Switches of the Kv. Below
220 to 154	220
132 to 110	132
88 to 66	88
44 to 22	44
15 to 6.6	13.2

Substantial savings in manufacturing costs would result. Substantial savings would accrue to users through more general interchangeability, reduction in stock of parts, etc.

There never has appeared to be any justification for development of 33,000-volt switches as a separate class between 22,000 and 44,000 volts, or for certain other intermediate classes.

All switches should be designed with ample factor of safety in service at voltages 50 per cent above rated voltage. Puncture and flash-over tests should be based upon the 50 per cent excess voltages to enable apparatus to meet known impulse and surge values to be encountered under service conditions.

The net result of this proposal should be a better and safer product at no higher, if not actually less, cost than at present. This proposal is not out of line with present practise in other branches of the industry, namely, one size of tank for several transformer sizes, one motor frame for several different motor capacities, etc.

The suggested elimination of certain classes of switches leads to the further suggestion that certain system voltages might also be eliminated from the standards, for example, 4600, 11,000, 33,000, and 88,000. These might be considered exceptions and no new construction be undertaken for these voltages.

The responsibility for the present situation rests upon all interests; users and manufacturers, utilities, consulting engineers, designing engineers, and owners of projects, all of whom have contributed to present conditions. Much construction has been created in which through lack of foresight, knowledge or appreciation of future requirements, great sums have actually been wasted. Even today construction is going forward which is limited in its future usefulness and as designed represents substantial waste.

Failure to supply conductors of adequate capacity and suitable operating facilities leads to ultimate losses which are enormous when compared with the small additional investment required for an adequate arrangement. Isolated construction is frequently noted which involves factors preventing the use of any standard apparatus.

It may well be that certain interests delay or obstruct standardization in recommending that motors be designed for operation for 90-110 per cent of normal voltage and then operate at the lower value contrary to the intent of the present standard. Systems should not be designed for 20 per cent variation in voltage at receiver end as suggested. In short, responsibility for some of these matters must rest where it belongs.

Standardization of voltages has been and is really being impeded to a great extent by manufacturing interests who, for competitive purposes, create new classifications in design of apparatus which might well be eliminated through liberality in existing designs. Users' specifications may be responsible for certain of this undesirable effort, but a brief review of the many types of similar equipment which are offered from year to year is most convincing. Cooperative effort such as is being considered here should eliminate many of these conditions.

Assuming that standardization is really effected, will costs be reduced? We believe not, at least so they can be distinguished since it appears that in high-voltage construction, for example, most equipment is non-standard and is usually designed to meet requirements of individual systems, hence if such methods are to continue there is little opportunity for cost reduction. With years of progress in present switch design, rising prices are encountered.

On the other hand a review of many transactions involving purchases of apparatus under highly competitive conditions, manufacturing prices seem to have no anchor. Possibly we are really saving as much now as would be represented by increases in cost of higher rated apparatus which seems so necessary. It has been suggested that the cost of non-standardization in matters of voltages may total $150,000,000 to $200,000,000.

This is really not an excessive expenditure to be incurred in the development of a $10,000,000,000 industry, it being only 2 per cent of the total. What industry can show equal efficiency through an extended development period? We are really not so badly off as might appear from some of the comparisons which have been made.

Finally, if standardization is actually accomplished, the following queries suggest themselves:

(a) Will prescribed standards be followed by all? We believe the answer is "no," that special construction will still continue as controlled by the acts of individuals, and that there will always be special classes outside of the standards which we may create.

(b) Will not special voltages still be selected for certain projects as best harmonizing with local conditions, such as load, distance, preferred sizes and types of conductors, economic conditions to be met, etc.? We believe the answer is "yes."

It is common knowledge that many projects are designed and built as isolated units, to meet certain local conditions with no thought of future connection with other systems. Where is this condition more prevalent than in industrial plants where every standard is sometimes sacrificed to make a sale. In many more important undertakings operating conditions are seriously affected by economical limitations, imposed by investment restrictions supposedly to meet some theoretical or calculated load cycle to the entire disregard of future requirements.

P. H. Chase: It seems to me that Mr. Elden's remarks reflect the well-reasoned attitude of the central station man considering the problem from the broad point of view, looking forward to the day when we will have more interconnection, when the voltage regulation must be taken care of by voltage regulating means for power flow in both directions.

W. R. Bullard (by letter): Messrs. Silver and Harding have presented a comprehensive picture of a rational and practical method of assigning voltage ratings to different types of apparatus, so as to maintain the proper voltage levels at different points in the system. Under this method, the starting point for assigning voltage ratings is the lamp socket. This is as it should be, since the lamp-socket voltage is fixed by service requirements and the values of other voltages are very largely dependent upon the necessity for holding this voltage practically constant at its nominal value. Therefore, in connection with the general problem of voltage standardization, it is highly desirable that a single lamp-socket or utilization voltage standard be ultimately

established, and a brief discussion of this phase of the problem may not be out of place.

A lamp-socket voltage standard of 115 volts was *assumed* by Messrs. Silver and Harding in building up the tentative assignment of voltage ratings. Of the two remaining voltages in general use—namely, 110 and 120 volts,—the popularity of the lower voltage is on the decline; 110 volts can therefore probably be eliminated from consideration as far as eventual standards are concerned. This leaves the choice of the ultimate standard between 115 and 120 volts, if the selection is to be made from existing standards.

Of these two voltages the latter has the advantage of providing a slightly higher copper efficiency in the low-voltage distribution circuits, while the former has the advantage of conforming, on the whole, more nearly to existing voltage standards of utilization and distribution devices and apparatus, as will be seen from the following:

Incandescent lamps are short-lived and are now furnished at the same cost and efficiency for both voltages. The selection of either 115 or 120 volts as a universal standard would therefore involve no difficulties as far as the manufacture of lamps is concerned.

In the case of motors and devices of the 220-volt class, existing designs are not entirely suitable for delta-connected distribution systems of either 115 or 120 volts at the lamp socket. They are, however, more suitable for the former than for the latter voltage in delta systems, since 240 volts, the delta voltage for the 120-volt standard, is nearly 10 per cent high for equipment rated at 220 volts.

Delta-connected distribution systems will doubtless continue to be used for many years. However, low-voltage systems of the 4-wire Y-connected type are rapidly coming into use in connection with underground distribution in business districts of both medium-sized and large cities, and therefore the relation of motor voltage standards to this type of system must be carefully considered. In Y-connected systems, the delta voltage corresponding to the 120-volt standard, or 208 volts, conforms more nearly to existing 220-volt apparatus designs than does the delta voltage corresponding to the 115-volt standard, or 199 volts. However, actual operating experience obtained in connection with several underground distribution systems of the 4-wire network type has demonstrated that 220-volt motors, both of ancient vintage and of present design, will with very few exceptions, function satisfactorily at 199 volts, in much the same manner as they will function satisfactorily at 240 volts in a 120/240-volt delta system.

In order to meet the demands of both delta and Y-connected systems and at the same time avoid developing two lines of motors and devices of the 220-volt class, the logical solution of this phase of the problem is to make slight changes in the future designs of this apparatus so as to make them conform to an intermediate voltage value between those of the two types of systems with the necessary tolerance above and below this value. This would be advantageous not only from the manufacturer's viewpoint but also from that of the customer, since the latter would be enabled to use his motors interchangeably in both types of systems. Assuming this procedure, there is little to choose between 115 or 120 volts as a universal standard as far as this class of apparatus is concerned. In one case the mean value between the delta voltages of the two types of systems would be 214.5 and in the other case, 224. Neither of these values conforms exactly to the present 220-volt rating, but the relation is so close in each case that the necessary changes would be slight.

The situation is slightly different with respect to appliances of the 115-volt class. Many of the existing standard lines are designed to apply to a voltage range from 110 to 120 volts. This of course makes them entirely satisfactory for 115-volt distribution and in some measure out of line for a universal standard of 120 volts. Consequently, it seems fair to assume that the adoption of 120 volts as a single utilization standard would eventually bring about some general changes in the design of appliances whereas a 115-volt standard would almost exactly fit existing designs.

The most serious phase of the situation is encountered in the case of 2300-volt distribution transformers. The present voltage rating in this case,—namely 115/230/2300 volts,—is primarily suitable for use in systems having nominal 110 lamp-socket voltage. In 115-volt systems, it is quite generally necessary to over-excite these transformers by some 5 per cent or more in order to maintain 115 volts at the lamp socket. This is working out fairly well in practise, particularly since present transformer designs are probably liberal as to the allowable upper limit of operating voltage. However, a lamp-socket voltage of 120 would in many cases require an overexcitation of more than 10 per cent and even then it would be difficult in many systems to maintain normal voltage at the lamp socket with generators and station transformers of present voltage ratings.

It can of course be assumed that these difficulties would eventually be taken care of by some comprehensive method of voltage ratings in the future design of system apparatus. However, the number of standard distribution transformers of present ratings in service, and the present capital investment represented by other apparatus involved in the question of system voltage levels, are so great that existing equipment in this case must be given serious consideration.

On the other side of the picture is the fact that the 120-volt standard would provide a slightly higher copper efficiency in the low-voltage distribution circuits. The difference would indeed be slight in the case of a-c. systems, since it would represent only some 10 per cent of the secondary copper losses or, in usual types of a-c. distribution systems, a fraction of 1 per cent of the delivered energy. In d-c. systems the situation is somewhat more serious, and it is worthy of note in this connection that the d-c. systems provide a very large portion of the present market for 120-volt lamps and appliances. This suggests that a satisfactory solution to the problem might be the general adoption of 115 volts for a-c. systems and 120 volts for d-c. systems. This, however, has the serious disadvantage that in cities having both a-c. and d-c. distribution it would be necessary either to maintain two utilization voltage standards, or to depart from the standard voltage in one of the two systems. In practically all except the very largest cities, d-c. systems are being converted into or merged with a-c. systems, and the importance of establishing standards which will facilitate this process can easily be appreciated. Furthermore, although lamps and appliances are now furnished for both voltages, and would have little influence upon the question of which voltage should be selected, nevertheless a considerable simplification of manufacture and stocking of these articles would be brought about by the establishment of a single standard.

The ultimate solution of the problem must of course be based upon a very careful weighing of all the factors involved, and it will no doubt be a difficult matter to bring about, in any reasonable length of time the complete application of a single lamp-voltage standard. Nevertheless, in view of the large ultimate saving which would accrue to the industry, it can hardly be doubted that a well coordinated effort to fix upon such a single standard should be made in the near future.

The general problem of standardization of apparatus voltage ratings is largely dependent upon the establishment of such a single standard. Messrs. Silver and Harding have suggested a schedule of standard voltage ratings that is entirely practicable if the ultimate lamp-voltage standard is to be 115 volts. If, however, 120 volts should ultimately be selected it would seem from the foregoing that a change from the existing standard voltage ratings of distribution transformers would be necessary. The logical form for this change to take would be a change in ratio. For instance, the ratio of 18-to-1 might be adopted, this

being an existing commercial rating in use in a number of systems. For a 120-volt standard this ratio would permit operating the distribution transformers at a more favorable excitation voltage than does the present standard 20-to-1 ratio in connection with 115-volt systems. Furthermore, with this one change in the schedule of voltage ratings suggested by Messrs. Silver and Harding, this schedule would apply as well to the 120-volt standard as it does in its present form to the 115-volt standard.

M. T. Crawford (by telegraph): I can endorse general plan of voltages proposed by Messrs. Silver and Harding as our distribution installations recent years conform thereto. There is considerable investment in 6600-volt/11,00-volt-Y systems in the northwest, which are very economical for rural distribution. I doubt the possibility of their eventual elimination. I suggest careful consideration in the discussion of Mr. Argersinger's scheme combining step-up and step-down types by adding taps.

H. Carl Wolf (communicated after adjournment): Voltage standardization has been discussed from practically every viewpoint except that of the public, and in the final analysis we all fall into this latter classification. Speaking broadly and collectively, the consumer wants standardization of voltages and wants it to begin at what is to him the most tangible point, his equipment. From data presented on the sales of lamps, it appears that lamp voltages will very soon be standardized at 115 or 120, either one of which provides a reliable starting point.

The consumer is interested in service and is willing to pay the price to get the very best service obtainable. He is also interested in flexibility, simplicity, sturdiness, and universality of equipment. Simplification of practise as to voltages is the most effective means of accomplishing these ends. A great deal of stress has been laid in discussions on this subject on the need for transformer taps in order to keep the voltage up during loads. Greater stress should, in my opinion, be laid on the regulation of voltage, thus necessitating more care in the design of lines and equipment in order to reduce voltage drop to the lowest point commensurate with the economics of the situation. With the development of equipment for changing taps under load, a larger number of taps might be justified, but until such time the other engineering features of the system should be stressed.

If we are to have simplified practise, the fewer the number of voltages agreed upon, the nearer will be attained the goal. It should not be forgotten that the electric industry is still in its infancy and present investment is still only a fraction of what will ultimately obtain. The present medley of voltages and practises should not be permitted to stand too much in the way of adoption of standards for the future. After all, this question of voltage standardization is nothing more than the preparation of a voltage budget within the limits of which good practise can move. Present equipment and present standards should not be rendered obsolete over night, but the industry should be given a goal toward which to work.

In selecting the voltages to be concentrated on and in considering the relative merits of the delta-Y or other systems of connections, the telephone situation should not be lost sight of. Joint construction is very desirable in a large number of cases and any standardization adopted should conform as far as possible to that operating practise which will reduce to a minimum inductive interference.

Combined Light and Power Systems

For A-C. Secondary Networks

BY H. RICHTER*

Associate, A. I. E. E.

Synopsis.—If the situation being created by the extensive use of combined light and power systems for secondary distribution is to be squarely met, widespread discussion is necessary.

The increase of alternating-current low-voltage network systems employing automatic sectionalizing equipment has been very rapid. This move has been attended by a diversity of choice of combined light and power schemes for the secondary mains.

Carrying this condition to its logical conclusion may result in an extremely complicated situation for apparatus connected to these mains. There might thus be imposed on the industry as a whole a heavy expense tending to cancel a part of the savings attributed to the advent of the combined system.

Previous investigation of the probable effect of each of the principal light and power schemes on apparatus connected to the secondaries has been confined largely to general purpose motors. A study of the effects of six other types of equipment concerned showed, however, that general purpose motors are hardly more important than most of the other devices.

This analysis included not only the applicability of existing apparatus standards to each of the combined systems but also the probable developments that the future may bring. For a comprehensive comparison of the various schemes it was found necessary to consider the commercial as well as the engineering aspects.

If the operating companies decide to employ the combined light and power system universally for secondary networks, it is urged that they will soon apply the practise of standardization to the combinations of connection and voltage. In this regard due consideration should be given to the bearing of numerous trends in the industry.

The avoidance of such uneconomic situations as have attended failure to standardize in similar cases in the past makes all the more desirable a nation-wide discussion of this problem immediately. Such a discussion would also bring out the various points of view for the use of those groups which would choose the standard and promote its application.

* * * * *

CLOSE contact with the discussion and use of the various combined light and power connection schemes that are rapidly being adopted as part of a-c. network systems brings the realization that:

a. The gross savings attributed to the combined scheme may be reduced by the expense incurred in the production of suitable utilization equipment,

b. This expense might range from a minimum of 75 million dollars to a maximum of 150 million dollars even under the favorable condition of a single combined scheme adopted universally, and

c. The latter sum may be exceeded if the three principal combinations are continued without the advantage of standardization on one system.

This gives good cause to wonder whether this may not be the proper time to investigate which method of supplying both power and light from the same secondary mains will give the greatest benefit with the least expense to the industry as a whole.

The rapidity with which this combined secondary system is spreading is indicated by the increase in the number of automatic network systems in use or under actual construction. Beginning about four years ago with a single network installation in New York City, the progress has been such that 11 cities will have in operation by the end of this year (1926) networks embodying combined secondary schemes of one design or another. Furthermore, early next year, this number will be increased by three and the possibilities of these networks are now being investigated in at least 16 other cities.

Where two networks are employed, one for light and the other for power, the distribution system may become very expensive and occupy too much space (ducts or pin positions). The combined secondary system, it is claimed, furnishes an economic solution for extending the a-c. network system into areas where lack of space would make very difficult the installation of two separate networks. And—just as in the d-c. three-wire system—the combined method permits the immediate servicing of any customer for either power or light, or both, from the same set of low-voltage mains.

In attempting to avail themselves of the advantages of this system, the operating companies have considered many different combinations of connections and voltages, each scheme admirably suited to the local conditions surrounding its development. Unfortunately, the three-phase schemes differ in the resulting voltages available for light and power, and the existence of the two-phase combined system further increases the number of possibilities.

All of the proposed arrangements that have received marked attention, except one, the two-phase, furnish some voltage that does not coincide with the voltages at present accepted as standard. While the exception gives voltages that do agree with existing standards, it has been claimed* that except for existing two-phase systems it has certain features which, from the standpoint of the industry as a whole, may outweigh all of its advantages.

There are indications that adoption of these various schemes on an extended scale may have considerable

*General Engineer, Westinghouse E. & M. Company, East Pittsburgh, Pa.

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

*Discussion of *Engineering and Economic Elements of Two-Phase, Five-Wire Distribution*, P. H. Chase, A. I. E. E. JOURNAL, XLIV, November 1925, p. 1249.

effect upon the operation of electrical devices now connected to secondary systems, and result in a more or less complete re-adaptation of many, if not all, of the devices for future applications. The magnitude of such a change in apparatus, for even one of the many types of combined schemes, can scarcely be realized without a careful study of all the factors involved. To gage the probable consequences of having several different schemes adopted for numerous large distribution systems is impossible without a careful study requiring the earnest cooperation of all the operating companies.

This paper is offered to show the result of an approximate analysis of what might be the effect on various types of apparatus were networks incorporating any one of the principal combined light and power systems adopted extensively. The analysis included consideration of such major lines as:

Lamps
Motors and Control Equipment
Appliances
Distribution Apparatus

This preliminary study revealed decided differences in probable expense to the industry when comparing the principal combined schemes. From a minimum of some $75,000,000 in one plan, this expense rose to as much as $150,000,000 in another. The considerable difference in probable expense of the various schemes, and the magnitude of even the minimum expense, urges the question whether there should not be initiated on the part of the operating companies a move to prevent the growth of an unnecessary number of new standards.

If the advantages of this step become universally apparent, this paper may be the starting point for a wide spread discussion of how to minimize the expense of adopting the combined secondary system for a-c. networks.

Present Status of Application of Combined Light and Power Secondary Systems

To better understand the nature of these combined systems and their extensive application, an outline of their present status may be of value.

Spread of Combined Secondary Systems. The steps that have preceded the spread of the combined light and power secondary system may be reviewed as follows:

1. In the usual radial distribution system, power loads greater than about five kw. each are mostly supplied by transformers separate from those carrying lighting loads, as shown in Fig. 1A. If the two loads are connected to the same transformer and its capacity is correct for both lighting and steady motor loads, this capacity, in conjunction with the design of the rest of the distribution system, is usually not great enough to keep the total voltage drop to the lamps within the limits required to prevent flickering of light.

2. Seeking to decrease the total number of transformers on their overhead radial systems, several companies use a single bank of three single-phase transformers for both power and light. This is done mainly in outlying districts when minimum installation cost is essential. Where better voltage regulation must be maintained at the lamps the lighting secondaries are separate from the power; also, transformer and secondary capacities are liberal. The transformer low-voltage windings are usually connected 230 volts delta and lighting loads at 115/230 volts are supplied from one of the transformers with mid-point grounded.

3. In one western New York city, a similar practise has been followed for the past few years in the down-

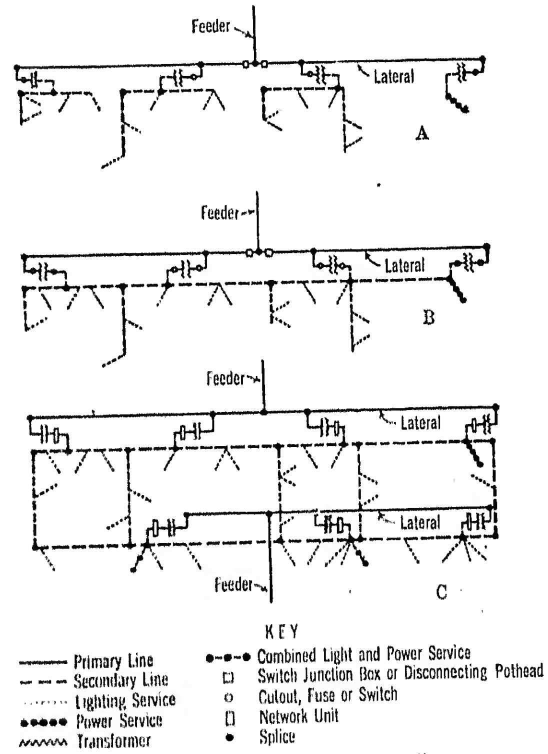

Fig. 1—Typical Distribution Systems

town area, but the transformers are connected in star to give 120 volts at lamps and 208 volts three-phase at motors. These banks are usually installed in basement vaults of large buildings and each serves only the building to which it is assigned. Power service lines are separate from lighting lines. The customers are well satisfied with the voltage supplied, even though motors up to 40 hp., including elevator motors, may be located in a pent house on the roof.

4. Some companies have experimented with the combined light and power method for secondaries, as well as for transformers and services, on radial systems. In most cases the practise has been abandoned upon the unexpected burning out of several motors, caused by heavy load occurring coincident with too low voltage.

5. For 14 years a city in California has operated a 120/208-volt three-phase four-wire system underground, using combined light and power secondaries as well as transformers. The latter are not banked and the secondaries are not bussed from block to block, but the low voltage mains are of ample size.

6. A city in Minnesota has for many years used on its overhead lines a four-wire combined secondary network system giving 230 volts three-phase delta for power, and 115/230 volts for lighting, taken from one of the three transformers in the bank. As the lighting load is carried by only one phase in each district, each network is of small size and confined to the transformers from but one feeder, as in Fig. 1B.

7. During the past 11 years a city in Tennessee has had a comparatively large three-phase underground network, supplied by numerous feeders and employing 115/199 volts at the utilization devices. Motors up to 50 hp. are connected to the combined light and power mains even at points between transformer banks. The majority of the motors are the standard 220-volt type; only rarely is a 200-volt motor encountered; and the very few complaints of low voltage due to the use of 199 volts have been remedied in a simple and inexpensive manner by means of small boosting auto-transformers.

8. About one year ago a city in Louisiana started up a combined light and power network system with nominal voltage of 115/199 volts. Many expected troubles proved imaginary and it was easy to dispose of the few that did materialize.

The combined secondary system was first publicly urged for universal application in this country by Mr. W. C. L. Eglin,* who recommended that this scheme, in three-phase form, be adopted as standard for all miscellaneous light and power distribution and street lighting. Active spread of the multiple primary feed low-voltage a-c. network using combined secondaries and automatic protective equipment, as illustrated in Fig. 1C, started shortly after it was demonstrated in 1924† that this system was successful in operation, and more economical and reliable, than any previous a-c. system.‡

Past Discussion. The subject of combined light and power secondary systems has been discussed in detail in one A. I. E. E. paper specifically confined to combined secondary systems, in several papers concerned with networks, and in two Serial Reports, dated 1925 and 1926, by the Electrical Apparatus Committee of the National Electric Light Association.§

Some Combined Schemes. The combinations of connection and voltage for combined secondary systems that have been given the most study are indicated in Fig. 2,—*A*, *B*, *C*, *D*, and *F* applying to three-phase and *E* to two-phase. It should be noted that Fig. 2D is a combined light and power transformer system and not a combined secondary system. A complete discussion of the advantages and disadvantages of each of these combinations is contained in the 1925 and 1926 Serial Reports previously referred to. The schemes of Figs. 2E and 2F are receiving the most attention at the present time.

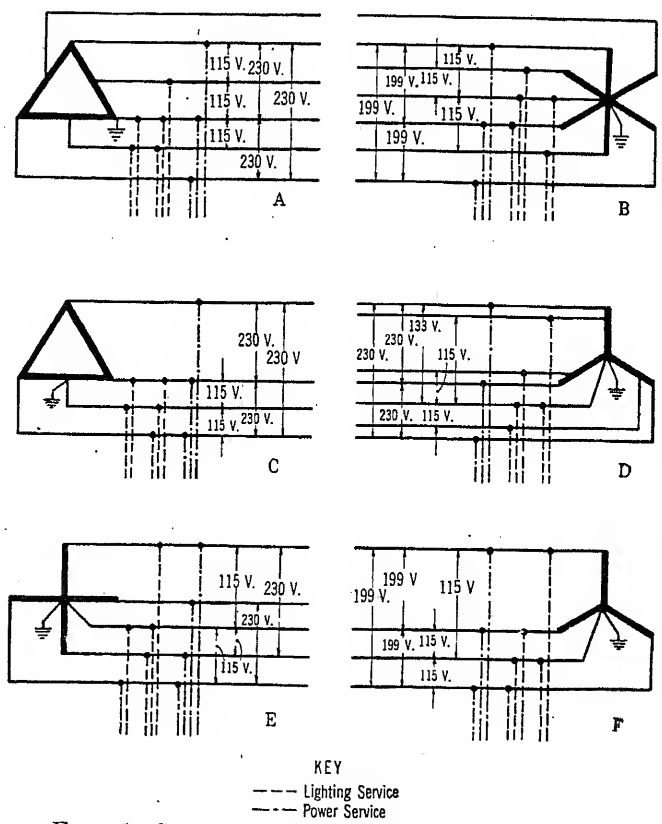

FIG. 1—SCHEMES FOR COMBINED LIGHT AND POWER

Of the network systems now under construction, eleven will use Fig. 2F arrangement, two Fig. 2E, one Fig. 2D, and one Fig. 2C as a preliminary to Fig. 2F. For the majority of the fifteen networks planned and under consideration, Fig. 2F scheme is favored for the underground. For overhead network systems Fig. 2C is planned in one case. In the three-phase distribution systems to which Fig. 2F applies, 125/216 volts is being considered in only one place; for the remainder, about half prefer 115/199 volts at the utilization device and half 120/208 volts. While there are no present indications that the number of two-phase combined secondary

*Paper before Association of Edison Illuminating Companies in 1922. See Bibliography.

†See A. H. Kehoe and W. R. Bullard in Bibliography.

‡Construction of such networks is now going on in 13 cities, which are, in chronological order of starting work: Manhattan, N. Y., New Orleans, La., Memphis, Tenn., Dallas, Tex., Philadelphia, Pa., Knoxville, Tenn., Atlanta, Ga., Bronx, N. Y., Miami, Fla., Ft. Wayne, Ind., Pittsburgh, Pa., Canton, O., and Brooklyn, N. Y. Construction has been started in one city in the east and a trial network is being installed in a western city. There are at least 10 networks of this type in successful operation in four of these cities. Adoption of such networks is now being planned for 3 other cities and is under consideration in at least 12 more. The number of cities thus totals 30. In two of them, overhead networks of a similar kind are also being considered.

§See Bibliography.

systems will increase in the immediate future, unfortunately the groups favoring 115/199 volts and 120/208 volts for three-phase networks appear to have found no common ground for preventing complication of the apparatus situation in the future.

Probable Result of Present Tendencies. It often happens that a given set of conditions, usually viewed separately, take on a different aspect when correlated. This is largely true when the probable effects of present tendencies within each of the three groups—three-phase network, two-phase network, and radial—are considered collectively in the light of past experience.

A. *Three-phase Networks.* There are indications that a move will be made, as the number of systems using the two principal combined secondary arrangements increases, to change the design of apparatus used on these systems to suit each combination. Such developments are matters of common occurrence. Whenever a new idea is adopted on a relatively small scale it is fitted to conditions as found, in order that an immediate gain may be obtained from it. As the application becomes more extensive, the natural tendency is towards a change in the conditions to make it more simple or economical.

Thus, 115/199-volt star systems are likely to require changes eventually in the design of polyphase and other apparatus connected between phase-wires. It is estimated that if all underground distribution systems, and the systems feeding two-thirds of the total overhead miscellaneous distribution load in cities, should adopt networks using the combined method, this would affect up to about one-fifth of all phase-to-phase apparatus, the remainder being used outside of the network areas and on isolated plant systems.

The 120/208-volt star system will probably require changes in design for both apparatus connected between phase-wires and that connected from phase-wire to neutral. An effort to estimate what part of all the phase-to-neutral equipment would be thus affected might place it at about half.

B. *Two-phase Networks.* For the few two-phase systems, production and stocking of two-phase apparatus will no doubt continue, tending to keep up the prices of all polyphase equipment. In addition, the copper in a two-phase motor is about 6 per cent less effective than in a three-phase motor; in some cases this appears as a decrease of 0.6 per cent in power factor, 0.4 per cent in efficiency, and 11.4 per cent in starting torque, as compared with a three-phase motor. Furthermore, the companies operating two-phase systems may have somewhat higher annual charges than with the three-phase system*.

C. *Radial Secondary Systems.* It is probable that radial three-phase 110/220- and 115/230-volt distribution systems, some of which use single-phase feed, and other radial systems giving 110 volts or less at the utilization devices, will be confined to miscellaneous load systems in cities, towns, villages, and farms where load density is light (up to about 2500 kv-a. per square mile); to bulk loads fed by operating companies; and to isolated plant systems. These would thus ultimately take a little less than half of all phase-to-neutral apparatus and four-fifths of all phase-to-phase apparatus. As any change in standards would inconvenience the engineers of these systems and their customers, the present lines of equipment would probably be required in addition to all new lines.

In an effort to obtain a more tangible conception of the relative effect these four systems would have on the total quantity of apparatus, exclusive of lamps, connected to secondary systems, Table I was derived. This assumes, for phase-to-neutral apparatus, that:

a. Of all equipment, 6 per cent would be on two-phase systems and 94 per cent on three-phase systems;

b. Of the apparatus on three-phase systems, half on radial and half on network systems; and

c. Of the apparatus on three-phase networks, half on 115/199-volt and half on 120/208-volt systems.

The same assumptions were used with phase-to-phase devices, except that for equipment employed on three-phase systems 80 per cent were assumed on radial systems and 20 per cent on networks. This ratio takes into consideration, first, the preponderance of polyphase apparatus in industrial plants on the outskirts of cities, and, second, the condition that a considerable number of large plants might follow the example of one in Brooklyn which buys its power wholesale and is planning to install its own automatic network system employing the combined secondary scheme. Practically all such plants have hitherto been supplied by the radial method.

The right half of Table I gives an approximate idea of the relative values of apparatus that would be affected by these four systems. Assuming the sales of phase-to-neutral equipment for the entire industry to be 69 per cent of the total sales of all apparatus applied to secondary systems, the percentages in the left half of the table were multiplied by 0.69; similarly, for phase-to-phase equipment the percentages were multiplied by 0.31.

It thus appears, if existing tendencies continue, that about 23 per cent of all phase-to-neutral apparatus and 9 per cent of all phase-to-phase apparatus would be of non-standard voltage, while 6 per cent of the latter type of equipment would be two-phase. About 19 per cent of all sales for both types of apparatus might be for non-standard voltages; also, about 2 per cent of all sales might be for 220-volt two-phase equipment. In addition to showing what a miscellaneous demand may arise if present tendencies continue, Table I indicates that the relative quantity and value of non-standard apparatus which would be affected by the

*P. H. Chase's paper (see Bibliography) shows the annual charges in one system to be from 2 to 3 per cent higher for two phase.

120/208-volt star system is much greater than that affected by the 115/199-volt system.

The requirement of supplying various standard lines of equipment for a plurality of distribution groups will have a tendency to increase apparatus development and distributing costs. It is only reasonable to expect, as these costs become greater due to uncontrollable economic factors, that an increase of prices in these lines is likely to occur; this presupposes that the quality is not to be lowered. That higher prices sometimes do not immediately follow changed conditions must not be allowed to obscure the fact that such causes contribute largely to price advances. It is thus clear how an unbridled growth in the number of connection schemes and voltages may eventually result in higher prices to all purchasers of apparatus connected to secondary systems.

Furthermore, an increase in the number of classes of apparatus and of types of distribution system may be expected to add complications in the choice of equipment having the proper rating, and confusion to customers by change of system in moving from city to city. With the higher prices, these factors would tend to reduce consumption of apparatus and electric energy.

Standardization as a Remedy. These troubles previously discussed could be avoided by the adoption, as a standard for combined light and power secondary systems, of that scheme which fits in best with existing standards. Such standardization would also result in this benefit—that, instead of spending time on problems introduced by various kinds of systems, all interested parties could confine their research to improving the one standard combined system.

Premises of the Qualitative Analysis

The result of an investigation into the effect of the various combined schemes upon the operation and manufacture of each of the types of apparatus connected to secondary systems will be presented as a Qualitative Analysis. Only the most important combinations have been chosen and each in turn has been assumed to be the standard. These are 115/199 volts three-phase star, 120/208 volts three-phase star, and 115/230 volts two-phase five-wire, since they are now in use; also 125/216 volts and 110/190 volts star because there appears to be some question as to the possibility of employing them.

In the absence of any definite data easily available for use in such an analysis, approximations must necessarily be made. Without some analysis of this sort as a guide, even though approximate, the complexity of the problem might result in unduly stressing some one aspect. It is not surprising that such undue emphasis might easily be given. For example, if motors alone are considered, there appears the astounding total of some 10,000 different ratings. These may be grouped as follows:

Capacities at least 30 sizes in small and general purpose motors

Windings three types in small motors and five in general purpose motors

Speeds four standard speeds

Enclosures three types.

Power Supply direct-current and alternating-current

Phases three kinds

Frequencies five

Voltages seven.

To add yet another voltage rating would further complicate a situation that already seems burdensome to the industry. And yet a similar condition with regard to the other types of apparatus, such as control equipment, transformers, etc., stands out with equal prominence. This can be observed in the analysis that follows.

Due to the numerous unforeseen factors that may affect the situation in the future, it is possible that the conclusions to be drawn from this analysis are as close to the conditions of the future as would be those based on a laborious research into the exact effect of every factor on each type of apparatus. It is the result of an investigation lasting over a period of over two and one-half years.

It should be clearly understood that in submitting this analysis there was no inclination to favor any particular system of secondary connection. Its main function is to point out what factors will tend to cancel the tangible savings and other benefits that have been counted on by those companies which are adopting the combined system.

Qualitative Analysis for Apparatus Connected to Secondary System

Effect of Change to Combined Light and Power System for Three-Phase Star Secondary Networks

This analysis applies to the seven classes of apparatus that would be directly affected by the application of a three-phase star connected combined system to network secondaries. These classes are:

1. Small motors,
2. General purpose motors,
3. Motor control equipment,
4. Safety switches,
5. Distribution transformers,
6. Miscellaneous apparatus, and
7. Electric heating devices.

The analysis was made on the assumption that all of the systems that may be networked would adopt this three-phase four-wire scheme, while all other systems would continue to be served by the three-phase radial method.

1. Effect on Small Motors. 110/220 volts is the present standard for this line, with allowable variation of 10 per cent plus or minus.

Polyphase Motors: 125/216 Volts. There would be no trouble with this voltage.

120/208 volts. Practically all standard 220-volt ratings could be used as they stand. However, it would be disadvantageous to put a double rating on the nameplate for, if performance guarantees at 208 volts must be given, these motors would be at a disadvantage as compared with lines designed for and rated at 208 volts. New designs could be reduced to a minimum, by having it generally agreed that 220-volt motors will be satisfactory for operation on 208-volt networks and that no change in the nameplate will be required.

Both study and experience have brought about a general assumption that five per cent voltage variation at utilization apparatus should be considered an extreme condition in low-voltage networks. If, as a result, five per cent plus or minus could be settled upon as the maximum tolerance for all types of apparatus connected to secondary networks, the extra expense due to adopting the combined system would be considerably reduced. This step would prevent penalizing a large number of customers for the relatively few cases where excessive voltage drop occurs in the interior wiring or distribution system.

115/199 or 110/190 Volts. A separate line of motors would have to be brought out and the expenditure involved would be fairly large; it would even be excessive for 190 volts if the greater production of the future is considered.

Single-Phase Motors, 2:1 Voltage Winding: For any voltage of the combined three-phase four-wire secondary system this class of motor must operate either across two phase wires or from phase-wire to neutral.

As this does not give a 2:1 ratio and the motor winding must be designed to operate satisfactorily on both the upper and the lower voltages, the tendency would be to design it for sufficient power on the series connection and with sufficient material to withstand the voltage to neutral on the parallel connection.

For instance, with the 120/208-volt scheme, instead of 208 ÷ 2 or 104 volts the parallel connection would have to withstand 120 volts. This means a range of 15 per cent in nominal voltage, and to this must be added 5 per cent to cover maximum regulation for the network. This would result in a motor considerably larger and from ten to fifteen per cent more expensive than the present standard. Double guarantees would be necessary and unusual care in application would be required to ensure that sufficient capacity be always available for the connection between phase-wires.

For these reasons, and also because the majority of single-phase small motors are used at the lower voltage (which would be phase-to-neutral voltage in the combined secondary system), it is hardly advisable to introduce 2:1 voltage winding motors for combined three-phase four-wire secondary networks. Any compromise using a double rating would also be unwise, as so many single-phase motors are sold to resale manufacturers who distribute their products throughout the country that it would be very embarrassing to these companies if they supplied motors with more than one rating.

Single-Phase Motors, Single Voltage Winding: Only a small percentage of these motors are used at the higher voltage. The present 220-volt ratings could be employed for 216 or 208 volts on network systems, but the risk at 199 or 190 volts would require the development of a separate line for these voltages.

On the few existing combined light and power systems where potentials higher than 115 volts are actually obtained at the motor terminals, 110-volt motors have caused almost no complaints. However, it is anticipated that if such systems become more numerous and are in the form of networks, whereby closer secondary voltage regulation is obtained, trouble may be experienced due to overheating, noise, increased starting current, and lower efficiency and power factor. This would be particularly true for 125 volts, which means that motors for this voltage would have to be redesigned almost immediately.

With small motors future results cannot be determined entirely from past experience of a more or less limited nature. For instance, in the case of 120 volts it is reasonably certain that difficulty would arise should customers begin to order 120-volt motors, making it necessary to give guarantees and eventually to mark the nameplates at 120 volts. To build a single line on the basis of such network voltages as 120 or 125 volts would result in unsatisfactory operation on the innumerable circuits that now deliver less than 110 volts to single-phase motors; for example, considerable trouble is already encountered on radial 110-volt systems due to low voltage at starting. Building and stocking a new line of 120- or 125-volt motors as a parallel to the present 110-volt line would require a fairly large expenditure. In addition, there would be considerable expense and confusion on the part of the utilization device manufacturers, for they would have to buy motors of both classes and carry large stocks at their factories and distributors' warehouses.

2. Effect on General Purpose Motors. 110/220 volts is the existing standard for these motors, with permissible variation of 10 per cent plus or minus.

The principal factors that limit the design of standard general purpose motors are:

a. Starting torque, especially in the smaller sizes;

b. Efficiency and power-factor (and principally the latter) which are of particular importance in low speed motors since heating ordinarily gives no difficulty if good performance is obtained; and

c. Heating, mainly in connection with high-speed motors as good performance is inherent in them.

The analysis, except for the sections on characteristic curves, is based on actual performance data for all sizes from 5 to 150 hp. in all lines.

125/216 Volts: There would be practically no difficulty with this voltage.

120/208 Volts: Starting Torque: Since starting torque varies approximately as the square of the voltage, the application of 208 volts to a 220-volt motor results in a reduction of about 11 per cent in starting torque. However, at least 50 per cent of the standard 220-volt ratings would still give satisfactory torque at 208 volts plus or minus 10 per cent.

For the remaining ratings it would be necessary to rewind the motors to provide the same guarantees. The expenditure in development and other costs would be large for the motors that would require rewinding. If the number of classes and sizes of motors that would have to be changed were relatively small it might be more expensive to keep a separate stock of motors for these ratings at 208 volts than to incorporate the rewound motors in one complete line good for 208 to 220 volts plus or minus 10 per cent. The latter course would, however, result in a reduction of the power factor of these rewound machines when operating on 220-volt circuits.

Were the principle of 5 per cent plus or minus voltage regulation in secondary networks established, these changes could be avoided, provided only a small number of 220-volt motors would require rewinding to operate satisfactorily on 208 volts. Where this procedure might result in too low a starting torque because of the reduced voltage at starting, the motors might be thrown directly on the line at 208 volts.

Starting these motors directly across the line at this voltage would probably not require any change within them. The starting current would be reduced at 208 volts, just as when using a reduced voltage starter on a

230-volt line. The starting torque, corresponding to the 208-volt point, would presumably be sufficient. That the motors could stand this method of operation mechanically seems assured because general purpose motors now in use, at least those up to 50 hp. in rating, can be and are connected directly across the line at the present standard voltages. Furthermore, with the frequency of starting usually encountered, there is also not likely to be any trouble so far as heating is concerned.

Should the number of motors that would need rewinding be fairly large, however, and this may come to be the average condition a few years from now, it might be desirable to establish a new line of motors rated at 208 volts. The performance in this case would naturally be improved as compared with the single line, but

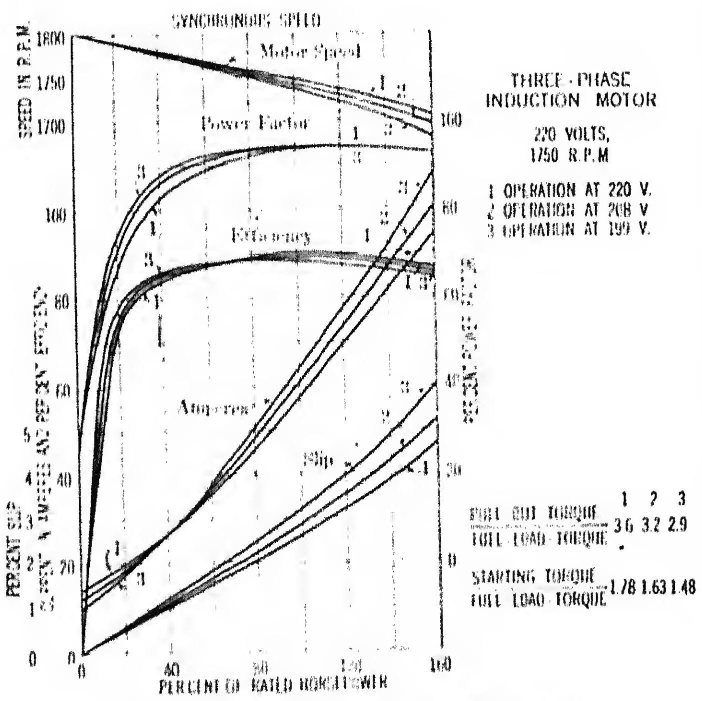

Fig. 3 Motor Performance Curves

the maintaining of a separate stock for each of the two lines would prove extremely burdensome from both the investment and delivery standpoints.

Characteristic Curves: The following characteristics are taken from the curves in Fig. 3 of a typical standard 220-volt three-phase squirrel-cage induction motor showing performance at rated voltage and at 208 volts. For speeds lower than 1750 rev. per min. the performance is not quite as good and the differences are somewhat greater. The values for 50 to 60 per cent of full load are added as it is found that this is the average load on general purpose motors connected to typical underground distribution systems and these values are therefore the ones that will be of more interest during the immediate future. All values are approximate.

PERFORMANCE AT 208 VOLTS COMPARED WITH 220 VOLTS

	At 100 per cent of full load	At 50-60 per cent of full load
Speed	0.3 per cent lower	0.15 per cent lower
Power-factor	0.5 per cent higher	2.3 per cent higher
Efficiency	0.5 per cent lower	0.5 per cent higher
Current	5.2 per cent higher	3.0 per cent higher
Pullout Torque	11.0 per cent lower	

115/199 Volts: Starting Torque: The starting torque of a 220-volt motor is reduced 18 per cent when a voltage of only 199 volts is impressed. The number of 220-volt ratings that would give satisfactory torque at 199 volts plus or minus 10 per cent ranges from about 50 per cent of the total to a percentage considerably below this.

The factors that would determine whether a single complete line of motors or two separate lines would be preferable are similar to those treated under the heading 120/208 volts. The decision between one line or two lines in this case, however, might lean towards the latter on account of the difference in conditions underlying the comparison between this and the 120/208-volt system. Two of the factors against a single line are the large number of motors that would require rewinding, and the fact that with a single line to operate at 220 or 199 volts the power-factor when 220 volts is used would be possibly 2 per cent lower at full load and 4 to 5 per cent lower at half load. Due to the greater number of ratings involved the expenditure would be much larger than in the case of 120/208 volts.

Characteristic Curves: The differences listed below are taken from the curves of operation in Fig. 3 at 220 volts and 199 volts.

PERFORMANCE AT 199 VOLTS COMPARED WITH 220 VOLTS

	AT 100 per cent of full load	At 50-60 per cent of full load
Speed	0.6 per cent lower	0.3 per cent lower
Power-factor	1.0 per cent higher	4.0 per cent higher
Efficiency	1.0 per cent lower	1.0 per cent higher
Current	10.3 per cent higher	6.0 per cent higher
Pullout Torque	19.0 per cent lower	

Temperature Rise: There is no reason for applying any higher temperature rise motor on 199 or 208 volts than on 220 volts. The customers will probably prefer 40 degree rated motors for general purpose application if the combined systems adopted require the use of 199-, 208-, or 216-volt motors. Should a motor rated at 220 volts be operated at 208 volts or at 199 volts a higher temperature rise may be expected. As considerable variation in the results may be secured and induction motors in general must be considered, only very general statements can be made.

The accepted custom which permits a maximum voltage variation of 10 per cent from the nameplate rating

is based on the assumption that when so operated at full load the motor may rise 10 deg. higher than at its normal voltage and rated load. It may thus be assumed that at 199 volts the standard 220-volt 40-deg. general purpose motors will usually operate at close to 50 deg. rise and that at 208 volts they will operate at about 45 deg. rise. These estimates will, of course, vary somewhat with the characteristics of the individual ratings.

110/190 Volts: A decrease to 190 volts from the present standard of 220 volts is very great. In addition, to provide for a further variation of 5 per cent (if this principle be accepted generally) widens the range to a point where difficulties might be encountered with the majority of existing motors. Should 10 per cent voltage variation be maintained as the accepted custom, the conditions would of course be even worse.

If the original guarantees were required, the adoption of 110/190 volts would necessitate two lines and the expense would be so great as to be uneconomic.

3. *Motor Control Equipment.* 220/440 volts is now standard for this apparatus, with allowable variation of 10 per cent plus or minus.

In the past the transformer secondaries of power banks have usually been connected in delta and two overload trip coils have sufficed for full protection of motors. A new National Electrical Code rule permits the use of two trip coils with a fuse in the third phase for motor starters on three-phase four-wire systems with grounded neutral such as are employed in the majority of combined network systems.

This rule may be used as an expedient to make unnecessary the equipping of existing control apparatus with additional trip coils when the secondary distribution system is changed to the combined light and power type. It is reasonable to expect, however, that considerable experience with or study of the combined secondary system for networks will bring about a demand for that form of apparatus which suits the application best.

It is thus justifiable to assume, regardless of the manufacturing costs involved, that extensive application of the combined system will finally result in a widespread demand for three-coil protection in starters for three-phase motors. Already there seems to be a move in this direction by numerous Underwriters' inspectors. This would necessitate rearranging all general purpose motor controller designs to provide the third trip coil, and that would entail a large item of expense.

125/216 Volts: The present standard coils could be used in most cases, but where the voltage is low special coils would be required.

120/208 Volts: 115/199 Volts: 110/190 Volts: Any of these voltages involves adding at least 33 per cent to the number of a-c. coils in stock and the maintaining of a double set of standards since the original standard of 220 volts will still hold for other than network systems. The expense of all necessary changes would be large, especially for 190 volts.

4. *Safety Switches.* 125/250 volts is standard at present for these switches and is the maximum rating.

To comply with the latest safety code ruling it will be necessary to change the construction of the standard triple-pole entrance switches by adding a neutral strap, for such services as will be three-phase four-wire. It is probable that this will apply to all standard sizes.

Where four-pole general purpose switches have been employed on delta-connected circuits, there might be a demand for three-pole switches with solid neutral connection. Motor starters having thermal cutouts may have to be redesigned to include an additional thermal cutout, for the same reasons as given under "Effect on Motor Control Equipment."

The expenditures thus incurred will be considerable.

5. *Distribution Transformers.* 115/230 volts is the standard now. A tolerance of 5 per cent plus is allowed for single-rated transformers. The majority of tranformers are triple-rated at 110/115/120 volts, and 120 volts is the allowable upper limit.

125/216 Volts: When the voltage impressed on a distribution transformer is raised within the limit that results in saturation of the iron, the per cent copper loss decrease is about the same as the per cent iron loss increase. In the sizes from 50 kv-a. up, which generally obtain in the present types of low-voltage networks, the copper loss is predominant at full load but is subordinate to the iron loss at light loads. Therefore, at full load an increase in voltage to 125 volts results in a net decrease in total loss.

Thus, for those networks in which the practise may be adopted of tripping out feeders during light-load periods to save iron loss and in which the transformers will be fairly well loaded throughout the day, heating will be reduced and efficiency improved by an increase in impressed voltage. But where all feeders will be left in service the entire day and the transformers will be lightly loaded for a considerable number of hours, the all-day efficiency will be decreased by voltage increase. In either case, regulation is improved.

The salient effect is on exciting current, which increases about 300 per cent when a 115-volt transformer is stressed to give 125 volts. As this is decidedly beyond the allowable limit for the majority of distribution systems, all ratings would have to be redesigned. The expense of this would be excessive.

120/208 Volts: Standard transformers will operate satisfactorily at this voltage. The exciting current of a 115-volt transformer, however, is still increased considerably when operated at 120 volts. The very commendable effort being put forth at the present time by the operating companies to reduce the exciting current on their lines may make such an increase undesirable. There is also the necessity of allowing for the voltage

drop in secondary mains, services, and house wiring. Thus, the possibility that a line of 115/120/125-volt transformers would be required is apparent. The cost of such a change in all ratings would be very large. To this expense might be added that of continuing the present standard line of transformers, due to the probability that conditions on the majority of radial systems might make the new ratings unsatisfactory.

115/199 or 110/190 Volts: No changes would be necessary.

6. Miscellaneous Apparatus. This group includes carbon and oil circuit breakers, relays, meters, instruments, voltage regulators, rectifiers, rectigons, fan motors, condensers, and line material.

115/230 Volts, with tolerance of 5 per cent plus, is the existing standard for the majority of this equipment.

125/216 Volts: As 120 volts is now the allowable upper limit for most of the apparatus, much redesign would be necessary, resulting in excessive expenditure.

120/208 Volts: With most of the apparatus there would be little serious difficulty in operation, but there would be considerable expense connected with changing the design of fan motors and rectifiers for 120 volts, and static condensers for 208 volts.

The application of condensers is comparatively new and growing rapidly, so that present estimates of the effect of a non-standard voltage on them should be multiplied by a large factor when considering the influence on future applications.

115/199 Volts: For this voltage the expenditure would be the least. The only change might be a new line of static condensers rated at 199 volts.

110/190 Volts: Some 220-volt apparatus could not operate satisfactorily on 190 volts and there would be considerable expense in redesign and extra stock.

7. Electric Heating Devices. 115/230 volts is the present standard, with allowable variation of 5 per cent plus or minus.

On a combined secondary system the lower voltage heating units are usually connected between the outside conductors and neutral, and balanced among the three phases as often as possible.

125/216 Volts: Since the upper limit would be exceeded at 125 volts, two separate lines of heating devices would very likely have to be maintained, both for industrial and household uses. The expense involved would be excessive and customers moving from one zone to another would undoubtedly experience trouble.

This voltage, if applied to the enormous number of heating appliances now connected on distribution systems, is so much in excess of their present voltage ratings that great trouble could be reasonably expected because of too high temperature or even burnout of elements.

TABLE VI

EFFECT OF VARIOUS THREE-PHASE SCHEMES ON CLASSES OF APPARATUS

	Classes of apparatus				Weighted according to total sales of each class			
	Scheme				Scheme			
	110/190 volts	115/199 volts	120/208 volts	125/216 volts	110/190 volts	115/199 volts	120/208 volts	125/216 volts

Net	−3	+1	+1	−1	−58	+36	+40	−46

Note: + Signifies net effect is favorable.
− Signifies net effect is not favorable.

120/208 Volts: There would be a small item of expense to allow for voltage variation up to 5 per cent above 120 volts in connection with a few types of equipment.

There is an advantage in having 230-volt elements for heavy duty service. In some cases the 230-volt elements in large electrically heated apparatus for industrial use, such as in furnaces and ovens, cannot be operated properly at 208 volts. This may or may not be a serious matter, according to the conditions encountered.

115/199 Volts: 115-volt elements are standard, but the condition described for devices operated at 208 volts applies more particularly with 199 volts.

110/190 Volts: There would be no difficulty with standard apparatus on 110 volts, but it is possible that a new line of 190-volt equipment would have to be developed, with considerable expense attached.

8. Summary for Three-Phase Combined Systems.

The study of the three-phase combined system for networks has included an analysis of the effect of the four voltages—all that have been seriously proposed as yet in this country.

The fact that 125 volts, the first voltage studied, has not yet been considered a recognized departure from the accepted standard lamp voltage, coupled with the excessive cost to consumers and operating companies for small motors, transformers, miscellaneous apparatus, and heating devices, would seem to weigh heavily against the general adoption of the 125/216-volt scheme.

The 110/190 volt system voltage of the analysis likewise appears to have serious disadvantages under existing conditions, due to similar excessive expense in connection with general purpose motors, small motors, and motor control equipment.

There remain for further consideration in the three-phase combined system group only the two voltages, 115/199 and 120/208. These will be studied later in the Quantitative Analysis.

Table VI summarizes the effects of the various three-phase voltage combinations on the different classes of apparatus discussed in the Qualitative Analysis. The numbers in the left portion of the table are those applied to the various classes in the Analysis. Basing a comparison between the various schemes only on the summary in the left portion might be incorrect, since the relative importance of each class of apparatus should be given due consideration. Hence, in the right portion of Table VI there has been substituted for each class a number proportional to the total annual sales of that product for the entire industry. The large adverse totals against 125/216 volts and 110/190 volts in this summary substantiate the proposition to eliminate those voltages; and the indicated parity between 115/199 volts and 120/208 volts points to the desirability of studying these two voltages further.

Effect of Change to Combined Light and Power System for Two-Phase 115/230-Volt Secondary Networks

This portion of the Qualitative Analysis considers only 115/230 volts, as that is the only two-phase voltage so far suggested for combined secondary systems. Similar to the analysis of the three-phase schemes, it is assumed that this two-phase five-wire scheme would be adopted in all areas that could be networked and that in all other systems the present methods of distribution would be maintained.

1. Small Motors. The widespread retention of three-phase radial systems in addition to the general adoption of two-phase networks would, under conditions of the present, have an important effect on small motors as regards the industry as a whole. This would be due to the considerable expense in the production, distribution, and maintenance of an increased number of two-phase motors to parallel the line of three-phase motors.

2. General Purpose Motors. As with small motors, if all networks were two-phase the production and stocking of two-phase motors would be greatly increased, with a consequent very large increase in motor costs.

For equal amounts of material, that part which is active in a three-phase motor is practically 6 per cent more effective than in a two-phase motor. In performance, the actual results of this difference depend, of course, on the balance struck between the various motor characteristics when designing the machines. In any event, all parties would have to share this loss of 6 per cent in the effective use of materials entering into the construction of apparatus.

Regarding the feasibility of changing three-phase motors to two-phase, the potential should be reduced to 188 volts when a three-phase 220-volt motor is reconnected for two-phase, 220 volts. If operated at 230 volts the power factor would decrease from 4 to 6 per cent depending on the motor speed, and efficiency would increase somewhat, but the motor would generally operate within its temperature rating. Where extra insulation has been provided between phases in three-phase motors, similar insulation is required between phases after reconnection.

3. Motor Control Equipment. Due to the use of a grounded neutral in two-phase five-wire combined secondary systems, four overload trip coils may be required to give full protection, which means the addition of two coils and rearrangement of all controllers for motors intended for connection to networks. A fourth pole must also be added. The combined increased expense in development, manufacture, and stocking would be very large.

4. Safety Switches. A neutral strap and fourth pole must be added where entrance switches will be used on five-wire services; all standard sizes will probably be affected. Four-pole general purpose switches used on lighting feeders may require the addition of a solid neutral connection. Motor starters must have a fourth pole added and it is probable that where thermal cutouts are used two extra cutouts may have to be provided to make a total of four.

The entire extra expenditure would be very large.

5. Transformers. Since the majority of the feeders would eventually be three-phase, transformers would require Scott tap construction. Subway transformers of this type would have to be furnished. As the Scott connection for distribution transformers requires interlaced windings, the design is special.

There is some question as to whether a separate stock would have to be developed. If there were general agreement that these transformers would be used at full rating for other than network installations and at reduced rating in three-phase to two-phase network banks, one line would suffice. However, if the operating companies employing networks should desire to operate the transformers at full rated capacity and

the other companies could see no value in the special design, a separate line for each of these groups would have to be carried in stock. The total extra expense would be very large.

6. Miscellaneous Apparatus. The main changes would be the addition of a fourth pole on certain oil switches and carbon circuit breakers, and the extra cost of two double-pole network protectors or one four-pole in the place of a triple-pole protector at each polyphase transformer bank. The expenditure involved would be very large.

7. Electric Heating Devices. The two-phase system uses devices of standard rating.

8. Summary for Two-Phase Combined Systems. The Qualitative Analysis for the two-phase 115/230-volt five-wire combined light and power system thus indicates the possibility of certain disadvantages with regard to small motors, general purpose motors, motor control equipment, safety switches, transformers, and miscellaneous apparatus.

To make it possible to gage how important these factors may be will require some form of quantitative analysis.

Quantitative Analysis

In any comprehensive study leading to a comparison between the most important of the combined secondary schemes thus far proposed, a qualitative analysis has its place. A quantitative analysis, however, may also be desirable, particularly to assist in forming a better conception of the increased cost that might be incurred if any one combination should be adopted for all network systems.

As a step in this direction, Tables II, III, IV, and V were developed. Employing the assumptions used for Table I, these tables offer an approximate measure of the percentage of all apparatus connected to secondary systems that would be affected by each of the three principal combined schemes and also by the radial system. The combined schemes chosen for consideration are the two-phase combination and the two principal three-phase arrangements selected for reasons previously explained in this paper.

The left portion of each table applies to number of apparatus units grouped as phase-to-neutral and phase-to-phase equipment. The right portions represent the percentages of the left parts weighted in proportion to total sales of the phase-to-neutral and phase-to-phase groups.

In Table II, all the three-phase network systems are assumed to be 120/208-volt, but allowance has been made for some two-phase systems still existing. Table III is similar to Table II with the exception that all two-phase systems are supposed to have been converted into 120/208 volt three-phase networks. Table IV gives the reverse condition, all systems operating as two-phase networks except the radial systems. In Table V the network system percentages of Table III are assumed to apply to 115/199 volt networks.

These tables indicate that apparatus to the value of about 37 per cent of the total sales would be different from the existing standard if all equipment in network areas were exactly suited to the 120/208-volt system; and that the 115/199-volt and two-phase schemes would each involve non-standard apparatus valued at only about 8 per cent of the total. As the preference for three-phase appears to predominate among operating companies and manufacturers, these tables show that the 115/199-volt scheme as a common choice for combined secondary systems would probably affect the least apparatus.

The main assumptions on which the Quantitative Analysis was based are listed in Tables VII, VIII, and IX. These tables bring out the changes that may be required in each of the seven apparatus classes of Table VI if any of the three principal schemes should be adopted as the standard for all networks. It was also assumed in this Analysis that the transition to network systems would be completed for the entire country within ten years.

Table X gives the results of the Quantitative Analysis. The relative index numbers represent the approximate expense to the entire electrical industry for small motors, general purpose motors, etc., and the totals summarize these expenses for each of the combined schemes considered.

The operating companies that have applied the combined light and power method of secondary distribution have been prompted mainly by the desire to effect a great saving to the entire electrical industry. Table X shows that if any type of combined secondary scheme is generally adopted for networks there will be a heavy expenditure tending to offset some of the gain. It also discloses that failure to standardize immediately will add further to this tendency.

Table X reveals the possibility that there may be a definite difference between the 120/208- and 115/199-volt three-phase systems, in favor of the latter; and that the adverse effect of the two-phase combined scheme may be relatively much greater than that of either of the three-phase combinations.

Relation of Trends in the Industry to This Problem

The Qualitative and Quantitative Analyses deal with the effect of the combined schemes themselves on apparatus as existing and as required in the future. If the task of choosing a standard scheme is undertaken, other influences should also be considered. For instance, what bearing may the numerous trends in the industry have on the contemplated standard? A discussion of a few of these tendencies will serve to illustrate the importance of giving them proper weight.

Trend of Low Voltages

The trend of system voltages throughout the country appears to have received the most attention among

these factors. Both the voltages now existing at utilization devices and the trend of the various voltages should be of value in guiding the choice of a standard tend to predominate in low-voltage distribution systems is the analysis of the lamp sales in the voltages of the 100-130-volt class. The curves in Figs. 4 and 5,

	Polyphase 110/220 volt motors probably satisfactory on 208 volts.	
2. General purpose motors	More than 50% of present ratings satisfactory on 208 volts.	Rewind less than 50% of 220 volt ratings for 208 volts: a. Some development cost. b. Some shop cost increase. Note: No stock increase.
3. Control equipment		Add third coil for 3-coil overload protection; re-design all 3 coils for 208 volts: a. Considerable development cost. b. Considerable shop cost increase. c. Considerable additional expense due to stock increase.
4. Safety switches	No change in motor starters that do not use thermal cutouts.	Add neutral strap in all entrance switches; develop 3-pole general purpose switch with neutral strap; add third thermal cutout to certain motor starters: a. Considerable development cost. b. Some shop cost increase. c. Some additional expense due to stock increase.
5. Transformers		Change standard rating to 115/120/125 volts: a. Some development cost. b. Large shop cost increase. Note: No stock increase.
6. Miscellaneous apparatus	Relatively small changes required in apparatus other than static condensers, fan motors, and rectifiers.	New line of static condensers for 208 volts; new lines of fan motors and rectifiers for 120 volts: a. Considerable development cost. b. Some shop cost increase. c. Some additional expense due to stock increase.
7. Electric heating devices	Changes in industrial apparatus for 208 volts would involve relatively little expense.	Modification of some 115 volt ratings for 120 volts: a. Small development cost. Note: No shop cost or stock increase.

scheme. Only a thorough survey can give a measure of the extent to which each voltage is now in use.

One method often used in gaging which voltages will applying to lamps sold during the past nine years, are based on data contained in reports of the National Electric Light Association Lamp Committees.

Fig. 4* gives, for each year, the percentage of the sales in 115-volt lamps (the recognized lamp standard) as part of the sales in the entire 100-130-volt group, and also similar percentages for 110- and 120-volt lamps (the two recognized departures from the standard).

TWO PHASE 115/230 VOLT SCHEME

Class No.	No changes required	Changes required
1. Small motors	Single-phase 110/220 volt motors satisfactory on 115 volts or 230 volts. No additional development required for polyphase motors.	Increased polyphase production cost and stock: a. Some shop cost increase. b. Some additional expense due to stock increase.
2. General purpose motors	No additional development required.	Increased production cost and stock: a. Some shop cost increase. b. Large additional expense due to stock increase.
3. Control equipment		Add 2 more overload protection coils and fourth pole: a. Very large development cost. b. Large shop cost increase. c. Considerable additional expense due to stock increase.
4. Safety switches		Add fourth pole and neutral strap in all entrance switches; add neutral strap to four pole general purpose switches; add fourth pole to motor starters, also two thermal cutouts to certain types: a. Considerable development cost. b. Considerable shop cost increase. c. Some additional expense due to stock increase.
5. Transformers		Add Scott tap to all ratings: a. Considerable development cost. b. Considerable shop cost increase. Note: No stock increase.
6. Miscellaneous apparatus	Practically no changes required in apparatus other than oil switches, carbon circuit breakers and automatic network units	Modifications in oil switches, carbon circuit breakers, and automatic network units: a. Considerable development cost. b. Some increased shop cost. c. Considerable additional expense due to stock increase.
7. Electric heating devices	This system uses devices of standard rating	

The approximate parallelism of the 115- and 120-volt curves appears to indicate that 120 volts is not displacing 115 volts as the preferred voltage. The slight convergence of these two curves between 1923 and 1925 is probably no more definite indication of a decided change in favor of 120 volts than was the divergence between the curves from 1921 to 1923 a sign that 115 volts would soon outstrip 120 volts.

*Taken from Fig. 3, Page 3, of 1925-1926 Report of Lamp Committee, National Electric Light Association. Publication 256-47.

The curves of Fig. 5 show another way of determining the probable tendency of system voltages. These curves give the total annual lamp sales for each of the three main voltages. In applying them it is assumed that the total number of lamps sold in a given voltage

*Too small to influence total.

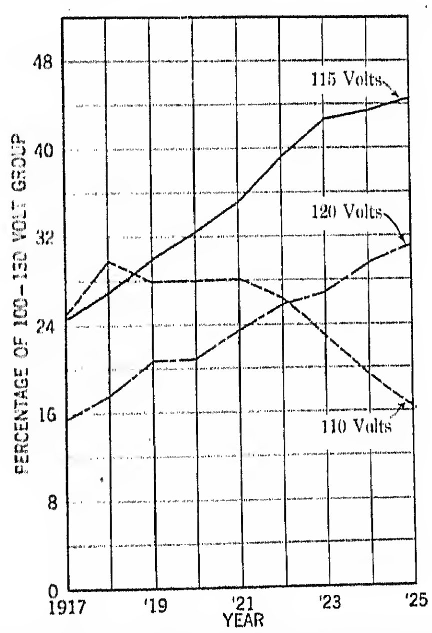

Fig. 4 Proportion of Lamp Sales in Recognized Standard Group to Total Sales in 100-130 Volt Group

is a measure of the number of customers served at that voltage and hence of the extent to which the voltage is applied.

Up to 1921 the total lamp sales for 120 volts appear to have kept pace with those for 115 volts, with the latter in the lead, but Fig. 5 shows that since 1921 there has been a more rapid upward climb of the 115-volt sales. If the tendencies indicated by these curves become the realities of the future, then it is likely that 115 volts will be the standard for many years to come.

Furthermore, there appears to be little evidence at present of any trend that may change this situation. Noting the continued decrease in the number of 110 volts lamps sold since 1921, it is interesting to determine whether the companies that are dropping 110 volts may be adopting 120 volts instead of 115 volts. It is difficult to draw any such conclusion from Figs. 4 and 5, for the curves give no indication as to how much of the increase in 115-volt or 120-volt lamp sales is attributable to normal growth of connected load in 115- or 120-

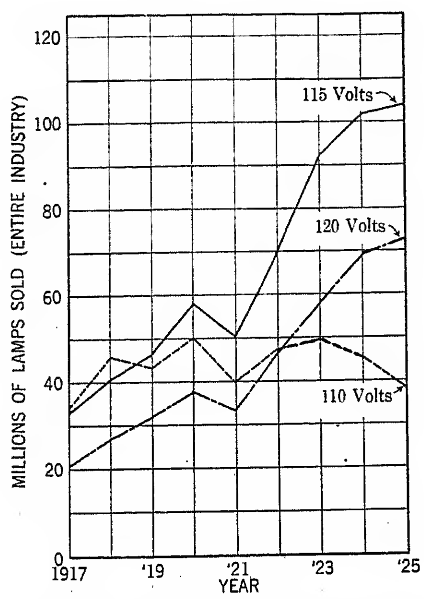

FIG. 5—TOTAL LAMP SALES IN RECOGNIZED STANDARD VOLT GROUP

volt systems and how much to acquisitions from 110-volt systems.

While the tendency in the past has been towards a steady upward climb of distribution voltage, this seems to have been checked by the approach towards standardization in the last few years. As an illustration, there is the action of a few of the larger syndicates in standardizing on 115 volts for their properties, even though it appeared that the extra capacity available at 120 volts would have resulted in greater return on the investment.

Considering the above deductions, namely: (a) the increase in use of 120 volts will probably not overreach that of 115 volts, while the use of 110 volts is declining; and (b) seemingly, no trend or development important enough to change these conditions has been brought to light thus far; it appears that what had the semblance of an endless process of increase in voltage standards has been halted.

The subject of lamp standards brings to mind the method that was employed when the situation regarding lamp voltages was at least as difficult as is the combined secondary situation today—adoption of a single lamp standard with recognized departures. This precedent should be of value when considering the recommendation for a basis of standardization for combined lig and power schemes to be made later in this paper.

GOOD PUBLIC RELATIONS

The maintenance of good public relations is a knowledged by operating companies as increasing important. System changes are being made in t manner that disturbs the fewest number of custome: Universal adoption of a standard combined system m: inconvenience some consumers at the start regardl of the kind of scheme chosen, but taking into accou good public relations calls for minimizing the numb thus involved.

The motor users that would be affected by a: standard combined system constitute a relatively sm part of the entire group of customers. The simp means that have been employed to remedy the mot troubles have been pointed out previously here: Thus, from the standpoint of good public relatio consideration of the other utilization devices would see to be of more importance.

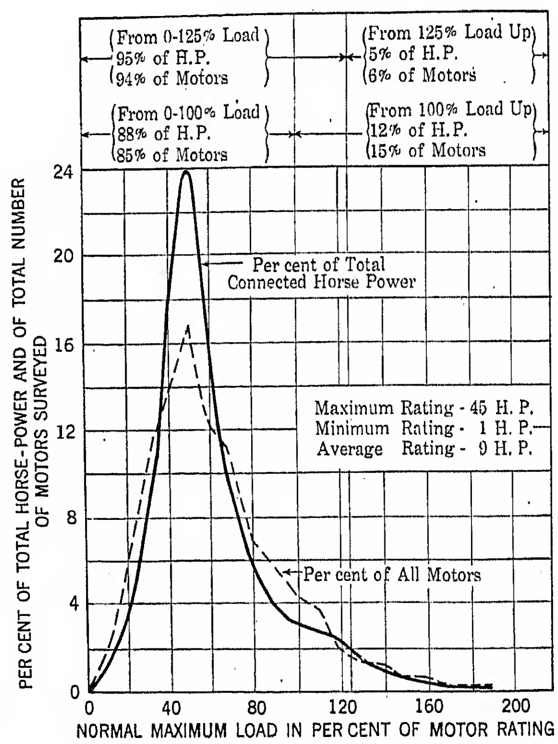

FIG. 6—LOAD SURVEY OF GENERAL PURPOSE MOTORS

STANDARDIZATION OF TRANSMISSION SYSTEM VOLTA(

The present trend toward standardization of tra mission system voltages will affect the ability of ma companies to apply a given combined light and po secondary scheme chosen as the standard. This m be given due weight. There are numerous compa operating secondary systems at 110 and 115 volts t cannot raise the potential to 120 volts at peak lo the limit of voltage capacity of all apparatus on tl systems having been reached. Usually 115 volts

the utilization device requires 120 volts at the transformer.

The choice of transmission voltage standards should take into consideration the possibility of adopting as the standard for combined secondary systems that scheme which conforms closest with *all* the requirements for a combined standard. These will be listed near the end of the paper*.

Standardization on Systems for Distribution

There appears to be a tendency for operating companies to standardize on certain designs of systems for distribution when the concensus of opinion agrees on such designs as the best obtainable.

Thus, almost all direct-current distribution systems have the same pattern, some form of three-wire network at 120/240 volts. The majority of primary systems in cities have been changed from 2300 volts three-wire three-phase and 2300 volts three-wire or four-wire two-phase to 2300/4000 volts four-wire three-phase or something similar. Sixty cycles has practically become the standard frequency for alternating-current distribution systems. Most street lighting systems use series circuits and railway distribution systems are usually 600 volts, d-c.

Standardization on a single system for combined light and power secondaries in network systems would not therefore be a radical departure from existing tendencies.

Over-Motoring

Many operating companies favor making use of the present degree of over-motoring where possible, yet discourage its continuance into the future. These tendencies will improve the power-factor and make less costly both the plant required to render power service and the motor installations. To avoid any injustice to customers who have purposely allowed spare capacity in motors for future increase in loads, these operating companies stand ready to install the boosting auto-transformers whenever required.

Fig. 6 is the result of a load survey of all the general purpose motors served by a large underground distribution system. Load concentrations averaging 20,000 to 40,000 kv-a. per square mile prevailed. Every type of motor encountered was tested carefully and it may be said that the results are fairly typical for most of the underground areas where a-c. networks will be applied.

These curves indicate that for the majority of motors and motor hp. in such districts the maximum load is only 50 to 60 per cent of the rating, and that in but 10 to 15 per cent of the cases is 100 per cent or more load encountered. How the power-factor of underloaded motors is somewhat improved by operation at reduced voltage has been disclosed in the Qualitative Analysis.

*It is also pertinent to take into account the probable choice of an international standard for low voltages in distribution systems. See Report of New York Plenary Meeting, April, 1926, International Electrotechnical Commission, Publication 36, Page 167.

Two-Phase Distribution

The original alternating-current system was two-phase. The fact that the use of the newer three-phase system has increased so rapidly in radial distribution practise leads one to the conclusion that it has some important advantages over two-phase. At the threshold of selecting a standard combined scheme for network systems it may be desirable to investigate whether the choice of three-phase would likewise be on a sound economic basis.

In some quarters there appears to be the general impression that two-phase is becoming obsolete, but there is not much information available whereby this may be investigated. A recent survey of motors used in industrial plants* indicates a decrease in the number of two-phase motors by slightly more than 18 per cent in five years. As was brought out in the discussion of a recent Institute paper,† the assumption that approximately 6 per cent of all polyphase motors in use are two-phase may not be far from correct. Combining this rate of decrease with this present status gives only about 2 per cent as the percentage of two-phase motors 25 years from now.

It costs a little more to manufacture a two-phase motor than a three-phase motor of the same nameplate rating. At some time in the future, when two-phase motors are fewer in number than at present, this extra cost may become proportionately so large as to warrant an increase in the price of two-phase motors over three-phase; deliveries of two-phase machines would also be slower. At that time, the combination of these factors may have a very noteworthy influence on the demand for three phase in those areas now supplied with two-phase.

Consideration from all angles makes it appear unlikely that there will be additions to the two-phase group from companies now operating three-phase systems or contemplating new systems. Due mainly to the motor problem, several companies have expressed great opposition to any change to two-phase for networks. Although a two-phase five-wire secondary network with mains on both sides of the street involves only a small increase in total annual charges over a three-phase four-wire network,‡ this difference would be much increased in the many systems that would desire or be compelled to use only one side of the street for mains. In such cases the companies object to the fifth wire even if it can be pulled into the existing ducts.

Supplementary Rating for Motors

The supplementary load rating of 1.15 that has recently been generally accepted for application to standard 40-deg. general purpose motors is based on permitting operation at 1.15 times the rated full load

*Electrical World, January 23, 1926, Page 206.
†A. I. E. E. Journal, Vol. XLIV, November, 1925, Page 1252.
‡Paper by P. H. Chase. See Bibliography.

provided the motor is operated at its rated voltage and frequency.

This rule has been interpreted as not applying to standard motors operated at either 208 or 199 volts. The same is true for 40-deg. 208- or 199-volt rated motors since these ratings have not been recognized as standard for general purpose motors. Hence, if the combined secondary system chosen as standard should employ a voltage less than 220 volts, it would be necessary to warn customers using motors in network areas to avoid applying the supplementary rating without a load check by the operating company.

It is likely, however, that the motor users in network districts receiving reduced voltage would also want the supplementary rating, as otherwise there would be a 15 per cent differential against their motors merely because they were not located in radial distribution districts. This would make the application of rated voltage to motors more necessary and so increase the tendency towards a change in motor design to fit the 115/199- and 120/208-volt schemes.

It has been previously noted that present lines of general purpose motors would probably require rewinding of almost 50 per cent of the ratings to give the original torque guarantees at 208 volts. If the supplementary rating were also applied, a large majority of the 220-volt ratings would have to be rewound to ensure satisfactory heating and characteristics at 208 volts. For operation at 199 volts, practicaly all of the ratings would need rewinding.

Standard two-phase motors need not be changed to permit application of the supplementary rating, but its use on three-phase motors at 199 volts might call for an entirely new line. A recalculation of the quantitative comparison between the costs of the 115/199-volt three-phase and the two-phase combinations was therefore made on that basis. The two-phase system still appeared to be considerably more expensive than the three-phase, the main reason for this being that general purpose motors constitute only one of six factors influencing the results, as can be seen from Table X.

Since the limiting feature in most applications of small motors, including fan motors, is not heating but torque, it is questionable whether the supplementary rating will even be applied to them.

Frequency of Redesign of Apparatus

The strides of the industry in the past seem to have brought about the impression that redesign of apparatus is not only frequent but periodic. It might be thought that these rapid changes will absorb the expense for such alterations in design as would be required if any one of the principal combined systems is chosen as standard.

Apparatus redesigns however, are very irregular in occurrence and are sometimes quite infrequent. In one case there was a lapse of 10 years for general purpose motors and in another a line of distribution transformers stood unchanged fo

effect of the scheme on future reven
projecting these studies beyond
period.

4. The scheme should be an im
operating point of view, by giving
plant and the least maintenance.

5. It should be such that non-standard systems can change to it with minimum expense and effort; for instance, in the case of changing two-phase systems to three-phase, or 110-volt systems to a higher voltage.

The completeness with which standardizing for combined secondary systems may be adopted would presumably be affected by the manner in which the plan is carried out. Having determined upon a single standard, its acceptance might thus be greatly helped if consideration were given to any other combination already employed by an appreciable number of companies.

It is therefore recommended that (a) in determining upon a basis for standardization, that combined scheme be chosen as the standard which is preferable according to the most important of the requirements that have been listed above, and (b) if the next best combined system has already received wide application, it be adopted as a recognized departure.

Concluding Suggestions

To have a complete study of these requirements made as promptly as the importance of the problem merits and to allocate to each its proper relative weight will require the concerted attention of the electrical operating companies. Nor can the manufacturing companies hope to avoid their proper share of any task that may arise as the result of a decision based upon that study. The full cooperation of both branches of the industry will be necessary to arrive at a solution involving the least burden to all concerned.

The following are a few suggestions for action whereby this purpose may be accomplished.

The active interest of the leading men in the industry should be enlisted. Their long experience with such problems and their intimate knowledge of the losses due to lack of prompt action in the past should be brought to bear. Their efforts would result in arranging in the order of importance not only the factors discussed in this paper but also those aspects that have not been brought out.

An intensive effort to improve the design of combined light and power systems for networks, in order to eliminate compromise as far as possible, would be of distinct value. The translator scheme is a praiseworthy step in this direction, but apparently it is not the final solution*.

Agreement among the operating companies on a standard scheme of connection and voltages, with an accepted departure if necessary, is recommended. Steps should be taken immediately to bring about such standardization before too much damage is done by the rapid increase of systems requiring non-standard apparatus.

*One authority describes it as "complicated, costly, and inflexible," although it delivers standard voltages in a three-phase light and power system. For other opinions see A. I. E. E. JOURNAL, Vol. XLV, February, 1926, page 180.

Cooperative effort will be needed to encourage the active support of this agreement on the part of all operating companies. Experience with other problems shows that this is usually necessary, for at the beginning of any standardization there is often considerable inertia to overcome. A conservative campaign of education on the value of adopting one standard for combined secondary systems would decidedly aid this effort.

The manufacturing companies should make sure that none of their policies tends to promote the use of such schemes and voltages for combined light and power secondary systems as may differ from the standard that will be chosen.

DETAILS OF NETWORK SYSTEM DESIGN APPLYING TO UNDERGROUND COMBINED LIGHT AND POWER SECONDARIES

Observations and analysis of the operation of combined secondary systems have shown that close attention to the details of system design is necessary to obtain the full benefits of the combined method of secondary distribution for networks. Without due regard to such details, complications detrimental to operating companies, or customers, or manufacturers, or all three, might result from some well-meant effort. For example, a certain part of the network system might be designed to better one condition at too great disadvantage to another part; or too expensive apparatus might be added to permit an economic advantage over d-c. network or a-c. radial systems, where continuity of service is not of paramount importance. Some types of network systems call for equipment that makes operation cumbersome or dangerous; for others, special apparatus might be considered necessary to meet a given local condition whereas a change of system plan would be more beneficial*.

*The desirable characteristics of network design, as distinguished from the necessary features, are discussed in "Evolution of Alternating-Current Secondary Networks," H. Richter, *Electric Journal*, July, 1925.

The following details of distribution system design, applying specifically to three-phase four-wire underground low-voltage networks, are suggested in the light of the present art. Some of these requirements are still controversial among those designing networks.

1. Where extra heavy motor load occurs in the same building with lighting load, the power service should be separate from the lighting service.

2. Service lines carrying power loads should be of ample size, and architects and electricians should be counselled to be particularly liberal in the design of power wiring in buildings.

3. Service lines should be as short as possible to cut down the voltage drop from the secondary mains to the utilization devices.

4. Where motors already installed require full rated voltage for normal operation, auto-transformers or booster starting compensators should be employed. This measure gives the least trouble to customers and the operating company.

There are several precedents for using such auxiliary apparatus. Among these are the small transformers or auto-transformers in street lighting systems to adapt the form of energy supplied to the form required by the lamps, in order to transmit by the most advantageous method. There are also the auto-transformers for serving 2300-volt three-phase motors from 2300/4000-volt star primary lines that have been changed over from 2300 volts delta.

The boosting apparatus employed should be well-built and have ample capacity. To reduce its cost it should be of indoor type and located inside the building where possible. Where manhole location is necessary, valuable space can be saved by mounting the auto-transformers on the ceiling or high up on a wall. When several power services coming from the same transformer bank all require full rated voltage for motors, one auto-transformer may be employed for all such services.

5. All three phase wires of a set of secondary mains should be put in the same duct. Where feasible, the neutral should also be installed in this duct.

6. The copper cross-section of secondary mains should be ample, that is 200,000 to 500,000 cir. mils.

7. Transformer banks should be of liberal capacity. As the saving in transformer capacity by diversity is usually large, some spare capacity to prevent high voltage drops on starting of the larger size motors can be afforded.

8. Care should be taken against spacing transformer banks too far apart.

9. High voltage for feeders (11,000, 13,200, and even 27,600 volt primary lines are being planned) will greatly assist in cutting down the voltage drop on motor starting. By this means one company will obtain a maximum voltage variation not exceeding 2 per cent when a 100 hp. motor starts up anywhere on the secondary network.

10. The copper cross-section of primary feeders should be of ample size, for instance, 1/0 to 300,000 cir. mils. This is inexpensive, due to savings by diversity and the ability to evenly load the feeders at all times.

11. There should always be connected to the network enough feeders to minimize the feeder voltage drop when the largest motor on the network is started. This usually fits in with the proper practise for securing continuity of service on the network on outage of one or more feeders.

12. The system design should be such that the voltage variation at lamps when a motor is started should be not greater than 2 per cent for the best class of service and 3 per cent for the next best.

Discussion

D. K. Blake: Mr. Richter's paper does not attempt to take sides. He tried very hard to avoid that. Some years ago, together with others, I made a similar study and obtained similar results, showing that the 115/199-volt system had the lowest cost, the 120/208 next, and then the two-phase system.

Of course this problem will not be settled in this meeting. It will have to be settled by the N. E. L. A., the Power Club, and the N. E. M. A., but I would like to state my positive convictions along these lines.

I believe, based upon my discussion with various operating engineers and knowing the manufacturers' conditions, that the 115/199-volt system will be the solution to our problem. I am just going to make three statements, without attempting to prove them. They are by no means all of the reasons.

The first is because of the lower cost. The second is because of the large number of consumers unaffected by retaining the 115-volt standard. When I stop and think of the data that were given in the *Electrical World* showing that we have somewhere around 14,000,000 domestic customers, about 2,000,000 commercial lighting customers, and about a half-million power customers, I think that in view of our attempts at good public relations, it is by far better to change things that affect the least number of consumers even though they may have more kilowatt demand and about an equivalent revenue.

The third thing is that I recognize the work that has already been done by the N. E. L. A. in attempting to make the 115-volt system a standard. Now of course if that is the answer, if the committee's work proves that 115/199-volt system is preferable, it means two lines of polyphase induction motors. I know positively that no manufacturer recommends the use of 220-volt motors on systems rated nominally 199 volts.

Now I want to say a word about the practise of using 220-volt motors on 208-volt systems. Suppose you decide on a 120/208-volt system, and use the old arguments of lower power factor and over-motoring, etc., to justify utilizing the 220-volt motor. You then have a system that 110-volt single-phase devices do not fit. I think those arguments are perfectly valid for existing conditions, and during the period of change-over, but I think it is wrong to continue to grow throughout the years without having a system supplying devices that do not fit the system voltage.

Therefore I can see no other answer than two lines of motors.

Now the manufacturers in the past have always, to the best of my knowledge, built additional lines of devices whenever there was a sufficient demand. I have no doubt in my own mind that they will do so in case it is the general opinion that two lines of motors would be desirable.

P. H. Chase: Mr. Richter's paper covers a very broad field and has so many angles both from the manufacturing point of view and also from the central station public relations and economic points of view, that it is difficult to make an adequate analysis.

I would like to take the liberty at this time of discussing a few of his assumptions and points of view. His paper, as I understand it, first presents a statement that the expense incurred in suitable utilization equipment may range from $75,000,000 to $150,000,000 even under the unlikely condition of a single combined scheme adopted universally.

Mr. Elden's remarks on voltage standardization could well be read into the record on this paper. It is open to serious question whether we ever can get to a single, universally adopted standard, because each operating company has its own local public policy, financial and construction conditions to meet. It may be true that one system compared with other systems theoretically may show an economic advantage a few per cent better. When that situation is reduced to terms of the existing system, as many of us have done, a change to another system may impair the quality of service, damage public relations, decrease flexibility, and involve expensive change over cost for at best a small saving, which may not even be realized. This leads one to question whether a figure of $75,000,000 to $150,000,000 spread over a ten-year transition period is really important, compared with the expense that must be incurred to effect the change and with the hazards involved.

Now this figure of $75,000,000 to $150,000,000 on a ten-year transition period means $7,500,000 to $15,000,000 a year. That is compared with what other plan or plans? The paper does not give any figures showing what it will cost to continue with the present standards so far as the utilization of equipment is concerned. In other words, we have no base line with which to compare these figures. It seems to me that there should be further analysis to draw up a bill of the costs of continuing with a diverse standard base. Certainly it will not be necessary to spend this $75,000,000 to $150,000,000 if the present standards are kept.

Possibly the central station companies may have to spend money in continuing with the development of existing systems which may not be quite so efficient theoretically as one universal system might be. However, those operating systems will have avoided the very heavy costs, which this paper does not pretend to deal with, of changing over to some other system than the one they now have. The paper does not deal with the extra operating expenses that will exist during the transition period which, on a ten-year basis, are very appreciable. There is also extra investment during transition.

To come back again to the $75,000,000 to $150,000,000, are those gross figures, or are they net figures, after allowing for the expected manufacturing economies that would come from the adoption of a single standard? If these are gross figures, then they are misleading. If they are net, the public in one way or another must pay what seems like a high price for standardization unless it is assumed that in the overall problem there are marked savings over the present diversity of systems.

The paper is admittedly written from the manufacturers' point of view. The magnitude of the potential savings to the operating company of any proposed system over the existing system gets down to a very elaborate analysis. Let us take the X. Y. Z. Electric Light and Power Co. operating in a metropolitan area, covering suburban areas and some rural areas. As has been brought out, by far the largest number of customers are the residence customers, and all their needs can be supplied by single-phase, three-wire service. Power loads may be three-phase, three-wire; three-phase, four-wire; two-phase, four-wire, and so on.

Most of its distribution plant and most of the load is not in the dense portion of the territory. Also, possibly the dense portion of the territory requires underground construction; possibly the local conditions require only 10 or 15 per cent of the low-voltage load to be underground.

Such a company will not determine its system for all its territory from conditions pertaining to a small fraction of the load. Can it afford to start out on a policy that involves asking its customers to have a different type of motor in different portions of its territory? Is that company going to consider seriously, without a great deal of study, changing its miles and miles of aerial secondary distribution and its hundreds of thousands of services to residence customers to conform to a system that may be slightly advantageous from a theoretical point of view only for this central densely loaded area?

I think, as has been mentioned by Mr. Blake, this whole subject deserves and must have extended study by the N. E. L. A. and the Power Club before there can be an overall answer.

H. L. Wallau: Mr. Richter has pointed out to us the enormous expense to be charged against the electrical industry due to the redesigning of utilization equipment if any of the present a-c. low-tension network schemes is adopted. The tentative figures set up by him are appalling.

In Cleveland for over ten years we have been using the three-phase, 230-volt system with the four-wire lighting neutral (Fig. C-2 of his paper) with radial feed. This system was first installed in a new underground district. Later, a similar system was used to replace a three-phase, four-wire, 115/199-volt system, then at least 15 years old. This system has the advantage of using lamps, appliances, motors, control equipment, etc., as now standardized.

Can this system be modified slightly and become suitable for network use? I believe it can, but do not recall that the following scheme has ever been suggested. Referring to the accompanying diagram you will note three primary feeders which may issue from one or more substations and are supposed to have the customary over-current protection at the substation end. I have shown these connected to merely one transformer bank each. The transformer banks are shown connected delta-delta but might be Y-connected on the primary. A network protector is assumed cut into the secondary leads between the transformers and the network. Cut-outs, etc., have not been indicated. The cables forming the three-phase, 230-volt mains are continuous and the transformer banks consist of three units of equal capacity, or of one three-phase unit. The lighting neutrals carrying the out-of-balance current are *discontinuous*, there being one section per transformer bank. Between a pair of 230-volt phase wires there is connected a balance coil at each bank location, each successive balance coil being rotated so as to be across the next successive phase. The middle points of these balance coils are respectively connected to the lighting neutral of their particular section. We now have a system having 230 volts between any two-phase wires and 115 volts between any neutral and its corresponding phase wires. There is also a difference of potential of 115 volts between any two lighting neutrals, hence these neutrals should preferably remain discontinuous but could be made continuous by the insertion of a suitable iron-cored reactance between the junction points. So far we have not grounded this system. A ground is provided by means of a star-connected auto-transformer, wound with 133-volt coils, the common junction point of which is grounded. This provides a difference of potential of 133 volts between phases and ground and $66\frac{1}{3}$ volts between neutrals and ground. If the secondary, three-phase mains are to be arranged for sectionalization at times, it would be desirable to have a grounding transformer for each section. If not so arranged, fewer might be used but at least two should be provided in case of failure of one. The total number would depend somewhat upon the extent of the interconnected network. The balance coils used need be only large enough to carry safely the maximum unbalanced load of any section. They would probably be standardized for

any network as of the maximum size required, due to local conditions. In certain specific cases where a large amount of lighting load was connected to one section, as compared with adjacent sections. it would be advisable to select certain buildings and connect their lighting load across phases other than that normally supplying that section, additional balance coils being located either in the street or in the buildings selected.

The lighting neutral should be fused preferably to at least twice the value of the phase wires at both service entrance and in all house circuit panel boards, in order that internal faults might not cause the neutral to open, thereby unbalancing the voltage across the three-wire lighting system. Should a ground develop on a neutral within a building, the neutral fuse would, of course, blow. No ground should be installed on any of the house or service wires but the grounding transformers should preferably have their neutral leads securely bonded to the nearest water system in some adjacent building. I assume that the present network protectors may be used as now designed or with some slight modification; possibly a zigzag, instead of a star-connected grounding transformer, would be required to obtain certain necessary phase relations for relay operations.

Before this system could be adopted, certain changes in the code would probably have to be agreed upon, such as over-fusing a lighting neutral in order that the neutral wire size need not be increased. There may be others.

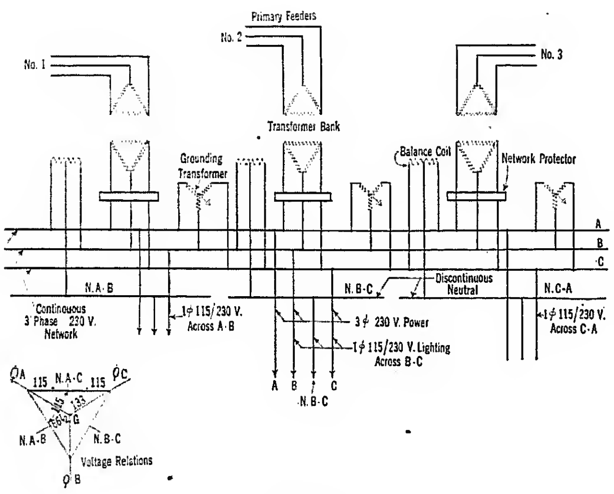

FIG. 1

I advance this scheme as being worthy of study at this time when standardization is still in the embryo. If feasible, I believe that the cost to the industry of additional equipment required, in the way of balance coils and grounding transformers, would be many millions lower than Mr. Richter's lowest estimate of the cost of the required changes in present equipment using the most favorable of the schemes at present contemplated. Perhaps Mr. Richter could contribute a comparative estimate later.

In the time at my disposal between the conception of this idea and the present, I have not thought of any vital objection to it. It may have some very vulnerable features which make it impractical. It should, therefore, be thoroughly checked for any such faults and if none can be pointed out, given serious consideration before being thrown into the discard.

A. H. Kehoe: I disagree with the conclusions which would be inferred from reading the paper, and claim that the 120/208-volt system is the preferable one to adopt. In discussions before the Institute on voltage standardization, it has been stated that 110-, 115-, and 120-volt systems are each being operated successfully throughout the country on a single-phase, three-wire basis. One unfamiliar with conditions might readily think in reading the paper that 120/240-volt supply existed only on some of the older d-c. systems. It should also be noted that items of cost are included for changes in single-phase equipment that is regularly sold by the manufacturers, who guarantee its successful operation for the same service which in the paper is indicated as causing these heavy redesign expenses. Such single-phase equipment, today, as in the past, is designed to operate successfully on 110-, 115-, and 120-volt services. It is difficult to understand how any charges for changes in these conditions will be incurred in time to affect the economics of the situation here under consideration.

The paper states in the qualitative treatment of the 120/208-volt system that there is a possibility of using either a 5-per cent or a 10-per cent maximum allowable voltage variation. The 5-per cent variation is ignored in the quantitative results. This omission is made regardless of the fact that it has been many times stated that the 120/208-volt system operating with a maximum terminal voltage variation of 5 per cent is the only one of the combined balanced light and power systems which can supply all of the standard utilization equipment within the limits covered by existing agreements at which the equipment is guaranteed to operate successfully. Needless to say, such a system is the only one which will avoid the expense which in the paper is estimated in the millions.

It is questionable whether third-leg protection on some motor circuits should be included in the costs, as the industry now uses this and will have to do so with any of the combined systems. Watthour meter costs, on the other hand, are not mentioned, presumably because the meters have been developed and are required in practise today. However, the watthour meter charge is an important one to consider in any three-phase case, and should not be overlooked when considering costs. A fact to note, in this connection, is that for the moment three-element meters cost more than three separate single-element meters.

I am not in accord with most of the statements made on public relations. It is paramount for good public relations that a customer never be inconvenienced from the viewpoint of our service to him, and that equipment which he wishes to buy, sell, or use can be readily utilized. Universal use covers more than equipment; it means service availability as well, on the fifth or fiftieth floor, if need be, without major reconstruction of the system while the consumer waits. The principal objection to the 115/199-volt system is due to public relations, in that it is impossible to guarantee delivery of a terminal voltage at which standard equipment is sold to operate successfully within its rating.

From time to time it has been stated that a special motor of 200 volts will be produced. Such a motor should not be produced unless it can be designed for universal application. However, if one is produced, it will be possible to operate it successfully on a well-regulated 120/208-volt system.

I am of the opinion that no single combined light and power system will be used for some time to come; but if one system should be generally adopted in the next few years, it will be the 120/208-volt, three-phase, four-wire with a maximum variation of 5 per cent in terminal voltage.

W. B. Kirke: I heartily agree with Mr. Kehoe on what he has to say in regard to the 120-volt versus the 115-volt system; I also am definitely on the 120-volt side.

If we look ahead to the future and consider possibly a 10- or 15-year period, we might make the assumption that in that time there will be a possible 10,000,000-kw. demand on network systems. If we ascribe a figure of \$20 or \$25 a kilowatt to the cost of secondary mains and subways, if it represents underground system, we shall have a capital investment of \$250,000,000. A comparison of the kilowatt capacity of the 115-volt system with that of the 120-volt system has to be based primarily upon voltage regulations, and in round figures one is 10 per cent greater than the other. Ten per cent of \$250,000,000

is $25,000,000 which you can add as a credit on the 120-volt system. That makes up the difference in cost between $75,000,000 and $100,000,000 as represented in the Table X, on the assumption that the other figures are correct. I seriously question the values as given.

L. L. Elden: In discussing this paper I must confess my inability to analyze some of the prospective savings which are computed for certain types of network systems. In some estimates which were presented recently it appeared that in a single system the cost of extensions during the next ten years was estimated to total something like $100,000,000 for distribution equipment if present methods of construction and supply were followed.

It was suggested that the adoption of the network system would mean a saving of approximately $7,000,000. I wonder if there is anybody here—engineer, commercial man, or otherwise—who will guarantee that over a period of ten years his estimate for such construction will fall within 7 per cent of the actual cost.

Such an estimate must take into consideration the future developments in the art, obsolescence of equipment, changing rates of interest, taxes, and many other contingencies. It is doubtful if anyone here would undertake such responsibility.

It has become increasingly evident that in the maintenance of favorable public relations, we must consider everything that we do primarily from the standpoint of the user and for that reason must carefully review any investment and its effect upon future operating and maintenance costs.

An important feature of the networks under discussion is the propriety of operating motors at subnormal voltages as appears necessary through the adoption of any four-wire, three-phase secondary networks where the lamp voltages range from 110 to 120 volts.

Manufacturers' data on motor operation show very conclusively that operation at the subnormal voltages referred to results in a reduction of efficiency if the motors are operated at anywhere near full load. This method of operation takes advantage of the 10-per cent tolerance factor provided by the manufacturers in their guarantees. From the point of view it may appear that our utilities are within their rights in providing for operating such motors at lower than normal voltages.

As this tolerance factor, however, is not intended to be used in such a manner since it is well known that there will be variations in almost any system voltage below normal voltage, it must be that in most cases the motor will be operated under conditions unfavorable to the customer.

It is unfortunate that this situation has arisen but while it is desirable to construct motors which are capable of operating within a 10-per cent range of voltage plus and minus from normal, it does not appear desirable to recommend the construction of systems on that basis as has been suggested in the consulting engineer's paper presented on this subject.

Considerable time has been spent upon a study of the motor situation in the hope that some development might be suggested to the manufacturers which would provide motors adapted to network operation and at the same time not require a change in present standards.

It appears that the bulk of the requirements will naturally fall in the 115-199-volt class, so that unless some special scheme can be developed, there appears to be a logical need for another motor possibly rated at 200 volts as Mr. Blake has suggested.

An extension of motor windings has been suggested with taps which may be utilized for either 200- or 220-volt operation as a possible solution. Motors are moved from one part of a system to another so that a motor arranged with a combination of taps as above suggested would be suitable for use in any location. If this method of construction is feasible, and I have been told by one designer that there is nothing to prevent such an arrangement being incorporated in motor construction except a slight additional cost, it may be the way out of the situation with which we are contending.

Mr. Blake has very definitely stated that manufacturers do not approve of the operation of 220-volt standard motors on 199-volt service. It appears, however, that manufacturers' representatives are guaranteeing such motors for operation on the lower voltages without hesitation. This appears to be a most undesirable procedure and in the end will be very destructive of any efforts which may be made to secure a definite standardization of motor ratings.

It is to be hoped that out of this situation something will be developed in the form of a motor product which will be universal in application and leave us free to develop networks at will without detriment to other interests.

D. K. Blake: It is by no means out of the question to have a motor that will operate successfully, a universal motor, on 199 or 220 volts. It may be a little difficult to do, but it seems that a great deal can be accomplished by a combination of parallel-*Y* and series-delta. I would merely suggest something like perhaps parallel-*Y* 195 volts, series-delta 225 volts. Not all motors can be built that way easily, but a large number can.

P. H. Chase: I would like to ask whether a motor of that type will run into considerable extra expense? It means heavier coil cost and it may affect the frame.

D. K. Blake: It is my understanding that it will not run into a very heavy expense except on some sizes and speeds. I can't say definitely because that has not been pursued far enough, but there is that hope.

W. B. Kirke: I would like to add one more point. In Brooklyn we have the 120-volt service standard. We attempt to keep that voltage within the limits of 116 to 124 volts.

Our complaints on utilization equipments connected from line to neutral due to 120-volt standard are practically nil. It may have some bearing upon the costs which Mr. Richter has given on rewinding of 120-volt parallel-connected or 220-volt series-connected motors. The network system that we intend to install will take care of loads up to 10-kw. demand from line to neutral. This will take care of the great majority of small motors. Above that capacity we expect to serve on a four-wire basis.

Our distribution transformers are operating above the 120-volt maximum rating. I should say 60 per cent of them are operating close to 124 volts or above, or rather 60 per cent are operating above 120 volts, and 40 per cent are operating below.

I would like to make one other reference to Fig. 4 showing the proportion of lamp sales. I believe the figures for 1926 on the 120-volt group are about 35 per cent, and on the 115-volt group approximately 47 per cent. This shows an increase of approximately 4 per cent during the past year at 120 volts and closer to a 3-per cent gain on 115 volts.

The parallelism is, therefore, converging, and there seems to be a very good economic justification for the increase in 120-volt service.

P. H. Chase: I would like to ask one specific question. These figures of $75,000,0000 to $150,000,000 stick in my mind very definitely. Mr. Richter explained that those figures were the net figures. In a ten-year period there would accumulate $75,000,000 to $150,000,000 deficit that somebody has got to pay. I don't imagine that the manufacturing companies will absorb that kind of a deficit out of profit and loss account. It will be passed on.

How many years after that ten-year transition period will it take to make up that deficit? In other words, I am asking in another way, what is the gross figure? After we have spent the $150,000,000, there must be some economies resulting at the end of the transition period that are going to pay back, we would hope very shortly, the money we spent.

I am much interested in that figure and how long it is going to take. If it is 25 years we must have a great deal of hope.

M. T. Crawford: (by telegraph) I suggest for discussion

that consideration be given to the delta system, Fig. 2c, as it permits the supply of full normal voltage to all utilization equipment which will become more necessary with increased use of heating devices. Seattle has had multiple primary feed low-voltage networks in operation six years with success, using this delta system for combined light and power on recent work. We have no difficulty in balancing phase loads on primary feeders.

H. P. Seelye: (by letter) One cannot help but agree that the adoption of one system as a standard would be very desirable, if possible. It usually occurs, however, that standardization follows considerably behind utilization and is accomplished for the purpose of bringing order out of chaos but after the chaos is pretty well established. It would appear somewhat doubtful if the use of combined secondaries has yet reached such a point as to make a general agreement on a single standard possible, no matter how desirable it may be. A comparatively small percentage of the industry is using such secondaries as yet although consideration is being given to the subject quite universally. A satisfactory generally accepted standard cannot be impressed on such a situation but will come only after a wide experience with all the variations points to one type as most desirable.

The present trend seems to be quite generally toward the adoption of a Y-connected, 4-wire, three-phase scheme at either 120/208 volts or 115/199 volts. There seem to be enough arguments in favor of both these voltage combinations to make it quite certain that neither one will be universally accepted for some time. Companies will probably choose the voltage which corresponds best with their present standards and those which they will use elsewhere on the system (the combined secondaries will in most cases form only a part of the total secondary system). This might point to the adoption of one as a standard and the other as an accepted departure, as Mr. Richter suggests, but aside from the probable controversy as to which will be the standard and which the departure, can the desired result be gained by such a standardization? The two voltages are far enough apart so that most of the changes noted by Mr. Richter for both systems would be necessary. The manufacturer would be bound to furnish apparatus both for the standard and the accepted departure. A possible solution might be a compromise between the two, say 117.5/203.5 volts for apparatus which would be only about 2 per cent away from either utilization voltage.

Regardless of which voltage might be accepted as standard, there will no doubt be a demand by motor users for motors in the 200-volt range. This demand will probably not be entirely satisfied by 220-volt motors either with or without supplemental ratings or understandings as to reduced allowable voltage variation. It will be met by some manufacturer by 200-volt motors. It would seem the best practicable solution to accept the fact that there probably will be systems at both 115/199 and 120/208 volts (as well as at 115/230 volts) and to develop a line of apparatus, if possible, which will be suitable for both voltages with satisfactory rating and guarantees.

H. Richter: The question was raised by Mr. Chase as to whether the diverse conditions in the various distribution systems will allow the application of any standard for combined light and power secondaries. I wish to call attention to the fact that when standardization of frequencies was suggested many years ago, and of lamp voltages more recently, similar doubts were raised. Time has shown that in the general good of the industry the numerous local objections were relinquished. Basically, the conditions treated in the paper are the same as were those of the frequency and lamp-voltage problems.

There seems to be a doubt that the cost of continuing the present unstandardized conditions would exceed the total of $75,000,000 to $150,000,000. An approximate analysis made a short time ago gave a sum greatly in excess of $150,000,000. The assumptions included the usual process of developing equipment exactly fitted to each of the different systems.

The total expenditures given in Table II, incidentally, are net. In pointing out that the paper omits consideration of increase in investment and operating costs due to incidentals during the ten-year transition period, Mr. Chase lends support to those parts of the conclusions that suggest a comprehensive study by the leading men of the industry. His question as to how soon the huge totals against the combined system may be cancelled by economies introduced by this system can also be answered properly only by such a study.

I fail to see wherein there would be undue difficulty in standardizing on one combined scheme for secondary networks because of objections to operating in the congested area of a city a system differing from that in the remainder of the city or to changing the rest of the distribution system to conform with the network. What of the numerous d-c. underground systems now surrounded by extensive a-c. overhead systems? At least, with the Fig. 2F scheme, many of the motors can be used interchangeably on both radial and network systems. In one large city there are 120/240 volts direct current; 120/208 volts, three-phase, four-wire; 115/230 volts radial alternating current; and 115/230 volts, two-phase, five-wire. Of course, this is ideal but it shows what is done in practise for expediency.

Mr. Wallau's suggestion, like J. C. Parker's translator system, is another of those admirable attempts to derive a combined scheme for three-phase networks which I hope will eventually result in eliminating compromises with existing standards. It should be given due consideration, but already I see some of the vulnerable features that he seemed to feel impending as he closed his remarks. The necessity of leaving the neutral wires ungrounded does not meet the National Electrical Safety Code requirement to ground the neutrals at all services. The advantage of a thoroughly grounded solid neutral network over the entire system is also lost. Similar to the translator scheme, Mr. Wallau's suggestion involves that added complexity in the distribution system due to auxiliary apparatus which is directly opposed to the simplicity of the Fig. 2F scheme and may therefore be undesirable to the operating companies.

Mr. Kehoe objects to those assumptions in the paper that provide for changes in phase-to-neutral apparatus to suit the 120/208-volt system. Surely we cannot ignore the fact that on a nominal 120-volt system the apparatus must be guaranteed for at least 120 volts plus or minus 5 per cent. It is incorrect to think that the guarantees on all standard equipment are covered at these limits, which are 126 to 114 volts. This would ignore the electric heating devices rated at 115 volts plus or minus 5 per cent, or 121 volts maximum; miscellaneous apparatus, including fan motors, rectifiers, static condensers, etc., with the same rating; and distribution transformers rated at 110/115/120 volts, that is, 120 volts maximum.

It was even considered necessary to assume 10 per cent plus or minus for the limits on small motors, general-purpose motors and motor-control equipment. The reason was that this is the only standard that has been definitely agreed upon. It can be readily understood that such limits may not suit metropolitan network systems maintaining very close regulation at utilization devices. But the guarantees are formulated according to the requirements of the majority of the systems in the country. For years the apparatus connected to radial systems in large cities has similarly had the same limitations as equipment for outlying towns and villages.

Likewise, it is probable that the combined secondary scheme acceptable to the majority of companies operating networks may not be applicable to skyscraper services as well as to small stores and apartment houses, without some modification.

Mr. Kirke claims that the 5-per cent economic advantage of 120 volts over 115 volts will cancel the difference between the $100,000,000 expenditure for the 120/208-volt system and the $75,000,000 for 115/199 volts. In view of the decision of the industry to standardize on 115 volts for lamps and the indications that this decision is being put into effect, it would seem that the

sum total of the disadvantages of going to 120 volts for phase-to-neutral apparatus must outweigh all the advantages.

In neglecting to be governed by this gain of 5 per cent, important consideration was apparently given to the condition illustrated by some figures published in the *Electrical World*. These state that the application of 110, 115, and 120 volts to residential customers is in the approximate ratio of 76 to 37 to 17.

The Europeans appear to be swayed by this economic factor and not only carry the process to its logical conclusion by using the 220/380 volt combined system but also point to the undue conservatism of our 115/230-volt separate light and power system.

Mr. Kirke thinks that the 1926 lamp sale totals will cause the 115- and 120-volt curves in Fig. 4 to converge further. It may be too early to make this prediction, as it is quite possible that there will be no further convergence. Furthermore, the 120-volt curve is not conclusive. No effort has been made to differentiate between the lamps on d-c. systems and those on a-c. I have obtained data from a reliable source that show that as of January 1, 1926, the percentage of domestic lighting customers using direct current to those served with alternating current was: for 110 volts 0.33 per cent; for 115 volts 0.25 per cent; and for 120 volts 25 per cent. Applying these corrections to the curves in Fig. 4 results in dropping the 120-volt curve considerably below the position shown. It is thus apparent that 115 volts is decidedly the standard at the present time.

If a standard combined system were chosen in conjunction with a recognized departure, Mr. Seelye believes the development of apparatus with guarantees for the departure would come about. I think this unlikely. At present, 120 volts is a recognized departure from 115 volts, yet the majority of electric heating devices, distribution transformers and those devices listed in the paper as miscellaneous are still rated at 115 volts plus or minus 5 per cent.

In the discussion of standardization of transmission voltages, mention was made that there had been omitted a review of the conditions that had brought about certain of the off-standard voltages. With these voltages so firmly entrenched, it certainly appears to be a difficult task to choose a series of transmission voltage standards satisfactory to the majority of systems. This situation is one more eloquent plea that the small differences here and there in the combined light and power secondary problem be reconciled as quickly as possible. There will thus be no past history to reveal the huge expenditures that might have been prevented by the adoption of a standard system at this time.

A New 132,000-Volt Cable Joint

BY DONALD M. SIMONS[1]

Member, A. I. E. E.

Synopsis.—*This paper describes what is believed to be a new form of high-voltage joint. The main novelties in the joint are that the metallic union of the conductors is insulated by wrapping on a single sheet of wide, impregnated paper by machine. The ends of the cable insulation are cut into a series of steps, or a taper, and knives on the machine cut the wide sheet of paper exactly to fit the steps or taper as the wide paper is being applied, until a smooth cylinder is built up to the original diameter of cable insulation. At this moment, the knives are removed, and at each end of the wide piece of paper, strips of tinfoil which have previously been cemented to the paper appear, and these strips gradually taper inward so that as the wide paper is applied, a flaring cone of metal is formed in the body of the insulation itself. This metallic cone acts as an electrostatic screen to control the longitudinal and radial stresses. It is formed automatically without any attention on the part of the splicer in the field, and it insures that all the insulation under stress is solid laminate paper insulation of the highest quality and breakdown strength, especially in the regions where the diameter is enlarged from that of the cable sheath to that of the joint sleeve. Test results are given.*

I. The Problem

THE problem to be faced (and our description will deal in terms of single-conductor joints only), can be explained in Fig. 1, in which we have diagramatically shown two single-conductor cable ends, the conductors of which have been mechanically joined by connector No. 1. For any single-conductor joint, the first problem is to insulate the region of No. 2, in order to build up the insulation over the connector to the

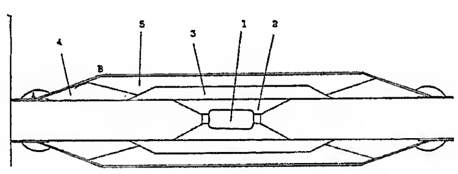

FIG. 1

diameter of the original cable. The classic methods of preparing the cable ends are to pencil (or bevel) the insulation as shown in the drawing, or to cut the surfaces into steps.

When this is done, additional insulation must be applied, and this is shown as made up of insulation No. 3, which is ordinarily applied in tape form. In place of this, tubes could be used, or a combination of tape and tubes. The metal sleeve is then passed over the insulated union, wiped to the lead at each end, and the whole is filled with compound. This is sufficient for the lower voltages.

As voltages go up, however, a new point of weakness appears, due to the concentration of stress at the point where the diameter of the outer electrode changes, under the slope *A B* in Fig. 1. For medium voltages, it becomes necessary to bell out the lead sheath, thus reducing the stresses at this point; and in fact joint casings have been designed so as to be practically a continuation of the bell of the lead, and act, themselves, as a flaring of the lead sheath. This, however, did not remove all the difficulties. As voltages became higher, it was found that the oil or compound in the region where the lead sleeve tapers under the slope, *A B*, would be overstressed, break down, and would lead to eventual breakdown of the cable at that point, or to a surface arc from the connector No. 1.

This phenomenon is rather an interesting one, and is apparently due to the following: A liquid insulator has the characteristic that its breakdown strength decreases with thickness. Of course the breakdown voltage (in volts) will increase the thicker the layer of liquid, but its specific strength (in volts per mil) will decrease. A certain voltage is impressed between the conductor and the outer electrode, which, in the cable, is the cable sheath and in most of the joint is the cylindrical surface of the joint sleeve. In the region, *A B*, however, there is a taper, and proceeding from *A* to *B*, more and more of the voltage is impressed on the oil or compound in the joint, and less and less on the factory-made insulation of the cable. As we proceed from *A* to *B*, however, the thickness of the oil which is under stress becomes greater and greater. From *A* to *B*, the voltage impressed on the oil becomes greater and greater, and yet its breakdown *strength* becomes less and less. A point

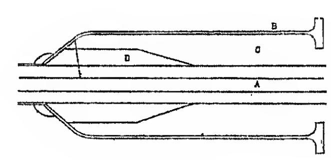

FIG. 2

is reached therefore at which the oil becomes overstressed and breaks down, and this leads to failure of the cable. The author once had a striking illustration of this principle in developing some extra-high-voltage cable terminals. The occurrence is illustrated by Fig. 2, which represents the metallic end-bell at the bottom of a terminal. *A* is the conductor, *B* is the end-bell. The end-bell was filled in the space *C* with oil, and of course breakdown would have taken place in the region where the taper of the end-bell approached the cable surface had we not taken some precaution to relieve the condition. This region, therefore, was wrapped with saturated fibrous material in the mass marked *D*.

1. Standard Underground Cable Co., Pittsburgh, Pa.

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

The diameter of this wrapping could not be increased further as we desired to do because of a projecting flange at the right of B; but we hoped that we had enough there to relieve conditions. Voltage was applied, and breakdown took place as shown by the dotted line. In other words, the puncture took place through an inch of cable insulation, about 1½ in. of saturated fibrous material, and about 1 in. of oil, rather than in the cable itself where we had merely the 1 in. of insulation.

The method of preventing breakdown in the oil under the tapering sleeve consists in general in filling this region with solid material, such as paper tape, V. C. tape, or impregnated candle wicking, shown as No. 4 in Fig. 1. The reason that these materials are effective is twofold; in the first place, these saturated materials have a higher S. I. C. than the liquid oil, and thus the actual voltage to be withstood is less; and secondly, the insertion of these materials in effect splits the oil up into thin layers, and we thus get away from the reduction in breakdown strength of oil in thick layers.

The question is, how to apply this principle. In one well-known and successful joint for high voltages, this was accomplished by building up a tapering surface of candle wicking at each end of the joint, the sleeve being split in the middle in a plane perpendicular to the axis of the cable. These two half-sleeves could therefore be brought up against the candle wicking, and since this is more or less flexible, it would take the shape of the tapering surface, $A\,B$. There are two objections to this method, though it has been entirely successful for the purpose for which it was designed. The objections are the time required to apply this wicking, which is considerable, and the fact that paper tape and V. C. tape have a higher breakdown strength. If it is desired to fill this region with tape insulation of paper or V. C., this also takes a long time and the tape has the disadvantage of being very difficult to apply to a given curvature, and when it is applied there is very little flexibility, and it is thus practically impossible to make

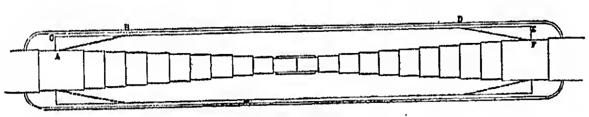

Fig. 3

the curvature at the ends fit the surface $A\,B$ which may have any desired curvature; the tapering surface of the wrapped material must therefore be metallized in some form, up to a certain distance, which again is a difficult process in the field.

It will be seen, therefore, that in a very high-voltage joint not only must the regions No. 2 and No. 3 of Fig. 1 be insulated, but steps must be taken to insulate the regions under the tapering section of the outer sleeve $A\,B$; namely the two regions No. 4. The taping by hand of the regions No. 2, No. 3, and the masses of insulation No. 4 at each end of the joint, and the application of metal to the outer surface of the latter sections, is something which requires time, the building up of large masses of insulation by hand application of thin tape being a slow process.

II. The New Joint

In the new joint which we will now describe, the insulations in No. 2, No. 3, and the two regions No. 4, as well as the metallization, is all done by applying *one sheet of insulation*, and this is applied by machine. The joint is shown in Fig. 3; the length of the joint is about 40 in., the distance from edge of sheath to edge of sheath being 38 in., and the inside diameter of the lead sleeve being

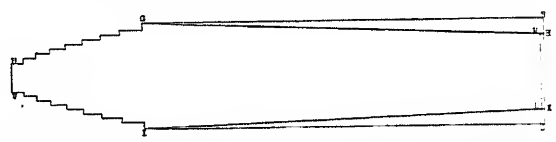

Fig. 4—Long, Unrolled, Single Sheet of Impregnated Paper, UGNOV, Used to Insulate the Joint of Fig. 3 (To very Different Scale) The Region to the Left has been Cut so as to Fit the Steps of the Joint when the Sheet is Rolled around the Joint. The Lines $G\,H$ and $I\,K$ are Thin Strips of Tinfoil Cemented to the Paper. The Region $H\,K\,L\,M$ is Covered with Tinfoil.

5 in., the length of the applied insulation $C\,E$ is 35.5 in., and its thickness $E\,F$ is 1 in.; the conductor diameter and cable insulation thickness are each about 1 in. An ordinary connector is used, and a few layers of ordinary hand-applied tape and saturated twine are applied over the beveled ends of the connector, filling up the lowest step until a smooth cylinder is obtained. From that point on up to the surface $C\,E$, a long roll of paper the full width of the joint is wrapped around, this being one continuous operation with one piece of paper shown diagramatically in Fig. 4. This long sheet of impregnated paper, which is 165 ft. long and 35½ in. wide, could be cut in advance to fit the steps, as shown in Fig. 4. Actually, we cut it by machine *as it is being applied*, thus making a very perfect fit. Referring to Fig. 4, lines $G\,H$ and $I\,K$ have been metallized (as will be described later) and also the region $H\,K\,L\,M$. It should be pointed out that Fig. 4 is quite diagramatic, as in the actual roll the ratio of length to width is about eleven times as great as in Fig. 4. When, therefore, this wide roll of paper is wrapped around the joint in its final position, it will be obvious that there will be formed in effect a solid tube of paper, containing metal cones. $A\,B$ and $D\,F$ in Fig. 3 are the metal cones imbedded in the tube, and the entire outer surface of the applied insulation $B\,D$ will also be metal-covered due to the metallized region $H\,K\,L\,M$. After the wide roll has been applied, the usual metal sleeve is applied, which may be of any diameter desired as long as it clears the line $C\,E$, and then this sleeve can be filled with compound which has low dielectric loss. It may be a hard compound if desired, so that the joint itself will require no maintenance at all, in view of the fact that

the compound is entirely shielded from stress in the joint. There is no problem of a suitable jointing compound for this joint.

As to the details of applying the wide roll of paper to the steps, and the latter part containing the metal, this is done by the machine shown mounted in place in the manhole, Fig. 5. The picture was taken actually on the laboratory wall, but the stanchions are actual stanchions used and the spacing between joints is the same as that used in the case of a Philadelphia company's 75-kv. cable. The cable ends can be seen sweated together by

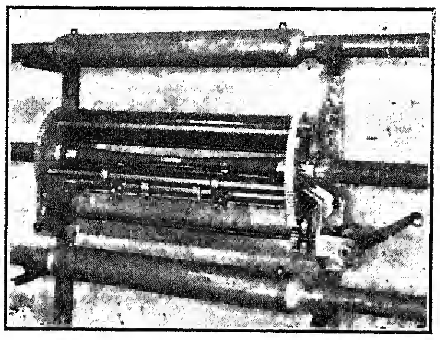

FIG. 5—MACHINE READY TO WRAP PAPER INSULATION IN STEPS

the connector in the middle, with the insulation cut into a series of steps. At the top of the machine is the wide roll of metallized paper, and on the bottom rods of the machine can be seen the knives for cutting the paper to fit the steps; also the two V-blocks which bear against the steps and hold the cable central in the machine against the tension of the wide paper. Fig. 6 shows the process after the steps have been filled with paper, the full-width paper being wrapped on. The strips of tapering tinfoil can be seen at each end. The roll of wide paper is mounted on the drum and the drum revolved around the cable, feeding off the wide paper as it goes. The paper passes in and out of alternate rods and is put under tension, adjustable by the number of rods used, by the course of the paper on the rods, and by the location of the movable rods. Tension is also applied by pressure on the roll of paper.

The two cable ends are stripped to have enough conductor exposed at each end to permit their being jointed together by a copper tube which is sweated to both of them. The lead sheath is then removed for the required distance from each end and the necessary number of steps are cut in the cable insulation by hand, though we have planned to have this also done by the same or another machine. The jointing machine is then clamped onto the cable, and in its latest form it is supported by brackets which are held by the same vertical racks that hold the cable hangers. After the steps have been cut, saturated twine and a few layers of paper tape are applied over the connector to build it up to a smooth cylindrical surface at about the level of the lowest step. In another form, no twine nor tape is used. Perforated tinfoil is then applied to the cable insulation for a few inches at each end adjacent to the lead sheath (*i. e.*, from the sheath to slightly beyond *A* and *F* respectively), and grounded to it so as to continue, electrically, the lead sheath out to the point where the tinfoil cone will eventually be formed. The foil is perforated so as to offer an easy path for the flow of fresh compound from the joint (and its reservoir, if used) to the cable insulation.

Then the wide roll of paper is put on the machine and the two small cutters are set on one of the tie-rods directly opposite the shoulders of the first step. The paper is drawn through the cutters by hand to cut a few inches of the right width, and this is fastened to the hand-applied tape around the connector. The machine is then started, being driven either by motor or by hand. As the paper is rolled onto the cable, the two knives cut it exactly to the width of the first step, the spare paper at each side being cut off and thrown away as it accumulates. When the space between the first steps is filled up, the cutters are moved out to the shoulders of the next step and the paper is cut to fit there, and so on, until the paper has been wrapped up to the diameter of the original cable.

At this point the tinfoil strips appear on the sheet of paper (points *G* and *I* of Fig. 4), and are wrapped over the tinfoil which extends out from the lead sheath at each end. The knives are removed from the machine and the machine revolves, wrapping on the wide roll of metallized paper continuously until it forms the completed tube, the metallized portions taking care of them-

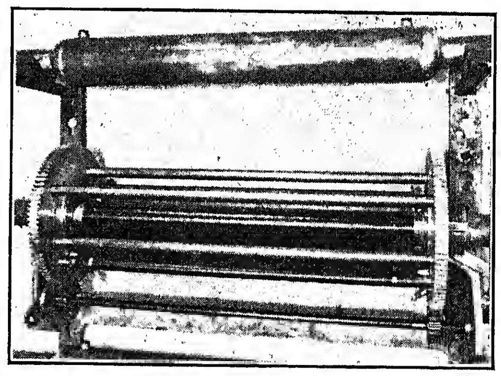

FIG. 6—SHOWING CABLE AFTER STEPS HAVE BEEN FILLED WITH PAPER AND FULL-WIDTH PAPER WRAPPED ON

selves. Compound is poured onto the wide roll at each revolution. The tension is maintained steadily, and thus the final result is a mass of solid insulation, free from air and of the highest quality.

The fundamental requirement of a joint is high breakdown strength, and the test results will be given later. We have, however, in this joint the fortunate combination of high breakdown strength with excellent and simple mechanical qualities. It will be seen that the whole operation is extremely simple, only one article

being applied to insulate the entire joint, and the difference in time between this method and the method of hand or machine taping is very great. For instance, in an actual field installation in a rather small manhole and with a crude and rudimentary form of machine, the entire process of applying the metallized tube, including cutting the paper to fit the steps and wrapping it on the steps, was done in a minimum time of 1 hr. and 2 min., and a maximum time of about 1 hr. and 30 min. In the field, with the final design of machine, 75-kv. joints have been insulated in as short a time as 20 min. This means that the entire insulating of the joint with the exception of one or two layers of hand-applied tape over the connector was done in these respective periods of time.

One additional feature should be emphasized: The first joints made were somewhat different. Narrow tape used to be applied to the stepped region by hand and then the metallized tube was applied from that point on, making a much longer process because of the time required for the taping. It is extremely difficult to start a sheet of paper as wide as 36 in. without entrapping air, and there is always some curvature of the cable core, which greatly increases the trouble. In fact, the only reason good results were obtained was because even though air-gaps may have existed when the wide paper was first put on, the later tension applied squeezed out the air and compound and straightened the cable. The author thinks that it would be almost impracticable, however, to attempt the use by hand of any roll of paper wider than the 3-ft. When wide paper is applied to the steps by machine, however, the paper roll is essentially a straight cylinder after its application. It will be seen, therefore, that as it is applied, the cable core is straightened automatically and gradually, as it is held central against the tension of the paper by adjustable arms on the machine. As soon as the paper has filled up any particular set of steps, that region is straight, and it is believed that the method could be used for almost any length of joint which need be considered, because the cable core will be straightened, step by step, and when the final metallized tube is to be applied, a perfectly straight cylindrical surface will be available.

III. Test Results

In developing this joint, there have been made and tested over 100 of the metallized tube joints. The first 60 joints tested were in the form of short, straight pieces of cable, there being only about 1 ft. of lead between the wipe of the joint and the temporary test terminal, this straight sample being tested in oil. From that time on, due to the difficulties with temporary terminals for the higher voltages, we have jointed two 15-ft. sections of cable, bending the cable into a U, and applying complete out-door porcelain terminals to each end.

The joint is of such a type that its breakdown strength for voltages applied for a short time will be considerably above its long-time breakdown strength. For that reason, most of our tests have been at voltages which the joint could maintain for a period of hours. It hardly seems worth while to present a tabulation of the tests on all the hundred odd joints made, as this would involve details of their construction, a great deal of which would not be of permanent value, due to changes later made in the joint. The author will therefore merely give the tests on the final design of joints, after numerous small modifications had been made in view of his earlier work. Table I gives the test results on all of the joints of the final design of cable insulated with 30/32-in.

After completing this series of tests, tests on cable insulated with 24/32-in. were started and it was found

TABLE I

EXPERIMENTAL JOINTS

SINGLE-CONDUCTOR CABLE INSULATED WITH 30/32-IN. PAPER

Test voltage	Time		Location of failure	Remarks
	Hrs.	Min.		
200 kv.	28	0	Joint

6 hr.	57 min.				Joint
6 hr.	1 hr.	1 hr.	1 hr.	6 min.	Cable

that the breakdown strength of the joint was by no means as good, the failures invariably occurring in the joint rather than in the cable. After a series of experiments, it was found that with the higher stresses due to the thinner insulation, it was necessary to make the change in the field less abrupt as the diameter enlarged in the joint. The angle between the cone of tinfoil and the axis of the cable in the joint described above was 11 deg. For a cable with 24/32 in., excellent test results could be obtained if the slope was decreased to 7 deg., and Table II gives a tabulation of the tests made on cable with thin insulation and modified slope of foil. For purposes of convenience, since the tests took such long periods of time and tied up the whole laboratory, it was decided to accelerate the tests by keeping the voltage at 200,000 for 6 hrs. only, and then increasing

the voltage 10 per cent per hour. Unfortunately, it was not practicable to make a series of tests to tie together the two tables and make them directly comparable.

All voltages mentioned in this section are 60 cycles, a-c. (r. m. s.) the voltage being measured by a crest voltmeter, checked by a 50-cm. sphere-gap with the load on, and are between the conductors and lead sheath of a cable.

In addition to this experimental evidence, six of the joints have been in service since February 1926 at 75 kv. in Philadelphia, at the end of a cable line and where it connects to an overhead line about 40 mi. long, where the joints are thus exposed to all incoming voltage rises. One hundred forty of these joints have been in service also in Philadelphia since October 1926, and it is planned to use this joint on three of the experimental lines of 132-kv. cable shortly to be installed.

IV. Metal-Bearing Paper

The principle embodied in the long sheet of paper which when applied forms a cone of metal, has a wider application than merely to joints. It may be applied wherever it is desired to reduce stresses by enlarging the surface of an electrode and at the same time to insulate

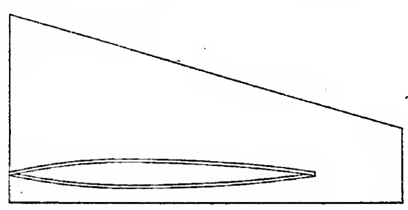

Fig. 7—Single Sheet of Impregnated Paper Bearing Two Strips of Tinfoil, Converging at Their Ends, used to Form the Terminal shown below. (The Vertical Scale is Correct; the Horizontal should be Increased about One Hundred Times)

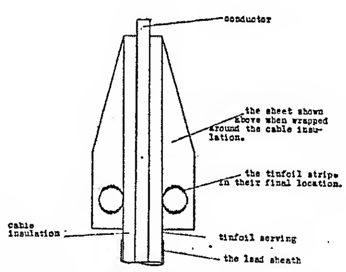

Fig. 7A—Temporary Test Terminal for a Cable

this enlarged surface. It has an obvious application in connection with terminals, either temporary terminals or permanent terminals, for cables, or in connection with bushings in general. One form we have tried out is illustrated in Fig. 7, where the lines of metallization of the paper and a cross-section of the completed terminal are shown. By applying metal to a wide roll of paper as shown in Fig. 7A, and applying it to the cable, a complete torus can be formed which, itself, is insulated positively and definitely by solid insulation of high quality. This greatly reduces the stresses at the edge of the sheath, and at the same time insulates the points to which flashover is likely to take place. There is an endless variety of shapes which can be thus formed by different methods of applying the metal to the long sheet of paper.

In regard to actual details of how the metal is applied, this can be done in various ways. A thin strip of tinfoil can be applied on one or both sides of the sheet. The paper can be metallized by a spray process on one or both sides, on one side by a spray process and having this region perforated so that the metal would go through the sheet. It also could be done in a very perfect way by metallic inlays so that the surface would be entirely smooth and there would be no building up of thickness at this point. In our actual joints, we have used throughout the very simple method of cementing a 1-mil strip of tinfoil 3/8 in. wide to one side of the paper. We have never had any trouble with the tinfoil; it stays on through impregnation, it is not bothered by the jointing machine, and it has given no difficulty. In fact, we had so little difficulty with the wide paper rolls that when we were using the wide paper over the outer part, applying it over a hand-taped stepped region, we used the same roll for as many as four test joints, reimpregnating each time. Even with this handling the foil gave us no difficulty. Obviously the foil does not make a continuous cylinder but is really in the form of a flaring spiral, whose edges simulate a cone. The only trouble we have had at all with this simple construction has been in making terminals such as that shown in Fig. 7. In this figure the layers of foil are superimposed over each other so many times that there is a building up, and some spaces are formed between paper layers, tending to form wrinkles. For a construction such as in Fig. 7, special means should be taken.

V. Conclusions

The main purpose of this paper is to describe what is believed to be a new principle in the making of cable joints and to give the experimental results obtained with a joint of given dimensions. Whether the particular tests shown in Table I are sufficient for cable for 132,000 volts, three-phase is a point which may be debatable. If it should be considered that they are not sufficiently high, better results may be obtained by making a larger joint, and this is entirely practicable. Obviously, it will be seen that the joint could be applied also to three-conductor cable with some modifications, or without modifications to the three-conductor Type H cable.

This method of making joints is applicable to the jointing of paper-insulated cable impregnated with such a thin and fluid oil that the oil would escape if the lead is cut. It is merely necessary to surround the present machine with a tank full of clear oil and, without going into all the details, remove the lead sheath of the cable under the oil, thus preventing any loss of oil. The present joint can then be made under oil, and, in fact, there are some advantages of insulating under oil in any

case, since the trapping of air is even more definitely impossible. The completed joint is then enclosed in a split oil-tight casing which can be bolted together, the machine and oil tank are removed, and finally an outer sleeve is wiped to the cable at each end around the inner sleeve and the space between them filled with oil.

The various features of the joint are covered by patents of the author, and the machine, by a joint patent held by him and F. D. Barbour, all being the property of the company with which they are both associated.

The cooperation and assistance of Mr. J. Cadwallader and Mr. W. C. Cadwallader, in the development of the joint, are gratefully acknowledged.

Discussion

D. W. Roper: Mr. Simons has introduced several new points in cable joint design for which he should receive due credit.

We have used a few of these joints in Chicago. In making up the joints, the cable splicers and the engineers who were supervising the construction, had occasion to suggest one comparatively minor change which they thought would improve the joint. The change was not acted upon or received with any great degree of enthusiasm and we did not urge it. However, in giving some further thought to the subject and in looking over some of the patents that have been issued on joints to others, we discovered that the suggestion which we had made for a change in this particular joint was covered by a patent issued to another individual, and controlled by another manufacturer.

This situation appears to be getting somewhat worse and apparently it is going to become more complicated within the next few years. During the past year the industry has, for a consideration, acquired a fundamental patent covering one feature of central station design which threatened to hamper the development of the industry, and after its acquisition threw the patent open to everybody without further charge.

If the cable joint patent situation develops into a somewhat similar state, it may be expedient for the industry to consider, in the same way, the taking over of the patents for a consideration, so that by a combination of the features, covered by the patents of various individuals, a much better joint can be made, than from the patents of any one individual or corporation.

T. F. Peterson: One point which the author emphasizes seems to me to be questionable. Failure of the composite structure consisting of oil, paper, etc., along the dotted line of Fig. 2 is attributed to the decreased strength of the so-called long oil path. This should be more fully demonstrated, or substantiated by proof before being adopted as to the true reason for the occurrence.

Consider the elementary case of two insulating materials in series,

length l_1, l_2 permittivities K_1, K_2

gradient g_1, g_2 and applied voltage E

$E = g_1 l_1 + g_2 l_2$, and since D, density of electric displacement $= g K$ (1)

$$E = \frac{D\,l_1}{K_1} + \frac{D}{K_2}\,l_2 \qquad (2)$$

$$D = \frac{E}{\dfrac{l_1}{K_1} + \dfrac{l_2}{K_2}} \qquad (3)$$

$$\frac{D}{K_1} = g_1 = \frac{E}{l_1 + l_2\,\dfrac{K_1}{K_2}} \qquad (4)$$

When l_1, the thickness of oil path is small

$g_1 = \frac{E}{l_2} \cdot \frac{K_2}{K_1}$ = Average Gradient $\times \frac{K_2}{K_1}$ which is maximum value possible.

From equation (4) it is evident that as l_1 increases g_1 decreases. It seems quite improbable that, even though oil with maximum stress is not broken down, a path can be found where a lower stress is actually in excess of breakdown value. Such a condition could exist only when rate of change of strength with increase in l_1 is greater than $\frac{d\,g_1}{d\,l_1}$. I doubt very much whether this is the case for series oil paths less than 1 in. (Breakdown gradient of oil remains fairly constant within this range.)

I should much prefer to consider failure as being due to overstressing a comparatively short path of oil ($K_1 = 2.5$) in series with a long path of paper (K_2 = approx. 3.5). This is in accord with my experience with testing crotches, composite insulation, etc. The latter has lead to our avoiding short paths of oil in series with high-dielectric-constant materials rather than long ones.

Turning now to the joint proper, it is indeed surprising to note that the author considers the use of hard compound permissible. In Brooklyn we have a great mass of data on the migration of petrolatum compound from joints. This has seriously weakened penciled paths and necessitated refilling at 6-month intervals or continually by means of reservoirs. If this has been found necessary at 33 kv., how much more so is it necessary to insure keeping even a "sticky" oil in paper of a 132-kv. joint.

Mr. Simons complains of difficulties experienced in wrapping metal foil on conical surfaces. We have been doing this in the field for about $1\frac{1}{2}$ years, without any apparent trouble.

I am somewhat skeptical concerning the use of the machine or single paper application to three-conductor joints in metal-sheathed cable. First, the general method does not lend itself very well to jointing sector cable. Then too, its use makes it impossible to maintain a lay or twist of conductors through joints. This is of considerable advantage in "phasing out" cable. It would seem that hand wrapping must needs continue in such cases.

In concluding I might say that I consider none of the fundamental principles used in the design of the joint as being new. We have used built-up conical structures of solid insulation wrapped with metal foil thus getting a flared zero-potential surface for several years; stepped insulation is standard in many joints; one-piece paper wrapping is an important feature of the Pirelli joint.

However, the method of construction which results in the practical introduction and use of all these principles, in one operation, is decidedly unique.

S. I. Oesterreicher: Aside from the new and comparatively simple method of making an almost factory-taped insulation in the field, it seems to me that this joint is no radical departure from other shielded cable joints.

The method of paper application may eliminate the much feared voids; however, the fact that the joint is also shielded, would indicate that there are other weak places besides voids in cable joints.

Naturally, one may ask, where?

Mr. Simons partly answers this by describing the breakdown of some extra high-voltage cable terminals which failed at a certain point on the flare of the end bell, where there was by far more insulation than in the cable proper. I have had similar disappointing experiences about the behavior of certain dielectrics. However, I do not believe that the insulation failed because I lowered the dielectric strength per unit thickness, but it failed because it had a greater stress along the line of breakdown than anywhere else.

In my opinion, the shape of the end bell, or that of a cable sleeve, or in more general terms the size and shape of two electrodes separated by a dielectric may considerably increase the dielectric layer stress at certain critical points.

In his classical work, Maxwell shows the field layer displacement upon unsymmetrical electrodes by his model condenser consisting of two electrodes, one a half plane, the other a full plane. While this model condenser might not be the exact duplicate of the conditions existing in a cable joint, the similarity is apparent.

Disregarding the ends and joints of a single-conductor cable, it may be represented by a concentric coaxial condenser of infinite length, or in a diagrammatic way by two symmetrical electrodes separated by a uniform dielectric. At the ends or at the joints the symmetry of electrode arrangement is disturbed, and the internal layer stress becomes distorted. With certain assumptions, Loebner, a research worker of the Duisburg Cable Works, obtained for cable ends identical curves to the ones of Maxwell's model condenser.

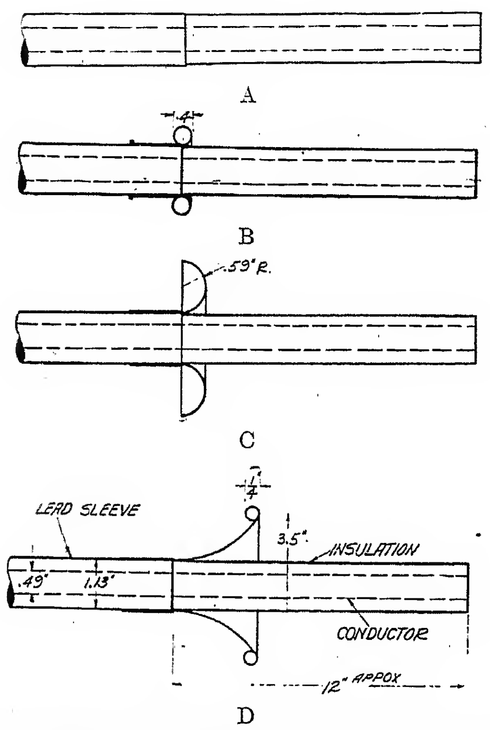

Fig. 1—Streamer Discharge Starts at A—30 Kv., B—40 Kv., C—60 Kv. and D—80 Kv., Plus or Minus 2.5 Kv.

From this data a nomogram was constructed by which—if the normal internal cable field intensity is known, the horizontal critical stresses may be readily found.

The practical importance of this investigation is readily understood by the following diagram from Loebner's work in which four sections of the same cable are shown. The outer sleeve of each section is formed to a different shape. While the straight sleeve shows streamer discharge at 30 kv., already, the funnel-shaped sleeve may be stressed to 80 kv. before streamer discharges appear.

Thus, I believe that a cable joint insulated in the most careful manner, may be unsatisfactory if the sleeve design is not fitted to the other characteristics of the joint.

While an electrostatic shield, if properly applied does distribute the unequal strains, it will not protect without reservations.

In view of this, it seems to me that the claim in the paper, that any diameter of a sleeve may be put over the insulated joint, providing it clears the paper insulation, should not be accepted in its strict sense.

R. J. Wiseman: For testing the joints, in Table I, Mr. Simons used 200 kv. In Table II, he started with 200 kv. and then raised the voltage in steps. Now we cannot evaluate just by looking at the tables, the relative advantages of this type of joint for the two different operating voltages. If we can only decide upon some single method of testing cable joints, and then evaluate to a specified voltage stress at the conductor rather than the average stress, I think we shall all get a better idea of how good joints can be. Today we do not do it, one company uses one method and another company a different method.

W. A. Del Mar: Dr. Wiseman has made a very good point, in my opinion, in making a plea for standardization of such tests.

One of the features that should be standardized is the internal pressure of the joint when it is being tested. Ordinarily, tests on joints have been made with the joint closed in the ordinary way. When voltage is applied, there is dielectric loss, which causes a temperature rise with consequent expansion, and internal pressure in the joint. The result is that the breakdown voltage in the joint is materially increased over what it would be with atmospheric pressure.

Under the term "dielectric loss" I include and refer particularly to the energy liberated just prior to failure by destructive ionization.

This situation can be averted either by attaching a bellows device to the joint, or by leaving an opening in the sleeve, either of which will introduce atmospheric pressure. If we do not do this, a high breakdown voltage may mean nothing more or less than a high dielectric loss or ionization in the joint, and this defect would be accounted a virtue on the basis of a high breakdown voltage.

C. N. Rakestraw: I want to discuss the fact that Mr. Simons apparently takes for granted that the type of joint should be a stepped or penciled joint, as far as the insulation is concerned.

As a good many of you probably know, in connection with our development work in Cleveland about four years ago we did a considerable amount of experimenting with just this type of joint, and in fact eventually did develop a joint of wrapped or taped insulation which apparently would stand up. Our experiments showed very conclusively that one certain number of steps was preferable to anything else, and a considerably less number than Mr. Simons has shown in his diagram. As a matter of fact, of course we later found a combination still better than that, and abandoned the idea of a stepped insulation entirely. We went to a conical connector obtained by undercutting the insulation, and the use of this conical connector increased the voltage of any joint on which it was used about 50,000 volts. So it seems to me that it is a step backward to use the insulation wrapped joint.

With a joint made by cutting the original cable insulation in steps, and then wrapping these with tape, I think it is universally found that a breakdown, when a breakdown can be accomplished, starts somewhere in the center of the joint, very often under the first step or the second step, and passes almost entirely within the original insulation, and then to whatever sleeve encloses the joint.

In Mr. Simon's joint, the end is protected at an angle of about 15 deg. Now, it doesn't seem to me that the difference made by wrapping the center of the joint with one single sheet of paper as compared with tape makes a great deal of difference; but it does make a great deal of difference if the insulation is carried unbroken to the center and the central connector is protected at an angle of about 15 deg. This, as I say, has shown an increase in breakdown voltage of about 50,000 volts on this type of cable.

E. D. Eby: This paper conveys the impression that there are insurmountable difficulties in the way of making a successful joint with tape, which is economically competitive with the joint insulated with a single sheet of paper. It would seem proper to correct this impression by referring to the fact, that practically all the joints which have been made on these high-voltage cables

during the past year, have been made either with paper tape or specially processed varnished cambric tape. The 75-kv. joints made in Chicago were produced complete in about 4 hr. The 132-kv. joints now being made in Chicago, I am told, are being completed in about 6 hr. In our experience, both in factory tests and customer's tests, this type of joint has proved stronger than the cable in every case. From these facts, I think it is evident that the taped joint is entirely practical.

With reference to the practice of removing the cable insulation in steps, the merit of this is well illustrated in its application to some of the Cleveland type joints in Philadelphia, which were made with the enlarged connector having the same diameter as the conductor insulation. Some of these joints failed when the cable line was tested, apparently because of incomplete filling of the undercut in the insulation with the solder. These joints were successfully repaired by stepping the insulation and applying varnished cambric tape, without having to renew the cable section.

I want to add a word to the subject of testing. It is highly desirable that our tests should be comparative and I would recommend, as a basis of tests for joints and terminals, the program of testing set forth in the A. E. I. C. rules for cables. We have been following these rules in our development work on joints so that our own tests could be compared. If this program were generally used, the different designs of joints could be readily compared.

Let me emphasize also that any high-voltage joint, as well as the adjoining cable, is greatly benefited if a thin mineral oil is used as a filler. The migration of the oil into the cable, if it is not already a so-called oil-filled cable, improves the cable by preventing the formation of voids in the insulation. By placing an oil reservoir in the form of an oil filled joint in each end of the cable section, each length of cable is fed from two directions. Some operating companies have already found that the filling of joints with oil has sufficiently improved the strength of old cable so that the operating voltage could be materially raised and successful operation secured.

D. M. Simons: Mr. Peterson apparently does not agree with me in my explanation of the failure shown in Fig. 2. There are of course two effects, namely the decreased strength of oil in thicker layers, and also the difference in specific inductive capacity between the oil and the impregnated fibrous insulation. Mr. Peterson emphasizes the latter, while I emphasize the former. The actual truth is probably a combination of the two effects, but I cannot agree with Mr. Peterson that the breakdown gradient of oil remains constant up to paths 1 in. long, and would refer him to Peek's Dielectric Phenomena, Table LXIV for instance. A third effect is undoubtedly the tangential or longitudinal stress in the fibrous insulation and particularly along the dividing surface between the fibrous insulation and the oil, which stress is a function of the slope of the sleeve as emphasized by Mr. Oesterreicher in his discussion.

It is of course very necessary that the correct slope should be used in the tapering portion of a joint or terminal, and I brought out the importance of this in the text immediately following Table II. Theoretically, I agree with Mr. Oesterreicher that the slope should not be a straight line. Practically, however, with the small angles used, there seems no sufficient justification for using other than the straight-line construction for the slope. Mr. Oesterreicher questioned my statement that the diameter of the sleeve was of no consequence. Possibly he has forgotten that the entire joint is shielded inside by a metal coating of the cylindrical portion and by the tapering tinfoil at the ends. That is, the joint is completely shielded inside, and the outer sleeve is merely a mechanical covering, and its shape and dimensions have no electrical function.

I heartily agree with all the remarks about joint-testing standardization. It is usually possible to obtain a joint or to design a joint, which will stand any given test up to the demands of present cable practise, if the correct design principles are used. One of the most difficult questions for a given voltage however is to determine what the proper tests should be.

Mr. Del Mar's remarks on internal pressures are much to the point. I might add that some of our tests on joints were made with the joints as cold as minus 10 deg. cent. and up to about 20 deg. cent. without observing any effects on the strength.

Mr. Rakestraw tells us that in their design of joint, they are able to add 50,000 volts breakdown strength by abandoning stepped insulation and developing their enlarged connector with undercut insulation. He unfortunately does not mention whether the increase of 50,000 volts was in short-time strength or in long-time strength, and there is a vast difference in significance between the two. He also indicates that a certain number of steps seems better than either a greater or less number. It is difficult to generalize on such questions, and all that can usually be stated is that a specific number of steps or a particular type of connector is better with a certain design of joint. I formerly shared Mr. Rakestraw's belief that a certain number of steps was the best. While not desiring to generalize too much myself, I believe now that the greater the number of steps the stronger the joint, but that the percentage gain is so slight after a certain number of steps have been chosen as not to justify the increased labor of cutting more steps. In regard to the enlarged connector and undercut insulation, while this construction has increased the strength of the type of joint Mr. Rakestraw was discussing, it distinctly is not as effective as the stepped insulation with our type of joint, as determined by practical experience. I do not believe that it is safe to state that any one construction of connector is better than any other, but merely that certain types are best for certain designs of joints, and the only criterion is the strength of the completed joint, which in our case is indicated in the tables given.

I am glad that Mr. Eby has commented on their success with applying tapes by hand, as opposed to the use of wide paper. I may state to Mr. Eby that my paper was actually written before the development of the joint to which he refers, and that possibly my statements were a little too emphatic. In general, however, the application of wide paper is inherently quicker than that of narrow tape. For instance, if the applied insulation is to be 3 ft. long and tape 1 in. wide is to be used, the roll of tape must be wrapped about 36 times around the joint to form one layer of insulation, while one turn of wide paper will do the equivalent amount of work. I am sure that we all agree with Mr. Eby in his remarks about oil for filling joints, and the beneficial effect of such oil upon the insulation of the high-voltage cable which is being jointed.

Mr. Peterson questions the novelty of the joint, and possibly I was not clear enough in emphasizing exactly what new points were presented in the paper. Stepped joints and electrostatic shields at the ends of a joint are of course known, but I believe that a stepped joint with wide paper in the steps (particularly a stepped joint with wide paper cut to fit the steps at the moment of application), and shields formed by metal previously applied to sheets of insulation in a predetermined slope are new developments. In addition, I might include the machine-wrapping of wide paper, which process insulates from the connector to the outside and automatically forms the electrostatic shields.

As a matter of general interest, I might add that eight of these joints have gone into service at 132,000 volts, three-phase, within the 2½ months since the presentation of the paper, on February 24 in an experimental 132-kv. line, and have operated without incident to the present time.

Oil Breakdown at Large Spacings

BY DOUGLAS F. MINER[1]

Associate, A. I. E. E.

Synopsis.—Much work has been done on the breakdown of insulating oil at small spacings between electrodes. Information for electrode separations of several inches is not as complete. It has been found that sources of ionization external to the gap influence the gap breakdown, so that the design of electrode supports and parts is of great importance.

Data on several sizes of spherically terminated rods or cylinders are presented. Short-time breakdown tests are shown to be quite erratic and a form of long-time test schedule was developed which gives more consistent results. The final test used is called a ten-minute-hold and yields values for a given condition representing the maximum voltage that can be held consistently. This is of special interest in design.

The empirical curves of oil breakdown are analyzed by mathematical methods. A general equation for breakdown voltage in terms of electrode diameter and separation is developed which agrees quite well with the experimental data.

Evidence is presented to show that water in globular form suspended in oil may increase the breakdown potential considerably with spherical electrodes if the separation is several times the diameter.

* * * * *

In common with other dielectrics, whether gaseous, liquid, or solid, transformer and switch oils exhibit a non-linear relation between breakdown voltage and spacing of electrodes in the dielectric. The breakdown value of the standard test cup spacing gives no clue as to the breakdown at large spacings. In bulk, oil has a relatively low dielectric strength due to the rapid increase in ionization by collision. Ionization at the electrodes leads to local breakdown and consequent total rupture. Thus the shape of the electrodes and supports is of prime importance. It is essential that the breakdown between the electrodes chosen is not influenced by corona in the neighborhood, originating in some part of the support with a smaller radius of curvature than the electrode itself. In order to yield useful data on large oil spacings, work has been carried on under carefully controlled conditions.

A number of excellent studies of oil breakdown at small spacings (below two to four in.) have been made[2] and reliable data are available. At larger distances, however, the data are not as complete. The results to to be discussed help to fill out this region and will serve as guides to design where such spacings are necessary.

When the characteristics of materials are investigated, it is always a question whether the material tested should be in ideal condition—a perfect sample, or an average. This will depend on whether the object is to arrive at the maximum quality or at that which can be relied upon for a general run. In the case of insulating oil, extremely high dielectric strength can be obtained with carefully filtered and vacuum dried samples (50 kv. r. m. s. for standard 0.1-in. gap between one-in. diameter flat electrodes).

This quality is exceptional, however, and cannot be commercially maintained. Both the designer and the operator of apparatus have to rely on what more nearly approaches the allowable minimum instead of the maximum quality. For example, good oil of commercial grade may test 30 to 35 kv., r. m. s. for standard test, but in apparatus the oil may be allowed to deteriorate to the point where it tests 22 kv., r. m. s. before it is considered unsatisfactory. The weakest point in insulation or the poorest condition the oil may be in, under normal good practise, may determine the factor

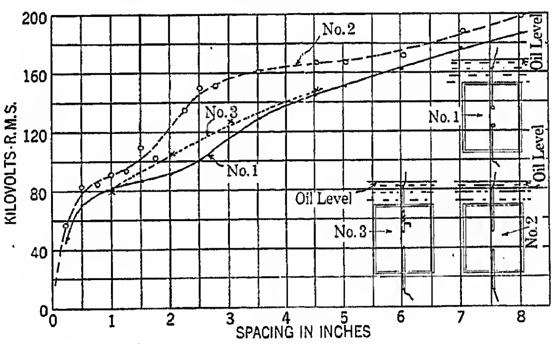

FIG. 1—OIL BREAKDOWN—EFFECT OF IONIZATION—⅝-IN. DIAMETER SPHERES. (EACH POINT IS AVERAGE OF THREE OR MORE TESTS)

of safety of the insulation. These tests, therefore, were made at room temperature using transformer oil of good commercial quality testing 30 to 35 kv. for 0.1 in. in the standard test cup.

I—Effect of Ionization on Oil Breakdown

Before considering the test data on large spacings, it will be necessary to present evidence to show why it is important to eliminate ionization other than that of the electrode itself. A set-up was made using ⅝-in. diameter spherical electrodes, placed vertically in an insulating frame under oil. Comparison of breakdown was made with

a. ⅝-in. sphere with $^1/_{10}$-in. diameter shanks,

b. ⅝-in. spherical ended rods,

c. ⅝-in. spherical ended rods with sharp wire attached.

Test Conditions. The oil was in very good condition, having been obtained fresh, and testing better than 35 kv. for 0.1-in. gap. The test tank was 3½ ft. in diameter and 5 ft. deep. Voltage supply was a 300-kv.,

2. Bibliography, 1, 5, 6, 7.

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

100-kv-a., 60-cycle testing transformer with drum controller giving 500-volt steps on the high side. The tests were what is known as three-minute-hold tests in which the voltage is raised continuously to about 70 per cent of breakdown and then increased at the end of three-min. intervals by five per cent increments. The value used is the last voltage successfully held. The frame for holding the electrodes was made of bakelite paper micarta strips ½ in. thick and four in. wide with a length of 24 in. and width of 20 in. The arrangement is shown in Fig. 1. The sharp wire was a piece of No. 18 B & S copper wire wound around the upper electrode and bent down, the tip being two in. back of the end of the electrode and two in. out to the side.

The three curves of Fig. 1 show clearly the relative breakdown. At spacings up to 1½ in., the rods show slightly higher breakdown (15 per cent) but with separations from 2 in. to 5 in., a pronounced increase over the spheres is apparent. The rod curve can be brought down nearly to the sphere curve by the addition of the auxiliary source of ionization shown. This test, being typical of results obtained, shows the effect of the electrode support shape. For this reason the tests

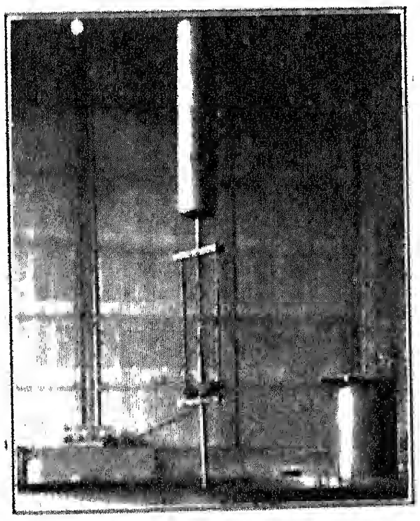

FIG. 2 ARRANGEMENT OF OIL TESTING ELECTRODES

subsequently described were undertaken with electrodes of such a design that no metal part had a radius of curvature less than the end of the electrode. Spherical-ended cylinders or rods satisfy this requirement.

II Oil Breakdown at Large Spacings

In undertaking to obtain data under the limitations imposed, a considerable amount of study and work was put on the design and construction of testing apparatus. A description of this will be given to show difficulties encountered and methods used. The two chief difficulties were in bringing the high potential lead into the oil and in building a test frame that would not fail mechanically or electrically.

A small-sized wire (No. 18) was first used for a lead-in, entering the oil surface in the center of a 20-ft. diameter tank and connecting several feet below the surface to the electrodes under test. This form of lead showed great disturbance, especially at the oil surface, and flashover occurred over a radial distance of 10 ft. at 350 kv. This was due to the excess gradient adjacent to the oil surface which accompanies the distortion of flux due to difference in dielectric constants of air and oil. Excessive corona was evident above the oil surface. A 3⅛-in. diameter brass pipe was later used, being suspended from a string of suspension insulators. This brought about very little improvement, allowing tests up to 400 kv. only, before flashover occurred. This means that the average gradient over the 10-ft. distance is only about three kv. per in. whereas needle points 10 ft. apart flash at 1200 kv. or 10 kv. per in.

The final form of lead adopted is shown in Figs. 2 and 3. It consists of a micarta tube 8 ft. long (spliced) and 21 in. in diameter, covered with thin sheet metal smoothly applied and carefully soldered at the joints. The lower end was fitted with a toroidal piece of wood sprayed with copper. The torus (4-in. section) was cut away to fit flush with the outside of the cylinder. This device was suspended from insulators and electrically connected to a 3⅛-in. diameter brass tube running through the center. The testing rig was hung on this tube. Test voltages up to 700 kv. or more are successfully brought beneath the oil surface with this form of lead.

The first structure used to hold the rod electrodes was a crude affair built to determine the requirements of the problem. It consisted of a spruce board on which two porcelain pillars were mounted 31 in. apart and the rods clamped to these. This arrangement was tied to an 18-ft. wooden ladder and suspended horizontally in the 20-ft. tank. Ropes on the ladder aided in raising and lowering the outfit for adjustment.

The board soon failed by leakage and when the ground wire was arranged not to touch the board, the ladder and supporting rope finally showed leakage and burned badly. The porcelain pillars were also chipped and fused. From this it was shown that a highly insulating frame must be made with no metal parts to cause corona or parts of widely differing specific inductive capacity to cause stress concentration.

The second frame was built of micarta tubes and wooden end clamps arranged for a vertical gap. See Fig. 3.

Two micarta tubes 2-in. in diameter were used with split end pieces of maple clamped around the tubes with ¾-in. threaded wooden rods and micarta nuts. The upper electrode was a 3⅛-in. brass tube passing through the upper wooden pieces for an adjustable length. The frame was clamped to this tube so that the whole rig was hung from it. The lower electrode was a similar brass tube extending below the frame three ft. and ending in a chain which was dropped to the bottom

of the tank for a ground connection. The inner ends of the brass tubes were closed with a hemispherical plug tapped to receive various-sized rods, so designed that no threads or parts were exposed with a radius of curvature smaller than the electrodes under test.

The conclusion drawn from these experiences is that for very high voltage tests under oil, wood, even the best seasoned hardwood commercially obtainable, is unsatisfactory as an insulator. It is suitable for a non-metallic spacer or mechanical support but the insulation must be obtained from porcelain, micarta, fuller board, or similar high class dielectrics.

Two transformers were used in these tests, one 500 kv., 500 kv-a., 60 cycle, 5000 volts primary; and the other 1000 kv., 1000 kv-a., 60 cycle, 5000 volts primary. Both of these are single-terminal, one end grounded units.

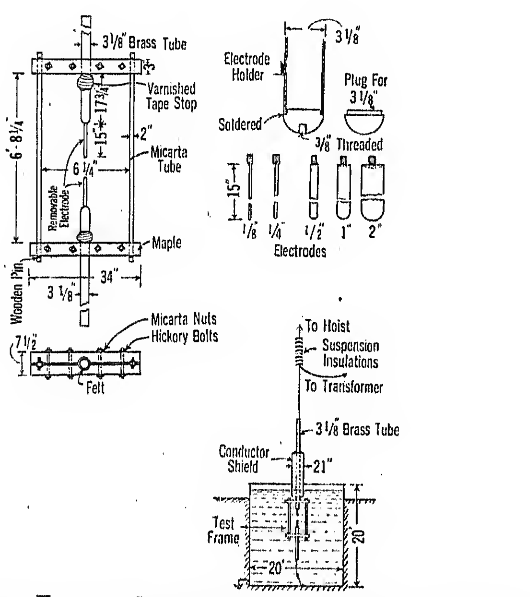

FIG. 3—TEST FRAME. ELECTRODES AND ARRANGEMENT OF APPARATUS

Voltage was measured by both crest voltmeter and ratio meter checked against sphere spark-gap values.

Test Methods and Results. Early tests demonstrated that with favorably controlled conditions (no neighboring ionization due to sharp corners, bolts, etc., and no adjacent field-distorting bodies) instantaneous breakdown values were obtained higher than those given in any existing data. This is of great value in determining the maximum strength of oil. Wide variations in test results were found, however. Later work involved the introduction of time tests and the tendency has been towards data on maximum holding voltages for longer times, one min., three min., five min., and finally 10 min. More consistent data, although much lower than instantaneous breakdown, are hereby obtained. From a design standpoint, these are the values usable in calculating oil insulation—the long-time holding voltages and not the occasional extra high voltages. The curves shown in this report are based on over 1850 observations or applications of potential, a large number being for 10 min.

The discouraging diversity of points shown in the instantaneous breakdown curves led to a study of test conditions, voltage measurement, etc., but reasonble control of these factors did not yield satisfactory results.

Curves of average values do not tell the whole story, especially with instantaneous breakdowns. We consequently have shown in some cases a number of representative points. The relation of average to maximum and minimum can be seen and the dispersion demonstrated.

Instantaneous Breakdown. It has been noted by several observers that oil breakdown for short-time application of voltage is quite variable, even when greatest care in controlling conditions is exercised. This deviation from an average value is far greater than with air[3]. This variation was shown by Hayden and Eddy to be a characteristic of oil apparently due to its chemical complexity. Other dielectrics, such as benzol, were not as erratic. Filtering, vacuum treatment, high temperature, etc., were found to be ineffective in changing this behavior.

Fig. 4, a typical curve, shows the individual breakdown points for one-in. diameter electrodes against spacing.

Voltage was raised continuously by induction regulator to breakdown in less than one min. It is at once

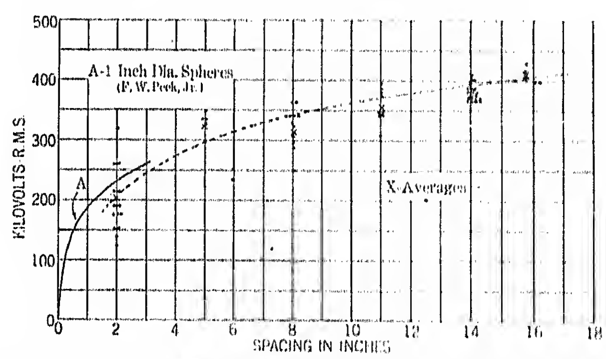

FIG. 4—INSTANTANEOUS BREAKDOWN VOLTAGES OF ONE-INCH DIAMETER RODS

apparent that the widest deviation occurs at small spacings (two in.). For example, with the one-in. electrodes, two-in. breakdown varies between 125 kv. and 320 kv., over 100 per cent.

The following table shows typical results obtained, being data for the two-in. diameter curve.

Spacing in Inches	Instantaneous Breakdown in Kv.
2	310, 285, 285, 285, 328, 260, 315, 190, 205, 315, 140, 180, 165, 175
4	320, 235, 310, 390, 275, 210
5	375, 340, 295, 285, 410, 365, 340, 295, 345, 325
8	360, 345, 390, 350, 345, 410, 450, 340, 470
11	425, 450, 390, 460, 340, 480, 475, 480, 480
12	380, 380, 380
14	410, 425, 370, 350, 450, 360, 460, 470, 450

3. Bibliography, 1.

This dispersion decreases in all cases with increased spacing, giving credance to the idea that with small gaps, there is an erratic lining-up of conducting particles or ionized oil. With longer distances, these variations are ironed out into an average state of conductivity. Thus the effect of poor oil will be more evident at small separation. The instantaneous data are presented to show that even an average of a large number of points cannot mean much when individual tests may depart

Fig. 5 Breakdown Voltages, One-Minute Hold Methods (Curve and Step)

50 per cent in either direction from the average curve. After spending months trying to improve the consistency by a study of test conditions and voltage measurement, we were thoroughly convinced that the proper form of test of oil spaces is a time test in which the minimum consistent holding value of potential will be found.

One-Minute and Three-Minute Tests. This test is defined as the maximum voltage that can be held for one min. without breakdown. Two methods were tried in determining these data, the step method and the curve method (see Fig. 5). After several series of tests made with these methods, the improvement in the matter of consistency hoped for, was not

Fig. 6 Breakdown Voltage, Three-Minute Hold One-Half Inch Diameter Rods

obtained. The step method was found to be preferable. The time was then extended to three min. Much better agreement between data taken at three different times some months apart is noted. The variation is still excessive for a relatively small number of tests. Fig. 6 shows a typical curve.

Ten-Minute-Hold Tests. Instead of increasing the number of tests, it was felt that a better method was to increase the time to 10 min., tending to eliminate the occasional freak values. This followed successful use of the method on transformer insulation tests. The method is very slow and tedious but seems to yield dependable results. A certain voltage is chosen below expected failure. This is applied for 10 min. and then taken off for five min. (to eliminate ionization), and is repeated five times. If no failure occurs, the voltage is raised a certain increment and the five 10-min. holds made. This proceeds until failure occurs

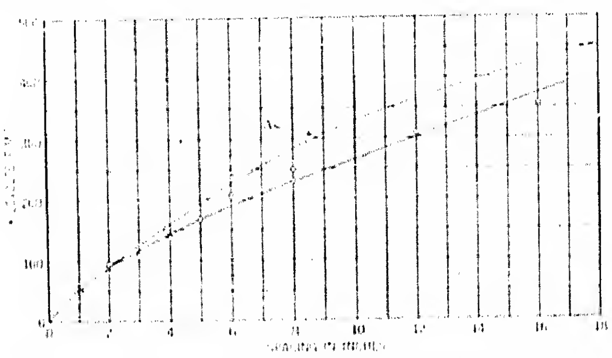

Fig. 7 Breakdown Voltages Ten-Minute Hold Between Points

A Needles, F. W. Peek, Jr.
o Solid curve drawn from data of present investigation (Kv.=53 $S^{0.7}$)
x Data from W. H. Tobey, A. I. E. E. 1910

during one or more of the five tests. Then the previous value is repeated five times and if checked (no failure), that value is selected as correct. Thus the least number of individual voltage applications necessary to determine one point is 15, requiring at least 225 minutes. Typical results of these tests are shown in Figs. 7 and 8, curves for points and one in. diameter electrodes. Fig. 9 gives a summary of 3-min. and 10-min. tests on logarithmic coordinates.

On some of the curves the data of various investigators have been shown for comparison. In Fig. 4, the curve for one-in. spheres given by F. W. Peek, Jr. appears slightly higher than the average curve of data obtained, but still well within the limits of individual points. Fig. 7 is an interesting comparison of

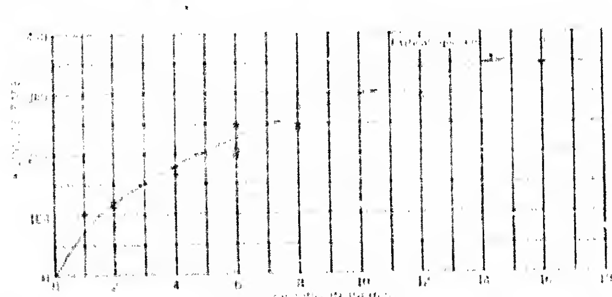

Fig. 8 Breakdown Voltages, Ten-Minute Hold, One-Inch Diameter Rods

data from three sources. The dash curve is taken from "Dielectric Phenomena," by F. W. Peek, Jr. and the solid curve is drawn from data of the present investigation (kv. = $53\,S^{0.7}$). The X's are from data of W. H. Tobey[4] and coincide nicely with the present curve. It seems probable that Peek's curve represents instantaneous breakdown and is consequently higher. The ten-minute-hold values are much lower.

4. Bibliography, 8.

General Remarks on Test Results. From the results of the tests, the following may be inferred:

1. The instantaneous breakdown voltage for oils is not very definite, depending on too many factors that are sometimes not controllable.

2. The "time" tests show better consistency.

3. At short spacings, the breakdown voltage decreases with increased time of application of voltage. At large spacings, the differences between the sparking voltages for a long time of application and those for a short time of application are small and negligible.

4. The breakdown voltage increases with the diameter of the electodes at short spacing rather rapidly. At large spacings these values seem to be the same; that is, independent of the diameter.

Analysis of Test Data. The wide diversity of the test data rendered average readings for instantaneous tests unintelligible. Although results for the three-min. and 10-min. tests were more consistent, still there were some very pronounced deviations. In order to obtain conclusions that might prove of value in design, these data were analyzed so as to bring out some general relation that seemed to be representative of all the test data.

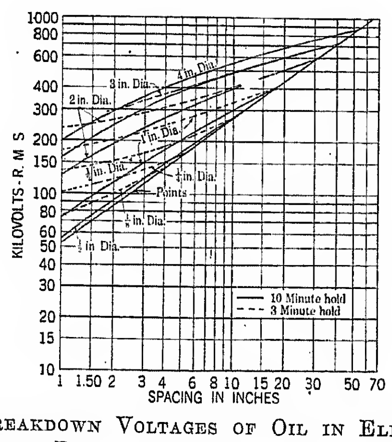

FIG. 9—BREAKDOWN VOLTAGES OF OIL IN ELECTRODES OF VARIOUS DIAMETERS ON THREE-MINUTE HOLD

A. THREE-MINUTE-HOLD VALUES

Plotting results of the three-minute-hold tests on logarithmic paper, (Fig. 9) shows that all the curves seem to be tangent to a straight line at large spacings. From the manner in which the curves behave, it seems probable that the straight line denotes the sparking voltage for electrodes with diameter equal to zero, *i. e.*, for needle points. That all other curves are tangent to and emerge into this straight line may be explained by the following speculation as to the nature of oil breakdown.

It is assumed that there is a definite breakdown potential gradient for oil. When this gradient is reached at the surface of the electrode, the oil surrounding the rod is ionized, the effect being to increase the effective size of the electrode. Whether a complete breakdown as shown by a spark over will follow this ionization or not depends on whether or not the increased size of the electrode causes the gradient to increase. Thus, if the spacing between the electrodes is large, the gradient decreases as ionization increases and in this case corona precedes a complete breakdown, so that if the applied voltage is not too high, only corona is observed. On the other hand, if the spacing is small, the gradient increases as ionization increases and a complete breakdown will follow as soon as the gradient at the surface of the electrode exceeds the breakdown value. It thus appears that for a given size of electrode there is a largest spacing—a critical spacing—at which no corona will occur before a complete breakdown.

Applying this to the case of two sharp points, it is seen that corona will always precede a complete breakdown. Thus, the sharp points are in effect two electrodes of varying diameter, their size being dependent upon the spacing and the applied voltage. For a given spacing the complete breakdown voltage is then the same as that for two electrodes having such a diameter that the given spacing is the critical one for such a size.

In the light of this speculation, we can readily explain why the curves for the electrodes with small diameters seem to intersect and finally emerge into the curve for sharp points. Thus the intersection of the ½-in. curve and the sharp point curve defines the critical spacing for ½-in. rod. At spacings greater than this, corona will occur first so that the breakdown voltage follows essentially the same curve given by the sharp points.

The points of tangency of the curves (on logarithmic scale) and the line denoting needle point might be thought of as those at which corona begins. These points as obtained from the curves do not agree with those that were obtained visually. The discrepancy might be due to the difficulties in making visual observations on the starting point of corona under oil or to the effect of surface irregularities. Above these points of tangency, the sparking voltage curves, on the basis of the above speculations, will follow a law different from that which holds below them. In constructing the sparking curves we should then expect a change in the direction of the curve at some point.

Mathematical Expression for Three-Minute-Hold Tests. As the plot on the logarithmic paper does not yield much information on the relations among the various curves, another plot was made on semi-logarithmic paper, since the general shape of the curves showed them to be of logarithmic form.

The straight line, *i. e.*, the probable curve for needle points on the logarithmic paper, becomes a curve on the semi-logarithmic paper. By trial it was found possible to represent the average test results approximately by a series of straight lines on the semi-logarithmic paper. The general form of the equations connecting the sparking voltage kv. and the spacing S is

$$\text{Kv.} = A \log S + B$$

or

$$\text{Kv.} = A \log \frac{S}{a}$$

where A and a are constants and Kv. = sparking voltage in kv., S = spacing in inches.

Moreover, when the various values of A and a were plotted on logarithmic paper against the respective values of the diameter of the rods, two parallel straight lines were obtained. Thus these two constants could be further expressed as functions of the diameter of the rods. These relations become

$$A = m\, d^n$$

$$a = c\, d^n$$

where m, c, and n are constants and d = diameter of rod in inches. Using these relations, it is then possible to express the sparking voltage in terms of the diameter and the spacing. Thus the general equation for the *three-minute-hold tests* is

$$\text{Kv.} = m\, d^n \log \frac{s}{c\, d^n}$$

With all the constants evaluated, this is

$$\text{Kv.} = 177 \sqrt{d} \log \frac{s}{0.16 \sqrt{d}}$$

It will be noted that the above equation does not become zero, for $S = 0$. It will be noted, further, that the quantity whose logarithm is to be taken is large in all our cases. Thus if we add one to the number $S/0.16\sqrt{d}$ and then take the logarithm, the values of the logarithm will not be increased greatly. In view of the fact that our data scatter more or less, such a modification will not change the results appreciably while the modified equations will give curves that do pass through the origin. Thus we have

$$\text{Kv.} = 177 \sqrt{d} \log \left(1 + \frac{S}{0.16 \sqrt{d}}\right)$$

for three-min. tests.

Curves calculated from this general equation have been plotted and found to be reasonably representative of the test data. For the smaller rods, these curves were calculated only up to the points where they intersect the probable needle-point curve. After that, since we assume the formation of corona, the curve is continued by the equation that represents the probable needle point, which, as already pointed out, is a straight line on logarithmic paper and hence is of the form Kv. = $D\, S^m$ in which D and m are constants. The numerical values substituted give the following as the equation:

$$\text{Kv.} = 53\, S^{0.7}$$

The following table gives the calculated values.

THREE-MINUTE-HOLD TESTS ON DIELECTRIC STRENGTH OF OIL

General Equation: Kv. = $177 \sqrt{d} \log \left(1 + \frac{S}{0.16 \sqrt{d}}\right)$

d = Electrode Diam., (in.)	Breakdown Kv.[1]
$3\frac{1}{8}$	$312 \log \left(1 + \frac{S}{0.282}\right)$
2	$250 \log \left(1 + \frac{S}{0.226}\right)$
1	$177 \log \left(1 + \frac{S}{0.16}\right)$
$\frac{1}{2}$	$125 \log \left(1 + \frac{S}{0.113}\right)$
$\frac{1}{4}$	$88.5 \log \left(1 + \frac{S}{0.08}\right)$
$\frac{1}{8}$	$62.5 \log \left(1 + \frac{S}{0.057}\right)$
0	$53\ S^{7.0}$

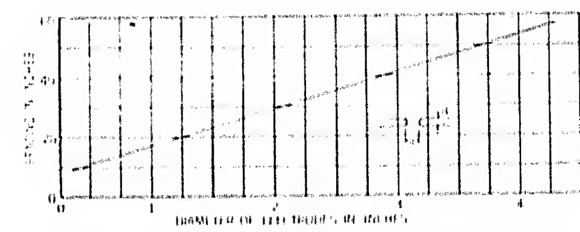

FIG. 10—CURVE OF CRITICAL SPACING TEN-MINUTE HOLD TESTS

Spacing of which curves of rods intersect and emerge into needle-gap curve (graphical solution from calculated curve)

B—TEN-MINUTE TESTS

Applying the same general equation, *viz.*,

$$\text{Kv.} = A \log \left(1 + \frac{S}{a}\right),$$

it has been found that the following equation agrees with test results quite well.

$$\text{Kv.} = \left[380 + 120 \left(1 - \frac{1}{d}\right)^4\right] \log \left(1 + \frac{d}{2} S\right)$$

in which Kv. = safe or holding voltage in kv.,

d = diameter of electrodes in inches,

s = spacing of electrodes in inches.

This is applied when ionization does not occur before breakdown. The same equation as before, kv. = $53\, S^{0.7}$, applies when ionization precedes breakdown.

The intersection of these curves is called the critical spacing and might coincide with appearance of corona if accurate data were available. Fig. 10 was plotted showing the relation between calculated critical spacings and electrode diameter. The equation satisfied by diameters between ½ in. and 4 in. is $S = 5 + 12\, d$.

Breakdown curves for 3-in. and 4-in. diameter were

calculated from the general equation. The equations for 10-minute-hold are as follows:

10-MINUTE-HOLD TESTS ON OIL

Electrode diam. (in.)	Breakdown Kv.
0	$53\ S^{7.0}$
½	$500 \log_{10}\left(1 + \dfrac{S}{4}\right)$
1	$380 \log_{10}\left(1 + \dfrac{S}{2}\right)$
2	$388 \log_{10}(1 + S)$
3	$404 \log_{10}\left(1 + \dfrac{3S}{2}\right)$
4	$418 \log_{10}(1 + 2S)$

Conclusions. The principal result of all this work is the development of more suitable test methods and the fundamental recognition of the inconsistency of short-time tests. Values obtained by long-time tests are much more reliable from a design point of view. On the basis of this information obtained with ideal or standard electrodes, future work of great value is possible, using electrodes of practical and special form.

III—Effect of Water in Large Quantities

Oil Breakdown. Low breakdown of oil samples is frequently ascribed to moisture or foreign materials. It has long been known that very slight percentages of moisture in oil, when in a dissolved state, lower the test value at small spacings. For example, one part in 10,000 will reduce the dielectric strength of dry oil to about 30 per cent of its original value.[5]

Some evidence exists, however, showing that under certain conditions water may increase the dielectric strength of a mass of oil. In Report No. 25 of Electrochemical Laboratories, Tokyo, Japan, Dr. T. Hirobe presents a curve (Fig. 11) which indicates a remarkable increase in breakdown between a point and a disk for a 300-mil gap in fiber-free oil. This increase from 21 kv. to 52 kv. takes place for an increase from zero to 0.028 per cent moisture content. Dr. Hirobe then goes on to show that with ½-in. spheres 150 mils apart there is a decrease from 90 to 61 kv. for the same moisture addition.

A number of tests were made by the author to find the effect, not of small traces of moisture, but of large percentages of actual water in visible globule form, such as may be present when leakage of rain into apparatus occurs.

Wet Oil Tests. A series of tests was made with ⅜-in. and ⅝-in. spherical electrodes using oil into which water had been stirred. The water was introduced in finely divided spray by definitely weighed amounts and agitated thoroughly before test. By this means the water was held in suspension in very fine globules less than one mm. in diameter.

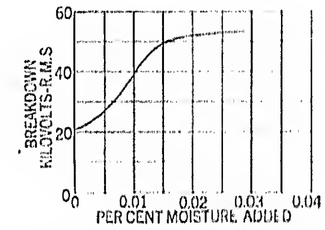

FIG. 11—EFFECT OF MOISTURE ON OIL BREAKDOWN
0.3-in. Gap—needle and disk (Dr. T. Hirobe, Report No. 25, Elect. Tech. Lab., Tokyo)

Preliminary Tests. Two ⅜-in. spheres were placed vertically in a large glass jar holding 25 lb. of oil. The gap was one inch. Various percentages of water were added and the test values were as follows:

Per cent Water	Instantaneous Breakdown	
0	56, 56, 54, 54	avg. 55 kv.
¼ (20 cu. cm.)	60, 60, 60	avg. 60 kv.
½	56, 56, 56, 56, 56, 58	avg. 56.3 kv.
¾	60, 62, 61, 62, 63, 62	avg. 61.6 kv.
1	61, 64, 59, 62, 64	avg. 62 kv.

More extensive tests were then run in a metal tank holding about 1000 lb. of oil. Percentages of water of ⅛, ¼, and ⅜ were introduced and instantaneous breakdown tests made. It was found that ⅜ per cent was about the maximum amount of water that could be held in suspension long enough for test. Instantaneous (rapid rise) values were obtained. As usual, a great divergence of points resulted, the average of which has no great significance unless hundreds of tests are made. With only a few shots (10), these averages are inconsistent, the ⅝-in. sphere breakdown being less than ⅜-in. spheres for some cases.

Average curves for the various water contents, (Fig. 12), were plotted and seemed to indicate that ad-

5. Bibliography, 1.

dition of water may increase the breakdown of oil gaps through gradient equalization. Small amounts (1/8 per cent or less) may possibly decrease the breakdown at small separation, probably because the water is either in partial solution or so finely divided that it has the elements of a low resistance path. Increase in water content causes agglomeration and the larger globules distribute the stress like a string of condensers. This effect increases with increase in voltage.

Another effect noted at high gradients is the throwing out of water from the strongest field. This gives a clarifying action that will ultimately improve the oil considerably if breakdown does not occur before this action is complete. These statements do not contradict the usual information about standard tests on oil with a test cup having 0.1-in. separation of electrodes for here the water bridges the gap and causes failure through conduction. In the curves for 3/8-in. spheres this appears to be the case below 1 1/2-in. with 1/8 per cent water.

The curves show a greater increase in breakdown for the smaller electrodes (3/8-in. diameter). These results differ from Dr. Hirobe's in that he could obtain

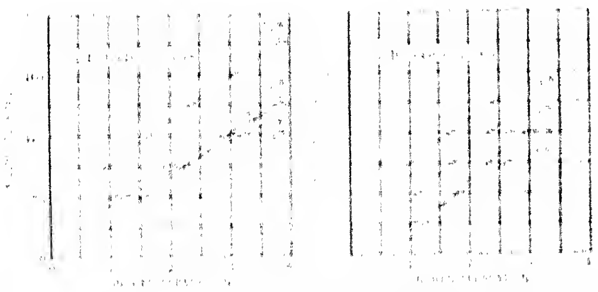

FIG. 12 OIL BREAKDOWN VOLTAGES—INSTANTANEOUS AVERAGES WITH VARIOUS AMOUNTS OF WATER ADDED

no increase with spherical electrodes. It may be concluded then that with spacings several times the electrode diameter, water in globular form evenly distributed may give a higher breakdown value than commercially dry oil, behaving entirely different from the case of dissolved water in small gaps.

The curves of oil breakdown under various conditions as described in this paper show the range of values to be expected but are not intended as accurate data. Exactly duplicable results on oil are impossible. It is the purpose of this account rather to emphasize two points: First, that short-time tests are hopelessly erratic and that the time test of several minutes' duration is preferable in establishing values of use in design; and second, that the experimental data on different sizes of electrodes are related and are subject to mathematical analysis, one form of which is presented herewith.

The author gratefully acknowledges the assistance given by Mr. A. P. T. Sah in analysis of test results.

Discussion

O. R. Schurig: The problem attacked by Mr. Miner, *i. e.,* that of oil breakdown at large spacings of from 1 in. to 15 in. and more, and when subjected to sustained voltage stresses, is of real importance to engineers because (1) the gaps in high-voltage apparatus are commonly of the order of 1 in. or more and (2) because the voltage stresses for a good part of the time are of a sustained nature. The designers of oil-immersed transformers and circuit breakers must therefore take into account the behavior of oils between widely spaced gaps and under sustained voltage stresses. Mr. Miner's data represent an advance of knowledge in this field.

At the same time, however, designers must also provide for sufficient dielectric strength at small spacings and under suddenly applied voltages. In oil circuit breakers, for instance, the sudden formation of ionized gases during circuit interruption has virtually the effect of shortening the clearances, for a few instants, between live and grounded paths of the oil vessel. Moreover, the temporary stresses acting on the oil at such times will often be higher than those occurring during normal operation under sustained voltages. Hence, in the design of such apparatus and in the selection of oils, engineers will need to take into account the dielectric strength of small gaps and for sudden voltages as well.

The second item that I wish to discuss is the point stressed by Mr. Miner that the results of short-time tests[1] are 'hopelessly erratic.' I believe that he does not intend to have that statement apply to tests properly conducted with small gaps, such as the customary 0.1-in. gap between 1-in. disks. If reasonable care is taken in cleaning and drying the electrodes before the test, results of good reliability are obtained.

The following table gives the short-time breakdown voltages with a 0.1-in. gap of three samples of oil of various degrees of purity.

Sample No.	Breakdown voltage kv.	Ave.	Probable error of ave. in kv.
1	51, 59, 59, 58, 62, 62, 48, 48, 47, 54	55	1.7
2	10, 40, 48, 5, 23, 5, 22, 12, 12, 21	20	3.7
3	30, 28, 31, 24, 29, 30, 22, 22, 35, 29	28	1.1

The breakdown values of samples No. 1 and 2 are taken from the test values from which the curve of the accompanying Fig. 1 (which will be discussed later) has been plotted, sample

1. Meaning tests in which the voltage is raised fairly rapidly from zero to the point of breakdown, at a rate of, say, 3000 volts per sec.

No. 1 is the oil sample before being mixed with water and sample No. 2 is the same oil after being mixed with water and standing 1.8 days. Sample No. 3 is a transformer oil containing fibrous particles which were purposely mixed in the oil. By the "probable error," as given in the last column of the table, is meant an error of such a value that the probability of having a

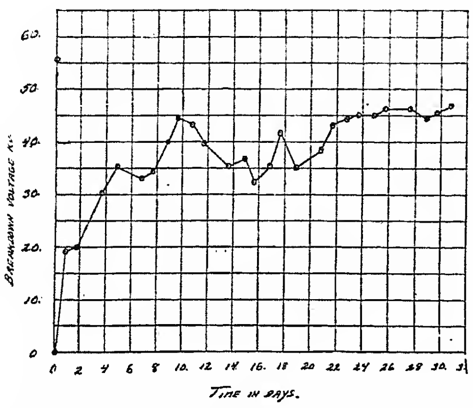

FIG. 1—THE RATE OF SETTLING OF WATER IN A TRANSFORMER OIL AS INDICATED BY THE BREAKDOWN VOLTAGE OF A 0.1-IN. GAP BETWEEN 1-IN. FLAT DISK ELECTRODES.

3 per cent of distilled water mixed in 1.5 liters of new oil by shaking for 4 min.
Number of breakdowns per point 10.
Rate of increase of voltage 3000 volts per sec.
Oil at room temperature, 20 deg. cent.
Breakdown voltage of oil before mixing with water; 55 kv.

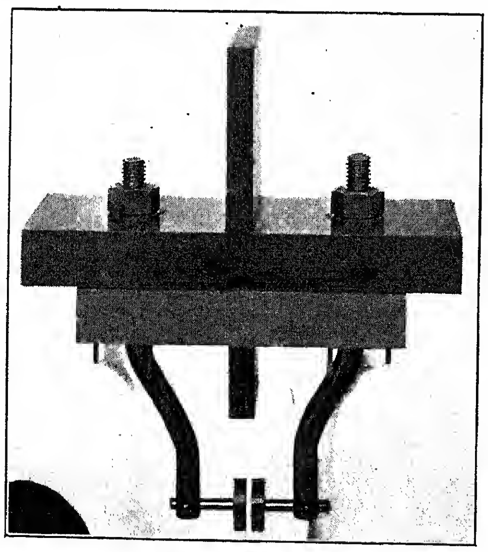

FIG. 2—ELECTRODES AND MOUNTING; 1-IN. DIAMETER BRASS DISKS, WITH 0.1-IN. GAP.

The electrodes were made for placing on a glass jar 3 in. by 5 in. by 7 in. high.

greater error is just equal to that of having a lesser error. This probable error is calculated from

$$P.\ E. = \frac{0.85\ a.\ d.^*}{\sqrt{N-1}}$$

where *a. d.* is the average deviation of the breakdown values from the mean and N is the number of breakdown values, in this case 10.

The third point that I wish to discuss refers to the effect of water on the dielectric strength of oils. Mr. Miner has presented data on the dielectric strength of oil containing water for wide gaps. I wish to outline the results obtained on the dielectric strength of oils mixed with finely divided particles of water.

The tests in question, made with some of the customary high-grade mineral insulating oils, tested with a 0.1-in. gap between 1-in. plane disk electrodes, showed that a thoroughly shaken up mixture of the oil with, say, 3 per cent of water gave initially less than 5 kv. dielectric strength, *i. e.*, when tested immediately after mixing, as is well known. After standing, however, the mixture began to separate with a consequent rising of the dielectric strength until after several days, the water had settled to the bottom, the oil had cleared up and had *regained a relatively high dielectric strength although there was a layer of water under the oil and in contact with it.* This result was consistently repeated in the absence of impurities other than water.

A typical curve is given in Fig. 1, showing the dielectric strength recovery of an oil-and-water mixture allowed to stand after throughly shaking up.

Fig. 2 is an illustration of the electrodes and their support.

The tests were made at Schenectady, as part of a research program aimed at determining the effects of various factors, such as water, carbon, heat, time, exposure to air, fibers, electric field, metals, etc., on the dielectric strength of circuit breaker and transformer oils.

V. M. Montsinger: Generally the breakdown voltage of oil is so erratic that few, if any, investigators have felt like trying to express it by a mathematical formula. The answer to this appears to be, as pointed out by Mr. Miner, that too small spacings have been used, spacings below the critical breakdown value.

I was interested to see that the author finds that for certain conditions, the dielectric strength varies as the spacing raised to the 0.7 power. For design purposes we have used in transformer work a similar law of strength varying as the $^2/_3$ power of the spacing or distance between electrodes. This expression seems to be one of nature's dielectric laws. Not only oil but solid dielectrics with similar electrodes follow somewhat the same law. However, if the electrodes are large flat planes with edges having large radii and the field is approximately uniform, the strength is practically a linear function of the spacing for both oil and solids. In other words, the strength varies almost directly with the spacing. This fact should be kept clearly in mind in generalizing on the laws of dielectrics.

The question of why the difference in the laws suggests itself naturally. The explanation for this is probably about as follows: When the electrodes are of such a shape as to produce a distorted field, this distortion becomes more and more pronounced as the spacing increases. Thus, for example, if the electrodes are small rods or spheres, at small spacings the dielectric field causing breakdown is more nearly uniform than when the spacing is increased. Finally, when the distance becomes great enough, the distortion becomes so great that the electrodes act like needle points, even though they may be many times larger. Mr. Miner's explanation of why they act like needle points above the critical spacing, by the ionization theory, seems a logical one.

The main points which I wish to emphasize are (1), that for uniform dielectric fields the strength of oil is approximately a linear function of the spacing and (2), for distorted fields the dielectric strength varies approximately as the $^2/_3$ power of the spacing or 0.7, as Mr. Miner states in his formulas. I prefer to use $^2/_3$ because it is a value very easy to remember. Roughly speaking, this means that if the spacing in oil is trebled, the strength is doubled, or to be more correct is increased 2.08 times. As regards uniform fields, in practise this condition is seldom, if ever, found. Consequently the $^2/_3$ power law is more nearly applicable than the first power or linear function law.

R. J. Wiseman: In regard to Mr. Miner's paper, where he refers to the effect of water or moisture in his oil, I wonder

*Precision of Measurements and Gaphic Methods by H. M. Goodwin, McGraw-Hill Book Co.

if he has taken into account the possibility that under high stress, with wide spacings, there is a certain attraction of the moisture toward the surface of the conductor, causing an increase in the diameter of that conductor which will decrease the stress temporarily until breakdown occurs. I think that is partially the explanation of why we are getting a higher breakdown voltage with a wide spacing and a large amount of moisture present.

I was very glad to see that Mr. Miner has tackled this problem from the point of view of ionization. We all know rather definitely ionization occurs in gases. Some of us have a pretty definite idea of ionization in solids. This is a sort of connecting link between the two, and I hope further work along this line will be carried on.

Mr. Roper suggested that we find a new way of testing cables for their quality. We are all interested in cables and want to know how we can determine what is a good cable and what is not. We make a good many tests today in order to pick out good cable. Another test means additional work on the part of the cable manufacturer; it is costly to both the purchaser and manufacturer. Apparently the tests today are not giving us what we want. When the cable leaves the factory, as far as we know, it is 100 per cent perfect. When it gets into service, it apparently breaks down. Is it a question entirely of tests in the factory, or is it also a question of operation in the field?

I hope we shall be able to find a new test that will help us to determine high quality cable, but if we are going to have additional tests, let us drop some of the tests we now make which are unsatisfactory, rather than simply add one or more new tests to the number we now have.

F. W. Peek: Those of us who have had experience with oil as used in apparatus know that it is not only the most reliable and consistent insulation but also one of the best. However, oil is very erratic under test, and I wish to point out a few of the reasons.

As used in apparatus, the oil spaces are always divided by barriers of solid insulation. These barriers change oil from an unreliable to the most reliable insulation by preventing lining up of conducting particles. Some of the principal causes of erratic changes in the breakdown voltage of oil are occluded gases and foreign particles such as moisture or fibrous materials. Foreign particles may line up in the electrostatic fields. In the case of large electrodes such as plane surfaces the lines of force are straight lines. In such a field particles readily form chains from electrode to electrode along these lines. A short gap with large electrodes has very high dielectric strength for very good oil but very low strength for poor oil. The percentage change is thus very great for such a field. Impurities are easily detected by such a gap. As the spacing is increased the chance of lining up becomes less.

The other extreme in electrodes is the needle gap. The lines of force are curved, and are very concentrated at the points or at the electrodes. Any particles in this field will tend to go toward the electrodes to make them larger and store a greater amount of energy. Those that strike the electrodes will be charged to the same potential and immediately repelled or shot away. There is no tendency to line up. In fact this action purifies the oil between the terminals. So, with a needle type of gap there will be very little difference in dielectric strength, whether the oil is very good or very bad. This is especially so if the spacing is large.

The same effect occurs with spheres or other forms of electrodes at large spacings. I had an experimental apparatus which showed this very nicely. It consisted of a test tube filled with a light-colored oil in which an emulsion was made with colored water. A wire was extended through a cork and down the center of the tube. About two-thirds of the lower part of the test tube was then placed in a jar of clear water. The wire acted as one electrode, the transparent water as the other.

As soon as voltage was applied the oil immediately cleared up. An examination showed the particles of colored water around the inner surface of the test tube as well as at the bottom of the tube. The water particles had been attracted to the inner electrode and then repelled to the opposite side where, because of the less dense field, they gradually settled down to the bottom.

F. M. Clark: The hope has been expressed by one of the previous speakers that continued research will eventually result in a thorough understanding of the dielectric phenomena occurring in oils which are subjected to high or low voltage stress.

The average theorist, in considering the insulation problem, becomes very largely discouraged as soon as he starts to look up the previous literature history. Solids themselves are bad enough and show a very erratic nature; oils we know are blamed much more. However, it is probably true that a large part of the blame, instead of being placed upon the insulation, should be placed upon the various investigators who have not carefully considered the physical and chemical characteristics of the materials tested. Oils for example must be considered as chemical mixtures, the constituents of which are variable to a large degree. To understand thoroughly the behavior of a mixture we must know something of the behavior of each of its constituents. This is a difficult problem involving much fundamental research. If, however, we work on "commercial grade" oil such as Mr. Miner has carefully stated he used in his experiments, we have increased the difficulties of the problem by increasing the number of constituents of the mixture on which we are working. And worse still, the added constituents are variable in amount from day to day since the chief "foreign" material in commercial-grade oil consists of water and fibrous material over which we have ordinarily but little control. It may be claimed that if the dielectric strength is maintained, the water content may be considered negligible or fixed. Yet we have some evidence that wet oil may have high dielectric strength if properly tested.

In the same way, much of the difficulty besetting the solution of insulating phenomena, is to some extent increased by broad conclusions drawn from limited data. Thus Mr. Miner states in his paper that solids and liquid insulators show a non-linear dielectric strength-thickness relation. If, by this, Mr. Miner means oiled solids, tested with small electrodes or oils tested with small electrodes, he is largely correct. Yet it has been shown in a previous publication (The Dielectric Strength-Thickness Relation in Fibrous Insulation—*G. E. Review*, Vol. 28, page 286 for 1925) by V. M. Montsinger and myself that this is very largely a function of the testing method for oiled solids at least. Thus with large electrodes, oiled paper shows a linear strength-thickness relation. Moreover, untreated papers also show a dielectric strength very largely independent of thickness. In certain unpublished researches which we have carried out at Pittsfield, it appears that oils behave likewise and show a linear strength-thickness relation when large electrodes are used for the test. We hope to present this research to the Institute at a later date.

Mr. Miner advocates a long-time test in preference to the standard, rapidly applied test on oils. A more reliable test result is claimed. With carefully prepared oils, I believe that considerable of the erratic nature of oil breakdown might be eliminated. Unless care is taken, long-time tests merely indicate the time and voltage relation necessary to "suck" sufficient impurities into the field to bridge the electrodes. The test becomes one for impurities (such as fibres) rather than a test on the oil itself. This is illustrated clearly by the researches detailed in the Seimen's *Zeitschrift* for January, 1925, page 29. The short-time test comes nearer being a test on the oil itself. The fact that benzol gives more reliable test results is merely an indication of the effect of purity. With benzol, a degree of freedom from foreign substances can be obtained which cannot be approached in oil unless extreme care is taken in preparing the sample.

Another contributing cause to the confusion at present existing in the study of dielectric phenomena is the lack of proper definition of the experimental conditions. The dielectric strength-thickness relation for oil can very largely be upset by varying the position of the testing electrodes. With 10-in. plane electrodes, the test results are largely dependent on whether the electrode face is vertical or horizontal.

In the consideration of insulation data from the standpoint of fundamental theory, we must be very careful in accepting results based on ordinary commercial-grade material. In the same way, the designing engineer must be very careful in accepting data based on material which appears to approximate his operating conditions. Thus the dielectric strength of oil can be made low by a variety of methods some of which may or may not be applicable to his special machine. It is very difficult and dangerous to attempt to apply laboratory oil data to the explanation of fundamental theory, or even to the design of electrical machinery, if the tests involved concern foreign material dissolved or suspended in the oil, rather than tests on the oil itself.

Jacob Katzman (communicated after adjournment): Mr. Miner circumvents the difficulty he encountered in the erratic action of oil for short-time tests by lengthening the testing time, and apparently the effect of the time factor on the breakdown voltage is not taken into account in the final conclusions. His results for 10-min. hold tests are obviously more consistent than his instantaneous results, consistent enough to be mathematically expressed. It seems to me that this subterfuge may seriously

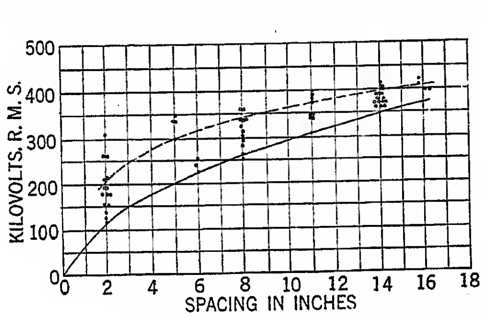

FIG. 3—COMBINED CURVES OF BREAKDOWN VOLTAGES FOR ONE-INCH DIAMETER RODS

Solid curve is from Fig. 8 of original paper and represents breakdown voltages for ten-minute hold.

Dash curve and circles are from Fig. 4 of original paper and is for instantaneous breakdown voltages.

mislead us if we are not on guard. Mr. Miner correctly recognized, (1), that the greatest variations obtained occur at small spacings, and (2), as shown under General Remarks on Test Results, that at short spacings, the breakdown voltage decreases with increased time of application of voltage. Is not the second phenomenon the reason for the first? Is it not likely that that condition which would really give a comparatively high breakdown for instantaneous voltage application, is brought to within the average breakdown by this extension of time?

The fallacy in ignoring the time effect is more readily appreciated when considering the behavior of a solid dielectric, such as oil-impregnated paper, under similar conditions. A number of apparently uniform dielectrics when given an instantaneous breakdown test, show very erratic results, perhaps more so than oil. Some will break down at voltages two or more times higher than others. However, every dielectric has a definite life at some particular voltage, and samples of one kind of dielectric show no more variable life than is shown by the instantaneous breakdown voltages. But, as is well known, the life of the dielectric varies inversely as the seventh power of voltage, and, hence at the high testing voltages, the life is rather small. If, therefore, instead of several seconds of voltage application, ten minutes is used, or, better still, five times ten minutes, then, of course, materials having variations of strength of 10 or even 20 to 1 will break down within that length [illegible] the weakest samples will break first, and the others [illegible] in the order of their strength. In other words even [illegible] their variations in strength are still existent, the time [illegible] long enough so that the life of almost all the samples [illegible] spent at the voltage applied. We have, therefore, [illegible] parently succeeded in obtaining uniform results by [illegible] the important element of time.

That this is actually the case also with the oil can be [illegible] Mr. Miner's own findings. He finds that short-spacing [illegible] down will occur at smaller voltages if applied for long [illegible] At these smaller spacings, time is, therefore, an [illegible] factor. Now, by plotting Mr. Miner's curve of Fig. 8 [illegible] same graph sheet with his curve of Fig. 4 retaining at [illegible] time all the points showing the large variations at instantaneous breakdown we get the curve shown in the accompanying [illegible] From this combined figure it becomes immediately obvious [illegible] for the 10-min. hold, he used in every case a voltage [illegible] equal to the lowest voltage obtained at instantaneous [illegible] and by extending the time to five times ten minutes, [illegible] in breaking down the oil that might otherwise show the instantaneous breakdown voltage.

The whole process seems to me to be akin to throwing [illegible] micrometer because it shows up inaccuracies, and using a carpenter's rule to avoid detection of these inaccuracies. [illegible] is evident that by making a time test the properties of the [illegible] not changed, and its molecular arrangement or arrangement [illegible] particles of impurities is not affected or controlled [illegible] varying instantaneous voltage breakdowns are merely [illegible] by varying lengths of time of breakdown at time-hold [illegible]

From the same combined curves too, it is hard to [illegible] Miner could deduce that at large spacings length of voltage application does not affect voltage breakdown [illegible] tween instantaneous and 10-min. hold a difference of [illegible] is seen at 16-in. spacing. Of course this is not as large [illegible] 100 per cent at 2-in. spacing. It should be noted, [illegible] get these changes, there was a change of length of time [illegible] few seconds to many minutes or probably a ratio [illegible] 100-to-1 to 1000-to-1.

It is interesting to note also that at the larger spacings [illegible] time is not as important an element, his results show [illegible] the same variation for long as for short-time tests.

D. F. Miner: I was very much interested in Mr. [illegible] remarks about the erratic results obtained on large gaps [illegible] to small gaps. It seems that we must define what [illegible] "large" or "small." We found a great deal of variation [illegible] obtained at 2-in. spacing, which we in our tests [illegible] small. But if you call a gap of 0.1 in. or 0.2 in. [illegible] I certainly agree with him. If we had to put up [illegible] vergence of results on small gaps in our standard [illegible] that we find on real large gaps of several inches, [illegible] would not complete very many standard oil tests per [illegible]

There seems to be a good deal in the literature and [illegible] presented by Mr. Schurig as to the effect of large [illegible] water on oil. In other words, if it doesn't improve the [illegible] oil, at least it doesn't harm it under certain conditions, [illegible] would not be a good reason for recommending [illegible] people: "Dump water into the oil in your apparatus [illegible] harm of the water in the oil is not in the decrease [illegible] strength itself, but the effect on the insulation; it [illegible] sulating surfaces and leads to creepage breakdown.

I was very much gratified to have the confirmation [illegible] results by Mr. Montsinger on breakdown formula [illegible] I agree with him that the two-thirds power of [illegible] much better figure to remember than 0.7. It appears [illegible] curvature electrodes, at large spacings, behave [illegible] needle gaps, as far as the actual voltage breakdown [illegible] but of course with sharp points or small electrodes, [illegible]

at an earlier voltage. So that the reason for increasing the diameter of high-potential parts is to suppress ionization and corona rather than to increase the total breakdown voltage.

In connection with the argument as to whether tests should be made on commercial grades of dielectrics, such as oil, or whether we should purify our oil to the greatest possible extent and obtain data on that, there is a divergence of opinion. In this particular investigation we were interested in information that a design engineer could use. Now, it does not help him much to know that a certain gap once stood 300 kv. but the next time it might go down to 150. The 300-kv. value is not going to be of use. He has to design for minimum breakdowns, with a factor of safety then added to that. So that theoretical considerations in the true dielectric strength of oil did not enter into this problem. It was an engineering problem which was part of a series of tests on other electrodes besides spherical, that is, actual shapes occurring in apparatus, to develop design information.

Maxwell's Theory of the Layer Dielectric

BY FRANCIS D. MURNAGHAN[1]

Non-member

(with an Introduction by J. B. Whitehead)

Synopsis.—*Maxwell stated in his "Electricity and Magnetism" that for a non-homogeneous dielectric built up of n plane layers of varying thicknesses and varying ratios of resistivity to specific capacity, the charging current will be given by a linear differential equation of order n-1 involving the nth derivative of the applied e. m. f. This equation and its detailed solution are given here and the two cases of greatest practical interest—namely the case where the applied e. m. f. is constant and the case where it is a pure harmonic—are treated fully. By a Fourier analysis the general case can be reduced to these two.*

Introduction

The phenomenon of dielectric absorption has recently attracted renewed interest by reason of its importance in problems of the insulation of high voltage electrical circuits. It is recognized that absorption causes energy losses in the body of the insulation; these losses increase the temperature, leading to deterioration and final failure of the insulation.

No completely satisfactory theory of the nature of dielectric absorption has been proposed. In recent years a number have been offered invoking newly discovered physical phenomena in the fields of gaseous ionization, dissociation, and conductivity in liquids, and the electromechanics of atomic structure. These theories, for the most part, however, are mere speculations and none of them is subject to exact experimental test. The earliest theory proposed to account for dielectric absorption is that of Clerk Maxwell. It shares with all other theories the disadvantage that it has never been satisfactorily supported by experiment. It has nevertheless maintained its position as the most satisfactory theory yet offered, largely because it invokes only well recognized properties of dielectrics, namely, specific inductive capacity and conductivity, and makes no appeal to new properties nor any molecular nor sub-atomic phenomena.

All students of dielectric theory are familiar with Maxwell's treatment. He assumes a dielectric built up of a number of plane strata of different materials, stating that a medium formed of a conglomeration of small pieces of different materials would behave in the same way. He does not support this latter statement by further analysis, however. The most familiar manifestation of absorption is a sustained but continuously decreasing current when a continuous electromotive force is applied to a condenser having a solid dielectric. The same type of phenomenon occurs when the condenser is discharged. In this case it is the outflow of the familiar residual charge of the condenser. In the case of Maxwell's layer condenser, the different values of the specific capacity and resistivity in successive layers accounts for the relatively long time necessary for complete charge or discharge.

Many experimental studies have aimed to determine the law governing the gradual decay of the charging current of a condenser. Some of these have indicated a simple negative power of the time, others an exponential relation, and still others more complicated relationships. Maxwell did not extend his analysis to the derivation of the form of the function controlling the decay of the charging current of a layer dielectric nor, apparently, has this extension ever been made, under his theory, for the completely general case. It may be readily shown, however, that for the case of two layers the charging current decreases in accordance with a simple exponential function of the time with negative exponent. It has been generally assumed by supporters of Maxwell's theory that in the general case of any number of layers, or of a dielectric consisting of a mixture of any number of different materials, the complex form of the charging current curve is due to the superposition of a number of separate exponential terms with negative exponents. This assumption is supported by Maxwell's statement that for n layers of materials having different values of the ratio of resistivity to specific capacity there will result for the charging current a differential equation of order $n-1$, involving the nth order derivative of the applied electromotive force. Max-

1. Johns Hopkins University.

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., Feb. 7-11, 1927.

well, however, does not derive the expression supporting this statement, and this omission has always constituted a difficulty for those seeking experimental means for testing the validity of his theory. Dr. Murnaghan has now supplied this deficiency and has derived in an elegant and satisfactory manner the expression for the charging current for the most general case of a layer dielectric. Equation (14) shows that this current is made up of a constant term, giving the final conduction current, plus $n - 1$ negative exponential terms of which the coefficients and constant parts of the exponents are given in terms of the constants of the various layers. This confirms Maxwell's statement and provides a ready means whereby one may use the convenient charging current as a basis for analysis and experimental check.

The extension of Maxwell's expressions to the alternating case has always involved great difficulty. Dr. Murnaghan has now made this extension in its most general form. His equations may be readily transformed to the simplest cases and they should offer frequent and convenient opportunity for application to experimental problems.

The National Research Council, through its division of Engineering and Industrial Research, has organized a Committee on Electrical Insulation. This committee during the past two years has been making a review of the widely scattered literature on dielectric behavior, in an attempt to point out the direction in which experiment may be prosecuted with the best chance of profitable result. As a result of conversations with the writer in connection with this review, Dr. Murnaghan has been good enough to undertake the analysis which he now presents and to consent to its being offered under the auspices of the committee mentioned above. The committee also has in progress reviews of our present knowledge of dielectric behavior from the standpoints of resistivity and dielectric strength, and in connection with all these reviews it is proposing problems for experimental research. Of particular interest in connection with Dr. Murnaghan's paper is a series of experimental investigations now under way at Johns Hopkins University on the origin and nature of dielectric absorption, one of the first phases of which will be an attempt to test the validity of Maxwell's theory. The investigation was suggested by the work of the Committee on Electrical Insulation, N. R. C., and is receiving substantial financial support from the Engineering Foundation.

* * * * *

CONSIDERING unit cross-section of the plane strata of Maxwell's layer dielectric, let X_1, X_2, etc., be the electric intensities in the several strata; f_1, f_2, etc., the displacements; k_1, k_2, etc., the reciprocals of the specific inductive capacities; r_1, r_2, etc., the specific resistances. Then at any instant the conduction current in the first layer is X_1/r_1, while the displacement current in the same layer is $\frac{1}{4\pi k_1}\frac{d X_1}{d t}$, so that we have $u = (X_1/r_1) + (1/4\pi k_1)\, d X_1/d t$ where u is the current density in the outer circuit and so in each layer. Denoting the thicknesses of the various layers by a_1, a_2, etc., the e. m. f. across the first layer is $a_1 X_1$, that across the second layer is $a_2 X_2$, and so on for each layer. If there are altogether n layers, the total e. m. f. across the dielectric is connected with the various intensities by the relation

$$E = a_1 X_1 + a_2 X_2 + \ldots + a_n X_n \qquad (1)$$

It is more convenient to deal with the displacements f than with the electric intensities X; on introducing the abbreviations

$$4\pi k_1/r_1 = b_1;\ 4\pi k_2/r_2 = b_2;\ \ldots\ 4\pi k_n/r_n = b_n$$
$$4\pi k_1 a_1 = \alpha_1;\ 4\pi k_2 a_2 = \alpha_2;\ \ldots\ 4\pi k_n a_n = \alpha_n \qquad (2)$$

the equations expressing the fact that the current density in each layer is the same, take the form

$$(D + b_1) f_1 = (D + b_2) f_2 = \ldots = (D + b_n) f_n = u \qquad (3)$$

where, for convenience, we have used the symbol D for the sign of differentiation $d/d t$. Also equation (1) takes the form

$$\alpha_1 f_1 + \alpha_2 f_2 + \ldots + \alpha_n f_n = E \qquad (4)$$

Solving for one of the displacements, say f_1, from (4) we have

$$\alpha_1 f_1 = E - \alpha_2 f_2 - \ldots - \alpha_n f_n$$

and on substituting this in the equation $(D + b_1) f_1 = (D + b_2) f_2$ we obtain

$$[(\alpha_1 + \alpha_2) D + (\alpha_1 b_2 + b_1 \alpha_2)] f_2 + \alpha_3 (D + b_1) f_3 + \ldots + \alpha_n (D + b_1) f_n = (D + b_1) E$$

In addition to this equation connecting the $n - 1$ displacements $(f_2, f_3, \ldots f_n)$ we have the $n - 2$ equations

$$(D + b_2) f_2 - (D + b_3) f_3 = 0$$
$$(D + b_2) f_2 - (D + b_4) f_4 = 0$$
$$\ldots\ldots\ldots\ldots$$
$$(D + b_2) f_2 - (D + b_n) f_n = 0$$

From the $n - 1$ equations now in our possession all but one of the displacements, say f_2, may be eliminated by the usual algebraic process. The determinant of the coefficients is quite simple; for convenience of writing let us take $n = 4$ although it will be quite obvious that the reasoning is general. The determinant of the coefficients being

$$\begin{vmatrix} (\alpha_1 + \alpha_2) D + (\alpha_1 b_2 + \alpha_2 b_1) & \alpha_3 (D + b_1) & \alpha_4 (D + b_1) \\ (D + b_2) & -(D + b_3) & 0 \\ (D + b_3) & 0 & -(D + b_4) \end{vmatrix}$$

we expand it in terms of its first row. The result is

$$\alpha_1(D+b_2)(D+b_3)(D+b_4) + \alpha_2(D+b_1)(D+b_3)(D+b_4) + \alpha_3(D+b_1)(D+b_2)(D+b_4) + \alpha_4(D+b_1)(D+b_2)(D+b_3)$$

In the general case of n layers we may write the determinant of the coefficients of our equations conveniently in the form

$$(D + b_1)(D + b_2)\ .\ .\ .\ (D + b_n)$$

$$\left[\frac{\alpha_1}{D + b_1} + \frac{\alpha_2}{D + b_2} + \ .\ .\ .\ + \frac{\alpha_n}{D + b_n}\right] \qquad (5)$$

This is a polynomial in the sign of differentiation D of degree $n - 1$, the coefficient of D^{n-1} being $(\alpha_1 + \alpha_2 + \ .\ .\ .\ + \alpha_n)$. This sum of the α's occurs so frequently that it will be well to have a single symbol for it; denote it simply by α and write the determinant of the coefficients in the form $\alpha\, \varphi\, (D)$, so that $\varphi\, (D)$ is a polynomial of degree $n - 1$ in D, the coefficient of the highest power in D being unity. The equation for f_2 is, then,

$$\alpha\, \varphi\, (D)\, f_2 = (D + b_1)(D + b_3)\ .\ .\ .\ (D + b_n)\, E$$

where the operator $(D + b_2)$ is missing from the product on the right. The equations for the other displacements are similar; they may be conveniently written in the symbolical form

$$\left[\frac{\alpha_1}{D + b_1} + \frac{\alpha_2}{D + b_2} + \ .\ .\ .\ + \frac{\alpha_n}{D + b_n}\right] f_r = \frac{E}{D + b_r} \qquad (6)$$

which means that the various denominators $(D + b)$ are first removed by multiplying through by the common denominator $(D + b_1)(D + b_2)\ .\ .\ .\ (D + b_n)$. It follows at once from (6) and (3) that the current density u is given by the equation

$$\left[\frac{\alpha_1}{D + b_1} + \ .\ .\ .\ + \frac{\alpha_n}{D + b_n}\right] u = E \qquad (7)$$

or, in non-symbolic form,

$$\alpha\, \varphi\, (D)\, u = (D + b_1)(D + b_2)\ .\ .\ .\ (D + b_n)\, E \quad (8)$$

Equation (8) is the equation to which Maxwell referred but which he rather unfortunately neglected to give explicitly. There is every probability that he arrived at it by the following reasoning; we may write the equations (3) in the symbolic form

$$f_r = u/(D + b_r)$$

and on inserting these values in (4) we arrive immediately at (7).

The equations (6) and (8) are linear differential equations with constant coefficients and are of the order $n - 1$ provided all the ratios of capacity to resistivity for the various layers are different; it is apparent from the symmetrical form of the left-hand side of (6) that the order in which the layers are supposed arranged is of no importance and if two of the b's, b_1 and b_2 let us say, are equal, we may combine the first two terms $\alpha_1/(D + b_1)$ and $\alpha_2/(D + b_2)$ of the left-hand side of (6) into the single term $(\alpha_1 + \alpha_2)/(D + b_2)$ and imagine that instead of the two layers 1 and 2 we have a single equivalent layer whose α is the sum of the two α's of the layers which it replaces. We shall suppose from this on, therefore, that all the b's are different. We shall also find it more convenient to consider the equations (6) rather than the equation (8) for the current density to which Maxwell called attention, the reason being that a determinate solution of a differential equation is not possible unless some information, such as the initial value of the unknown and its various derivatives, is at hand. Now the initial values of the displacements were shown by Maxwell to be all equal, the dielectric being supposed initially uncharged, his reasoning being as follows. From (3) we have, on integrating with respect to the time from 0 to Δt, results such as

$$\Delta f_1 + \int_0^{\Delta t} b_1 f_1\, d\, t = \Delta f_2 + \int_0^{\Delta t} b_2 f_2\, d\, t$$

each side being equal to the charge per unit area $\int_0^{\Delta t} u\, d\, t$ which flows through the dielectric in time Δt. If we let the time interval Δt tend to zero and assume that the displacements f remain finite during the sudden imposition of an e. m. f., we have the limiting equation $\Delta f_1 = \Delta f_2$, and if f_1 and f_2 were zero before the e. m. f. was applied this says that their initial values, *i. e.*, the values immediately after the imposition of the e. m. f., will be equal. If $E\,(0)$ denotes the initial value of the applied e. m. f., we find from (4) that the common initial value of the displacements is

$$f_0 = E\,(0)/\alpha \qquad (9)$$

where

$$\alpha = \alpha_1 + \alpha_2 + \ .\ .\ .\ + \alpha_n \qquad (10)$$

We now proceed to solve the equations (6) in the particular case where a constant e. m. f. of amount unity is applied at time $t = 0$ to the uncharged dielectric, the initial values of the displacements f being accordingly $1/\alpha$. A possible solution of (6) in this case where $E = 1$ may be found by giving f_r the constant value $1/b_r\,(\sum_r \alpha_r/b_r)$ but this is not the solution of the problem before us since it does not give all the f's the same initial value. The difference between this value of f_r and the solution we need, however, will satisfy the homogeneous equation

$$\left[\frac{\alpha_1}{D + b_1} + \ .\ .\ .\ + \frac{\alpha_n}{D + b_n}\right] f_r = 0,$$

$$i.\ e., \qquad \alpha\, \varphi\, (D)\, f_r = 0 \qquad (11)$$

which, being a linear homogeneous differential equation with constant coefficients of order $n - 1$, has for its general solution a combination of $n - 1$ exponential functions of the time with arbitrary constant multipliers. To determine the exponents of the exponential

functions we observe that since $\varphi(D)$ is a sum of n terms each of which has all the $(D + b_r)$ but one as a factor the value of $\varphi(-b_r)$ is $\alpha_r (b_1 - b_r)(b_2 - b_r) \ldots (b_n - b_r)/\alpha$. Now let us suppose the quantities $(b_1, b_2, \ldots b_n)$ arranged in ascending order of magnitude; then $\varphi(-b_1)$ *will* be positive since all its factors are positive but $\varphi(-b_2)$ will be negative since one of its factors, $(b_1 - b_2)$, is negative. $\varphi(-b_3)$ will be positive since two of its factors are negative, and so on. This tells us that the polynomial φ of degree $n - 1$ has all its zeros real and negative and that they lie in the intervals between the negative values of the b's. Let us denote these zeros by $(-\beta_1, -\beta_2, \ldots -\beta_{n-1})$ where the β's are supposed arranged in ascending order of magnitude. We have, then, the series of inequalities,

$$b_1 < \beta_1 < b_2 < \beta_2 < \ldots < b_{n-1} < \beta_{n-1} < b_n \qquad (12)$$

and the most general solution of (11) is a linear combination with constant coefficients of the exponential functions $\epsilon^{-\beta_1 t}, \epsilon^{-\beta_2 t} \ldots \epsilon^{-\beta_{n-1} t}$. Remembering the relation $(D + b_r) f_r = (D + b_s) f_s$ connecting any two of the f's and noting that $D(\epsilon^{-\beta_r t}) = -\beta_r \epsilon^{-\beta_r t}$, we write the general solution of (11) in the form

$$\frac{A_1}{(b_r - \beta_1)} \epsilon^{-\beta_1 t} + \ldots + \frac{A_{n-1}}{(b_r - \beta_{n-1})} \epsilon^{-\beta_{n-1} t}.$$

In other words, the most general solution of the equations (6) (with $E = 1$), which obeys the relations (3) is

$$f_r = \frac{1}{b_r \sum_r (\alpha_r/b_r)} + \frac{A_1}{(b_r - \beta_1)} \epsilon^{-\beta_1 t} + \ldots + \frac{A_{n-1}}{(b_r - \beta_{n-1})} \epsilon^{-\beta_{n-1} t} \qquad (13)$$

where the A's are arbitrary constants. All that is necessary to complete the solution is to so determine the values of these constants that the f's may all assume initially the common value $1/\alpha$. Before proceeding to do this we may remark that it follows at once from (3) and (13) that the current density u is given by the expression

$$u = 1/(\sum_r (\alpha_r/b_r) + A_1 \epsilon^{-\beta_1 t} + \ldots + A_{n-1} \epsilon^{-\beta_{n-1} t} \qquad (14)$$

where the A's have the numerical values we are about to determine. The first term in this expression is the value to which u tends as t increases indefinitely and gives what is known as the permanent or conduction current.

The equations which determine the numerical values of the A's are found by putting $f_r = 1/\alpha$ and $t = 0$ in (13). They are

$$A_1/(b_r - \beta_1) + A_2/(b_r - \beta_2) + \ldots + A_{n-1}/(b_r - \beta_{n-1}) = 1/\alpha - 1/\alpha_r (\sum_r \alpha_r/b_r) \qquad (15)$$

where r is to be assigned, in turn, the values $(1, 2, 3, \ldots n)$ so that there are n equations in all. As there are only $n - 1$ A's to be found, these equations cannot be independent of one another; in fact if we multiply the equation written above by α_r and add all the results obtained by giving r the values 1 to n, both sides of the total vanish identically, showing that a set of A's satisfying $n - 1$ of the equations will satisfy the equation remaining. We may confine our attention, therefore, to the first $n - 1$ of the equations (15). A direct solution of these $n - 1$ equations would not be very elegant, however, on account of the lack of symmetry involved in the omission of one of the equations and it is better to proceed as follows:

Consider the quotient of the two polynomials of degree n

$$(x + b_1)(x + b_2) \ldots (x + b_n)/x\,\phi(x)$$

where $\varphi(x)$ is the function defined by the statement that $\alpha\,\varphi(D)$ is the expression (5). This quotient can be written in the form $1 + \dfrac{g(x)}{x\,\varphi(x)}$ where $g(x) = (x + b_1) \ldots (x + b_n) - x\,\varphi(x)$ is a polynomial of degree less than n. From its very definition the quotient $g(x)/x\,\varphi(x)$ has the value -1 when x is assigned any one of the n values $(-b_1, -b_2, \ldots -b_n)$ and, furthermore, since the zeros of φ are the $n - 1$ numbers $-\beta_r$, we have $g(-\beta_r) = (b_1 - \beta_r)(b_2 - \beta_r) \ldots (b_n - \beta_r)$. Now the usual method of analysis of the quotient of two polynomials into a series of simple fractions[2] tells us that

$$\frac{g(x)}{x\,\varphi(x)} = \frac{g(0)}{x\,\varphi(0)} + \sum_r \frac{g(-\beta_r)}{-\beta_r\,\varphi'(-\beta_r)(x + \beta_r)}$$

where $\varphi'(x)$ denotes the derivative of $\varphi(x)$ with respect to x. Giving x the n values $-b_s$, in turn, we have the n equations

$$-\sum_r \frac{g(-\beta_r)}{\beta_r\,\varphi'(-\beta_r)(b_s - \beta_r)} = 1 - g(0)/b_s\,\varphi(0); \quad s = 1, 2, \ldots n. \qquad (16)$$

Now $g(0)$ has the value $b_1 b_2 \ldots b_n$ and $\varphi(0)$ has the value $b_1 b_2 \ldots b_n [\sum_r (\alpha_r/b_r)]/\alpha$, so that $g(0)/\varphi(0)$ has the value $\alpha/\sum_r (\alpha_r/b_r)$. On substituting this in (16) and comparing the result with (15) we see that the desired values of the A's are furnished by the formulas

$$A_r = -\frac{1}{\alpha}\left[\frac{g(-\beta_r)}{\beta_r\,\varphi'(-\beta_r)}\right] = -(b_1 - \beta_r)(b_2 - \beta_r) \ldots (b_n - \beta_r)/\alpha\,\beta_r\,\varphi'(-\beta_r) \qquad (17)$$

Since

$$\varphi(x) = \frac{1}{\alpha}(x + b_1)(x + b_2) \ldots (x + b_n)$$

2. See note at end of paper.

$$\left[\frac{\alpha_1}{x+b_1}+\ .\ .\ .\ +\frac{\alpha_n}{x+b_n}\right]$$

and since the factor in square brackets vanishes when $x = -\beta_r$, we have

$$\varphi'(-\beta_r) = -\frac{1}{\alpha}(b_1-\beta_r)\ .\ .\ .\ (b_n-\beta_r)$$

$$\left[\frac{\alpha_1}{(b_1-\beta_r)^2}+\ .\ .\ .\ +\frac{\alpha_n}{(b_n-\beta_r)^2}\right]$$

so that

$$A_r = \frac{1}{\alpha\,\beta_r\left[\frac{\alpha_1}{(b_1-\beta_r)^2}+\ .\ .\ .\ +\frac{\alpha_n}{(b_n-\beta_r)^2}\right]} \qquad (17^{bis})$$

This form is not particularly suited for purposes of calculation but it has the advantage of showing that all the constants A_r are positive. The expression for the initial value of the current, *i. e.*,

$$\frac{1}{\sum_r \frac{\alpha_r}{b_r}} + A_1 + A_2 + \ .\ .\ .\ + A_{n-1}$$

follows directly from the equations (3). Denoting initial values of the subscript zero, we have $(D\,f_1)_0 = u_0 - b_1 f_0;\ .\ .\ .\ (D\,f_n)_0 = u_0 - b_n f_0$ and on substituting these in the equation $\sum \alpha_r (D\,f_r)_0 = (D\,E)_0$ obtained by differentiating (4) and then setting $t = 0$, we find

$$\alpha\,u_0 - (\sum_r \alpha_r\,b_r)\,f_0 = (D\,E)_0$$

so that

$$u_0 = \frac{(D\,E)_0}{\alpha} + \frac{(\sum_r \alpha_r b_r)\,E\,(0)}{\alpha^2} \text{ by (9)}$$

In the case of a constant unit e. m. f. we have

$$u_0 = \frac{\sum_r \alpha_r\,b_r}{\alpha^2}$$

Upon substitution of the values given in (17) in the expressions (13) and (14), the displacements and current density at any instant are determined and the problem may be regarded as completely solved. We proceed to give an example of the method of procedure in the simple case of two layers.

When $n = 2$, $\varphi(D)$ is the simple linear expression $D + (\alpha_1 b_2 + \alpha_2 b_1)/\alpha$. Hence there is only one exponential term and the value of β_1 is

$$\beta_1 = (\alpha_1\,b_2 + \alpha_2\,b_1)/(\alpha_1 + \alpha_2) \qquad (18)$$

It is rather noteworthy that when the thickness of one of the layers gets very small so that α_1, say, tends to zero, the value of β_1 tends to the definite limit b_1. For numerical calculations it is well to express β_1 *directly* in terms of the capacities and conductivities of the layers. In Wagner's notation[3] we have $b_1 = 4\,\pi\,k_1\,\lambda^{r} = \gamma\,\lambda_1/\epsilon_1$; $\alpha_1 = \gamma\,a_1/\epsilon_1$ where $\gamma = 36\,\pi\,.\,10^{11}$ is a constant depending on the choice of units. Hence β_1 has the form $\gamma\,(a_1\,\lambda_2 + a_2\,\lambda_1)/(a_1\,\epsilon_2 + a_2\,\epsilon_1)$; the reciprocal of β_1 measures the time taken for the transient part $A_1\,\epsilon^{-\beta_1 t}$ of the current to reduce to the fraction $1/\epsilon$ of its original value, and is called the time constant of the dielectric. For two equally thick layers the time constant has the expression

$$T = (\epsilon_1 + \epsilon_2)/\gamma\,(\lambda_1 + \lambda_2)$$

while in general if the second layer is m times as thick as the first one, $T = (m\,\epsilon_1 + \epsilon_2)/\gamma\,(m\,\lambda_1 + \lambda_2)$. For paper ϵ_1 may be taken around 2 while λ_1 is around 10^{-11} and for glass the values are around 8 and 10^{-15} respectively. If $m = 1$, so that the layers are equally thick, $T = 0.09$ sec., while if $m = 2$, so that the layer of glass is twice as thick as the layer of paper, $T = 0.05$ sec.; if $m = 1/2$ so that the layer of paper is twice as thick as the layer of glass, $T = 0.16$. The larger the ratio of the thickness of the paper to that of the glass the larger is the time constant, the theoretical limit when $m = 0$ being $\gamma\,\epsilon_2/\lambda_2$ which is about 700 sec.

The constant A_1 is given by (17); since $\varphi' = 1$ it is $(\beta_1 - b_1)\ (b_2 - \beta_1)/\alpha\,\beta_1$ which reduces to

$$A_1 = \alpha_1\,\alpha_2\,(b_2 - b_1)^2/(\alpha_1 + \alpha_2)^2\,(\alpha_1\,b_2 + \alpha_2\,b_1)$$
$$= a_1\,a_2\,(\lambda_2\,\epsilon_1 - \lambda_1\,\epsilon_2)^2/(a_1\,\epsilon_2 + a_2\,\epsilon_1)^2\,(a_1\,\lambda_2 + a_2\,\lambda_1)$$
$$= (\lambda_2\,\epsilon_1 - \lambda_1\,\epsilon_2)^2/(a_1\,\epsilon_2 + a_2\,\epsilon_1)^2\left(\frac{\lambda_1}{a_1} + \frac{\lambda_2}{a_2}\right) \qquad (19)$$

It will be observed that if the thickness of one of the layers, say the first, tends to zero, A_1 also tends to zero on account of the term λ_1/a_1 in the denominator; if, however, λ_1 is very small in comparison with λ_2, it is possible that a_1 will be small in comparison with a_2 without the term λ_1/a_1 becoming significant.

In Wagner's notation, the constant term in the expression (14) for the current has the form $1/(\sum_r a_r/\lambda_r)$ which is, for the two-layer dielectric, $\lambda_1\,\lambda_2/(a_1\,\lambda_2 + a_2\,\lambda_1)$. The initial value of the current is $\frac{\alpha_1\,b_1 + \alpha_2\,b_2}{(\alpha_1 + \alpha_2)^2}$ or $\frac{(a_1\,\lambda_1\,\epsilon_2^2 + a_2\,\lambda_2\,\epsilon_1^2)}{(a_1\,\epsilon_2 + a_2\,\epsilon_1)^2}$; for the case of two layers of equal thickness d this is $\frac{\lambda_1\,\epsilon_2^2 + \lambda_2\,\epsilon_1^2}{d\,(\epsilon_1 + \epsilon_2)^2}$.

SECTION 2. THE ALTERNATING CASE

Here we suppose an e. m. f. of the form $E = e^{\,i\omega}$ applied at time $t = 0$. Since $(D + b_n)\,e^{\,i\omega t} = (i\,\omega + b_n)\,e^{\,i\omega t}$ and so on, our equations (6) for the various displacements take the form

$$\alpha\,\phi\,(D)\,f_r = \frac{(i\,\omega + b_1)\ .\ .\ .\ (i\,\omega\,b_n)}{(i\,\omega + b_r)}\,e^{i\omega t}$$

3. See article in *Die Isolierstoffe der Electrotechnik* edited by Schering, H., pp. 1-59. Berlin, 1924.

A particular solution of these equations, which is consistent with the equations (3), is

$$f_r = \frac{B\, e^{i\omega t}}{i\,\omega + b_r} \tag{20}$$

where the constant B is determined by the equation

$$\alpha\, \phi\, (i\,\omega)\, B = (i\,\omega + b_1)\,.\,.\,.\,(i\,\omega + b_n) \tag{21}$$

i. e.,

$$B = 1/\left[\frac{\alpha_1}{i\,\omega + b_1} + \frac{\alpha_2}{i\,\omega + b_2} + \,.\,.\,. + \frac{\alpha_n}{i\,\omega + b_n}\right] \tag{21^{bis}}$$

The general solution of the equations (6) is of the type

$$f_r = \frac{B\, e^{i\omega t}}{i\,\omega + b_r} + \frac{B_1\, e^{-\beta_1 t}}{b_r - \beta_1} + \,.\,.\,. + \frac{B_{n-1}\, e^{-\beta_{n-1} t}}{b_r - \beta_{n-1}} \tag{22}$$

where the factors β in the exponents are the same as before and the $(B_1, B_2, \ldots B_{n-1})$ are arbitrary constants. The values to be assigned to these must be such that the initial values of the displacements f are all $E\,(0)/\alpha$, (see (9)); or, since here $E\,(0) = 1$, $\frac{1}{\alpha}$. The $n - 1$ constants $(B_1, \ldots B_{n-1})$ must therefore satisfy the n linear equations

$$\frac{B_1}{b_r - \beta_1} + \frac{B_2}{b_r - \beta_2} + \,.\,.\,. + \frac{B_{n-1}}{b_r - \beta_{n-1}}$$

$$= \frac{1}{\alpha} - \frac{B}{b_r + i\,\omega};\; r = 1, 2, \ldots n \tag{23}$$

That these equations are not independent follows at once on multiplication by $(\alpha_1, \ldots \alpha_n)$ and addition when both sides vanish. To find the values of the B's, consider the analysis of the quotient $(x + b_1) \ldots (x + b_n)/(x - i\,\omega)\,\varphi\,(x)$ into its simple fractions. Writing it in the form $1 + \frac{g\,(x)}{(x - i\,\omega)\,\varphi\,(x)}$ where $g\,(x)$ is of lower degree than n, we find

$$\frac{(x + b_1)\,.\,.\,.\,(x + b_n)}{(x - i\,\omega)\,\varphi\,(x)} = 1 + \frac{(b_1 + i\,\omega)\,.\,.\,.\,(b_n + i\,\omega)}{\varphi\,(i\,\omega)\,(x - i\,\omega)}$$

$$- \sum_r \frac{(b_1 - \beta_r)\,.\,.\,.\,(b_n - \beta_r)}{(\beta_r + i\,\omega)\,\varphi'\,(-\beta_r)\,.\,(x + \beta_r)}$$

Setting $x = (-b_1, -b_2, \ldots -b_n)$ in turn in this identity, we obtain the n relations

$$\sum_r - \frac{(b_1 - \beta_r)\,.\,.\,.\,(b_n - \beta_r)}{(\beta_r + i\,\omega)\,\varphi'\,(-\beta_r)\,(b_s - \beta_r)}$$

$$= 1 - \frac{\alpha\, B}{b_s + i\,\omega};\; s = 1 \ldots n;$$

and on comparing these with (23) we see that the $n - 1$ quantities $(B_1, \ldots B_{n-1})$ are given by the formulas

$$B_r = -\frac{1}{\alpha}\,.\,\frac{(b_1 - \beta_r)\,.\,.\,.\,(b_n - \beta_r)}{(\beta_r + i\,\omega)\,\varphi'\,(-\beta_r)} \tag{24}$$

From this it follows that

$$B_r = A_r \frac{\beta_r}{\beta_r + i\,\omega} \tag{25}$$

where the A's are the constants of the unit e. m. f. case whose values have been given in (17).

If we introduce the time constants T_r which are the reciprocals of the β_r, our equation (25) takes the form

$$B_r = A_r/(1 + i\,\omega\, T_r) \tag{25^{bis}}$$

The two-layer dielectric in an alternating field.

Here the equation for the constant B is

$$B = \frac{(i\,\omega + b_1)\,(i\,\omega + b_2)}{(\alpha_1\, b_2 + \alpha_2\, b_1) + (\alpha_1 + \alpha_2)\, i\,\omega}$$

$$= \frac{(i\,\omega + b_1)\,(i\,\omega + b_2)}{(\alpha_1\, b_2 + \alpha_2\, b_1)\,(1 + i\,\omega\, T)} \tag{26}$$

This is but a particular case of the general formula (see (21))

$$B = \frac{(i\,\omega + b_1)\,.\,.\,.\,(i\,\omega + b_n)}{\alpha\,\phi\,(i\,\omega)}$$

$$= \frac{(i\,\omega + b_1)\,.\,.\,.\,(i\,\omega + b_n)}{\alpha\,(i\,\omega + \beta_1)\,.\,.\,.\,(i\,\omega + \beta_{n-1})}$$

$$= \frac{(i\,\omega + b_1)\,.\,.\,.\,(i\,\omega + b_n)}{b_1 \ldots b_n\left(\sum_r \frac{\alpha_r}{b_r}\right)(1 + i\,\omega\, T_1)(1 + i\,\omega\, T_2)\,.\,.\,.\,(1 + i\,\omega\, T_{n-1})} \tag{27}$$

Since

$$\alpha\,\beta_1 \ldots \beta_{n-1} = \alpha\,\varphi\,(0) = b_1 \ldots b_n \left(\sum_r \frac{\alpha_r}{b_r}\right).$$

In Wagner's notation (26) takes the form

$$\frac{\left(\lambda_1 + i\frac{\omega\,\epsilon_1}{\gamma}\right)\left(\lambda_2 + i\frac{\omega\,\epsilon_2}{\gamma}\right)}{(a_1\,\lambda_2 + a_2\,\lambda_1)\,(1 + i\,\omega\, T)}$$

or

$$\frac{\left(\lambda_1 + i\frac{\omega\,\epsilon_1}{\gamma}\right)\left(\lambda_2 + i\frac{\omega\,\epsilon_2}{\gamma}\right)}{a_1\,\lambda_2 + a_2\,\lambda_1 + i\,\omega\,\frac{a_1\,\epsilon_2 + a_2\,\epsilon_1}{\gamma}}.$$

Similarly, the general expression (27) for n layers becomes

$$B = \frac{\left(\lambda_1 + i\,\omega\,\frac{\epsilon_1}{\gamma}\right)\ldots\left(\lambda_n + i\,\omega\,\frac{\epsilon_n}{\gamma}\right)}{\lambda_1\ldots\lambda_n\left(\sum_r \frac{a_r}{\lambda_r}\right)(1+i\,\omega\,T_1)\ldots(1+i\,\omega\,T_{n-1})} \tag{27bis}$$

In the two-layer cases the constant B_1 in the complete expression

$$u = B\,e^{i\omega t} + B_1\,e^{-\beta_1 t} = B\,e^{i\omega t} + B_1\,e^{-t/T}$$

has the value

$$B_1 = \frac{A_1}{1+i\,\omega\,T} = \frac{(\lambda_2\,\epsilon_1 - \lambda_1\,\epsilon_2)^2}{(a_1\,\epsilon_2 + a_2\,\epsilon_1)^2\left(\frac{\lambda_1}{a_1}+\frac{\lambda_2}{a_2}\right)(1+i\,\omega\,T)}$$

from (19) (28)

When $\omega = 0$ the expression (27bis) reduces to the conduction current $\frac{1}{\sum_r \frac{a_r}{\lambda_r}}$ under a constant unit e. m. f.

If the dielectric were uniform, the electric intensity would be $\frac{1}{\sum_r a_r}$ and so we write $\lambda = \frac{\sum_r a_r}{\sum_r \frac{a_r}{\lambda_r}}$ and call it the effective conductivity. For very high frequency we see from (21) that B tends to $\frac{i\,\omega}{\alpha}$ i. e., $\frac{i\,\omega}{\gamma\sum_r \frac{a_r}{\epsilon_r}}$.

Writing $\epsilon = \frac{\sum_r a_r}{\sum_r \frac{a_r}{\epsilon_r}}$ for the capacity constant of the dielectric for very high frequencies, we may consider the difference

$$(\Sigma\,a_r)\,B - \left(\lambda + i\,\omega\,\frac{\epsilon}{\gamma}\right) = \bar{\lambda} + i\,\omega\,\frac{\bar{\epsilon}}{\gamma},$$

say, as due to the lack of homogeneity of the dielectric. Writing B in the form

$$B = \frac{(i\,\omega + b_1)\ldots(i\,\omega + b_n)}{\alpha\,\phi\,(i\,\omega)}$$

the difference in question is the product of $\sum_r a_r$ and

$$\frac{(i\,\omega + b_1)\ldots(i\,\omega + b_n)}{\alpha\,\phi\,(i\,\omega)} - \frac{b_1\ldots b_n}{\alpha\,\phi\,(0)} - \frac{i\,\omega}{\alpha}$$

On reducing to a common denominator the numerator lacks the term in ω_n and also the constant term. Thus in the case $n = 2$ where $\phi\,(i\,\omega) = i\,\omega + \beta_1 = i\,\omega + \frac{1}{T}$ the numerator is $i\,\omega\left[\frac{b_1+b_2}{T} - \frac{1}{T^2} - b_1\,b_2\right]$ or

$$\frac{i\,\omega\,\alpha_1\,\alpha_2\,(b_2 - b_1)^2}{(\alpha_1+\alpha_2)^2} \text{ since } \frac{1}{T} = \frac{\alpha_1\,b_2 + \alpha_2\,b_1}{\alpha_1+\alpha_2}.$$

Hence $\bar{\lambda} + i\,\omega\,\frac{\bar{\epsilon}}{\gamma}$

$$= \frac{(a_1+a_2)\,i\,\omega\,\alpha_1\,\alpha_2\,(b_2 - b_1)^2}{(\alpha_1+\alpha_2)^2\,(\alpha_1\,b_2+\alpha_2\,b_1)\left(i\quad+\frac{1}{T}\right)}$$

$$= \frac{(a_1+a_2)\,i\,\omega\,\alpha_1\,\alpha_2\,(b_2-b_1)^2}{(\alpha_1+\alpha_2)\,(\alpha_1\,b_2+\alpha_2\,b_1)^2\,(1+i\,\omega\,T)}$$

In Wagner's notation this is

$$\frac{i\,\omega\,(a_1+a_2)\,(\lambda_2\,\epsilon_1 - \lambda_1\,\epsilon_2)^2}{\gamma\,(1+i\,\omega\,T)\,(a_1\,\lambda_2 + a_2\,\lambda_1)^2\left(\frac{\epsilon_1}{a_1}+\frac{\epsilon_2}{a_2}\right)}$$

Writing this in the form $\frac{i\,\omega\,\epsilon\,.\,k}{\gamma\,(1+i\,\omega\,T)}$ the "absorption constant" k has the value

$$k = \frac{a_1\,a_2\,(\lambda_2\,\epsilon_1 - \lambda_1\,\epsilon_2)^2}{\epsilon_1\,\epsilon_2\,(a_1\,\lambda_2 + a_2\,\lambda_1)^2} \tag{29}$$

Writing $a_2 = m\,a_1$ this becomes $\frac{m\,(\lambda_2\,\epsilon_1 - \lambda_1\,\epsilon_2)^2}{\epsilon_1\,\epsilon_2\,(\lambda_2 + m\,\lambda_1)^2}$; regarded as a function of m it has a maximum value when $m = \frac{\lambda_2}{\lambda_1}$, the corresponding value of k being $\frac{(\lambda_2\,\epsilon_1 - \lambda_1\,\epsilon_2)^2}{4\,\epsilon_1\,\epsilon_2\,\lambda_1\,\lambda_2}$. If the dielectric consists of paper with impurities in the form of moisture, we may set $\lambda_1 = 10^{-11}$, $\epsilon_1 = 2$ (paper) and $\lambda_2 = 10^{-4}$, $\epsilon_2 = 80$ and k becomes $0.025\,m$.

We may indicate, in conclusion, some of the calculations for the three-layer case although some of the formulas become quite complicated. Here there are two exponential terms and $-\beta_1$, $-\beta_2$ are the zeros of the quadratic polynomial

$$\alpha\,\phi\,(x) = (\alpha_1+\alpha_2+\alpha_3)\,x^2 + \{\,\alpha_1\,(b_2+b_3) + \alpha_2\,(b_3+b_1) + \alpha_3\,(b_1+b_2)\,\}\,x + \alpha_1\,b_2\,b_3 + \alpha_2\,b_3\,b_1 + \alpha_3\,b_1\,b_2$$

We have $\phi\,(i\,\omega) = (i\,\omega + \beta_1)\,(i\,\omega + \beta_2) = (1 + i\,\omega\,T_1)\,(1 + i\,\omega\,T_2)/T_1\,T_2$; the numerator of the expression

$\bar{\lambda} + i\,\omega \dfrac{\bar{\epsilon}}{\gamma}$ has two terms, one involving ω and the other ω^2. On using the relations

$$\frac{1}{T_1\,T_2} = \frac{\alpha_1\,b_2\,b_3 + \alpha_2\,b_3\,b_1 + \alpha_3\,b_1\,b_2}{\alpha_1 + \alpha_2 + \alpha_3};$$

$$\frac{1}{T_1} + \frac{1}{T_2} = \frac{\alpha_1(b_2+b_3)+\alpha_2(b_3+b_1)+\alpha_3(b_1+b_2)}{\alpha_1 + \alpha_2 + \alpha_3}$$

we find

$$\bar{\lambda}+i\,\omega\frac{\bar{\epsilon}}{\lambda} = \frac{i\,\omega\,(a_1 + a_2 + a_3)\,[L + M\,i\,\omega]}{\dfrac{(\alpha_1+\alpha_2+\alpha_3)(\alpha_1\,b_2\,b_3+\alpha_2\,b_3\,b_1+\alpha_3\,b_1\,b_2)^2}{(1 + i\,\omega\,T_1)\,(1 + i\,\omega\,T_2)}}$$

where

$$L = \alpha_1\,\alpha_2\,b_3^2\,(b_1 - b_2)^2 + \alpha_2\,\alpha_3\,b_1^2\,(b_2 - b_3)^2 + \alpha_3\,\alpha_1\,b_2^2\,(b_3 - b_1)^2$$

$$M = \alpha_1\,\alpha_2\,b_3\,(b_1 - b_2)^2 + \alpha_2\,\alpha_3\,b_1\,(b_2 - b_3)^2 + \alpha_3\,\alpha_1\,b_2\,(b_3 - b_1)^2.$$

We hope in a second paper to give a rigorous proof of the Boltzmann-Hopkinson Principle of Superposition, from which all the formulas given above for the alternating case can be deduced, and to apply it to the case $E = t$ where an e. m. f. with constant time gradient is applied.

Note on the analysis of a quotient of two polynomials into simple fractions.

The quotient $G(x)/F(x)$ where $G(x)$ is a polynomial of degree less than n and $F(x) = (x - x_1)\,.\,.\,.\,(x - x_n)$ may be written in the form

$$\frac{G(x)}{F(x)} = \frac{A_1}{x - x_1} + \ldots + \frac{A_n}{x - x_n}$$

where $(A_1, \ldots A_n)$ are constants to be determined. To find them we multiply up by $x - x_1$, say, and then let $x = x_1$ giving

$$\frac{G(x_1)}{(x_1 - x_2)\,.\,.\,.\,(x_1 - x_n)} = A_1.$$ Now $F(x) = (x - x_1)\,H(x)$, say, where $H(x) = (x - x_2)\,.\,.\,.\,(x - x_n)$ and so the ordinary rule for the derivative of a product gives

$F'(x) = H'(x)\,.\,(x - x_1) + H(x)$

Whence

$$F'(x_1) = H(x_1) = (x_1 - x_2)\,.\,.\,.\,(x_1 - x_n)$$

Hence

$$A_1 = \frac{G(x_1)}{F'(x_1)} \text{ and, in general, } A_r = \frac{G(x_r)}{F'(x_r)}.$$

We have supposed here, as is the case in the text, that no two of the numbers $(x_1, x_2, \ldots x_n)$ are equal.

Discussion

Vladimir Karapetoff: The phenomenon of absorption in a composite dielectric, each layer of which separately shows no absorption, has been graphically explained by Grünewald[1]. Referring to the accompanying sketch, consider the simplest case of two slabs $A\,B\,C\,D$ and $C\,D\,E\,F$, of equal thickness and of equal insulation resistance to direct current. Let the material I be of much lower permittivity than the material $I\,I$. Let $A\,B$, $C\,D$, $E\,F$, represent very thin layers of metal foil, to insure the positions of equipotential surfaces. Assume the metal sheet $A\,B$ grounded at G and a d-c. potential of value $N\,F$ suddenly applied to the surface $E\,F$. The instantaneous distribution of potential may then be represented by the broken line $H\,K\,F$. The permittivity of the layer I being lower, a major portion, $S\,K$, of the total voltage is applied across it, and a minor portion, $K\,C$, across $I\,I$. The slopes of the two lines are inversely as the permittivities, or directly as the elastivities of the two materials.

At the first instant, there can be no electric charge on the surface $C\,D$, and the displacements of electricity through both dielectrics must be equal to each other. The line $P\,R$ indicates this condition, the ordinate $H\,P$ representing the displacement of electricity or the charge on the plates. It will be seen that the positive and negative charges on the plate $C\,D$ cancel each other, leaving equal and positive charges on $A\,B$ and $E\,F$.

Now, let the same voltage remain applied indefinitely, causing a conduction current through the dielectrics. Since, by assumption, the resistivities of the two materials are equal, the final distribution of potential will be represented by the straight line $H\,L\,F$. The voltage gradient in the material I has been reduced in the ratio of $L\,S$ to $K\,S$, and consequently the displacement of electricity will be reduced in the same ratio, say

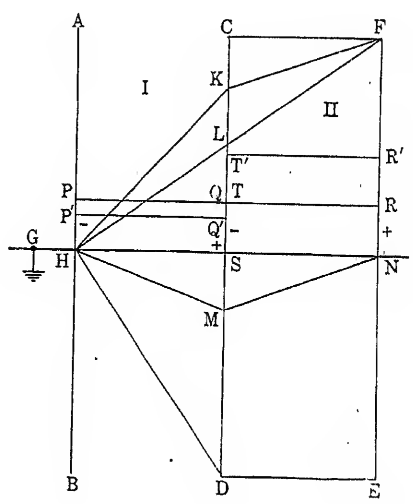

Fig. 1

from $H\,P$ to $H\,P^{\mathrm{I}}$. The potential gradient in $I\,I$ has been increased from $C\,K$ to $C\,L$, and the displacement increased in the same ratio, say from $N\,R$ to $N\,R^{\mathrm{I}}$. Thus, the middle plate $C\,D$ receives a positive charge $S\,Q^{\mathrm{I}}$ and a negative charge $S\,T^{\mathrm{I}}$, or a net negative charge $Q^{\mathrm{I}}\,T^{\mathrm{I}}$. An electroscope connected to $C\,D$ would indicate this charge, corresponding to the difference $K\,L$ in the voltages at the first instant and under steady-state conditions.

Let the potential $N\,F$ be suddenly removed and the plate $E\,F$ immediately grounded. The new distribution of potential will then be represented by the line $H\,M\,N$, the potential of the middle plate being negative because it carries a negative charge. Numerically, $S\,M = L\,K$. The charge on $C\,D$ will be equal to $-\,Q^{\mathrm{I}}\,T^{\mathrm{I}}$, and that on each of the grounded plates $+\,0.5\,Q^{\mathrm{I}}\,T^{\mathrm{I}}$. Should the plate $E\,F$ be left grounded indefinitely, the charge $Q^{\mathrm{I}}\,T^{\mathrm{I}}$ would ultimately leak to the ground in both directions.

Let the plate $E\,F$, however, be grounded for an instant only, and then an equal and opposite voltage, $N\,E$, applied to it.

1. *Arch. für Elek.*, 1923, Vol. 12, p. 98.

The new instantaneous distribution of potential will be $H\ D\ E$, where $M\ D = S\ K$. In other words, the new distribution of potential may be considered as a result of superposition of the distribution $H\ K\ F$ in the neutral state and of the distribution $H\ M\ N$ due to the accumulated charge on $C\ D$.

It will thus be seen that the new distribution involves a greater stress in the material I than without absorption. Moreover, the absorbed change can reach $C\ D$ only through conduction which involves heat loss. The materials themselves have no property of absorption, but because the ratio of their conductivities is different from that of the permittivities, a residual charge, alternately positive and negative, accumulates on the dividing surface as the applied voltage changes its sign. This graphical interpretation may be carried further, to include more layers or layers of different thicknesses and different resistivities. Some years ago, the writer designed a kinematic model to show dielectric absorption according to Grünewald's representation. Certain linkages were connected through a spring and a dash-pot. At the first instant, as the point N on the linkage was suddenly raised to F, the linkage assumed the shape $H\ K\ F$. Then the spring gradually moved point K to L, overcoming the resistance of the dash-pot. Moving the point F suddenly to E gave the configuration $H\ D\ E$. Some parts of the model were made but the work was never completed due to a pressure of other investigations.

While Maxwell's theory of absorption has considerable methodological value, its practical usefulness is limited by the fundamental assumption that the layers which constitute a dielectric possess no absorption when tested separately. This may be true of such pure materials as white paraffin and xylol, but dielectrics used in practise show considerable absorption even in their constituent parts, such as paper, oil, mica leaves, etc. It is, therefore, not clear how to apply Maxwell's theory to a given case of say molded insulation, built-up mica, paper and oil, etc.

For this reason, it seems necessary for the present to assume the existence of the phenomenon of absorption in a given piece of insulation as a fact, and simply try to express mathematically the observed behavior, having made plausible assumptions about the shape of the functions expressing variations of current and flux density with the time. This method is used in the writer's paper on the subject presented at the 1926 Winter Convention.[2]

D. W. Roper: I should like to comment upon the necessity for such fundamental research. The industry at the present time is forging ahead of the science in cable dielectrics, particularly in high-voltage cables, and in this country that means paper-insulated cables. We are not yet able to test a cable and predetermine with reasonable accuracy its operating characteristics. A cable which has passed all of the requirements of the specifications agreed upon by the manufacturers and committees of the various associations will fail in service, and sometimes within a few months after being placed in service. Two instances of that sort have occurred within the past year. They were not confined to any one operating company, nor to any one manufacturer. In each case, after one or two failures had occurred, the manufacturers looked over their factory records and found evidence which caused them to be suspicious of certain other sections of cable that had been sent out from their factories, so they arranged with their customer to remove and replace certain other sections that had not yet failed, but which the manufacturers thought would probably fail, and the expense of the change was borne by the manufacturers. Now there is perfectly definite evidence that the manufacturer, from his factory records, can tell something about the cable that was not shown by any test that we know how to make, either in the factory or after it is placed in service.

We can make life tests on cable, and if we do, we get a fairly definite line between the voltage and the time. If we plot the logarithm of the kilovolts against the logarithm of time, we obtain a straight line, and for the types of cables that we are getting nowadays the kilovolts vary inversely as the seventh root of the time. Now, if you test that cable for a part of its life, there is no way of which we know at the present time to determine what fraction of that life has been spent, except by looking at the clock and the voltmeter. There is no electrical test that can be made to determine deterioration.

The lower part of that curve is of great interest because if you simply extend that curve, you get a finite time for zero voltage; but we know that if you get the voltage low enough, the time becomes infinitely long.

We have that problem before us continually. As a company increases in size and builds new generating stations, it scatters them about the territory which it supplies, so as to reduce the transmission distances, among other things, and that means that every time a new station is built, it is necessary to take out of service some cable which is no longer of value in its original location and remove it to some new location. As the voltages increase and we operate a little closer to the limit, there is every prospect that we shall at some future time be taking out of service cable which has lost so much of its life that it would hardly pay to reinstall it in a new location, but there is no way of telling that except to go ahead and install it and then replace it if it fails.

There is one other point: In connection with the cable failures in Chicago and the determination of their cause, we found it expedient to train some of our younger engineers in methods of systematic and careful inspection and analysis of cable in the vicinity of the failure and at points on the same section remote from the failure, so as to tell whether the cause of the trouble was one which existed throughout the entire length or which was local. A local case of trouble might for example, be due to irregular impregnation,—spotty impregnation, as the manufacturers call it. As these young engineers have competent supervision and instruction, you might say that their ability is proportional to their experience, and along certain lines the circumstances have been such that they had ample experience.

A few years ago we had some trouble with the joints on 33-kv. 3-conductor cables, and we had to remake the joints so as to use a different joint-filling compound. The one used was unsuitable for the purpose. In remaking these joints, we carefully examined the ends of the factory insulation in the joint, in some cases cutting back a few inches or a few feet, if necessary, and in a few cases replacing entire sections, because examination disclosed the evidence of ionization, and when those evidences of ionization were sufficiently definite and numerous throughout the insulation at one point, we removed that cable either by cutting it back in the manhole or by replacing the entire section. That gave us a very good opportunity for getting an average idea of the insulation of the entire line and from the evidence so gathered, the engineers making the inspection predicted the failure of the line very shortly from ionization. They reported that the life had been well spent at the operating voltage. The prediction was verified within six months.

The point to which I wish to call attention is that we can get this evidence and this prediction from a *visual examination*, but we cannot make any tests whatever, that we know now how to make, which will warrant the same prediction. We are now making, I believe, all the tests that we know how to make, on the data that we have available, and apparently what we need is more fundamental research that will enable us to make more tests and determine some of these features that we can now determine by visual examination or other methods which are not electrical tests.

Joseph Slepian: I should like to raise the question as to how much actual information about dielectrics such mathematical investigations can give. Essentially, Dr. Murnaghan shows,

2. (A. I. E. E. TRANS., 1926, Vol. 45, p. 124.)

following Maxwell, that if a dielectric is composed of n layers of dielectric with different dielectric constants and resistivities the relation between voltage and current is one which satisfies an nth order differential equation and hence there must be a certain final relation between current and voltage. But it does not follow that if for any particular dielectric the voltage and current do satisfy such a relationship that the dielectric must be composed of n layers.

They are infinitely many hypothetical structures of the dielectric which will give the same relationship between voltage and current. For example, if we insist on explaining the behavior of the dielectric by inhomogeneities, we will have equally great success by imagining the inhomogeneities to be in the form of little spheres. Wagner, I believe, has carried out a mathematical investigation of such a dielectric. A year ago Professor Karapetoff also considered the mathematical theory of a dielectric with what he called particles, each particle having dielectric properties expressed by means of a first order of differential equations.[3] By suitable hypotheses as to the distribution of these particles, any relationship between voltage and current satisfying the principle of superposition may be derived.

The fact that an actual dielectric has voltage-current relationships which correspond to the results obtained by such analyses throws no light upon the structure of the dielectric itself at all, since all these hypotheses lead to the same results. By merely measuring voltage and current no information can be obtained which permits one to decide which hypothesis, if any, is the actual truth.

Hence I want particularly to point out the need of other kinds of information than relations between current and voltage. Before we can attach importance to any inhomogeneity theory, we must somehow show by other means the existence of the inhomogeneities which the theory postulates. In this connection I am glad to mention the work of Professor Joffé of Leningrad, whom I was fortunate enough to hear not long ago in Pittsburgh. Professor Joffé described some experiments upon crystals of rock salt in which, a priori, you wouldn't expect any inhomogeneity at all. In spite of this apparent homogeneity Professor Joffé did observe absorption, and after voltage had been applied to the crystal long enough for the absorption current to die down to nearly its zero value, he investigated the distribution of the potential through the crystal. By a very skillful technique which consisted of shaving away with insulated knives exceedingly thin layers of the dielectric he found that the distribution of potential through this dielectric consisted of a very small gradient through the body of the material with almost all of the potential concentrated in thin layers immediately next to the electrodes. Thus he showed the actual existence of a layer, next to the one electrode which had such different characteristics from the rest of the dielectric as to cause the voltage to be highly concentrated on that layer. The most significant thing about Joffé's experiment is that the layer in question had its peculiar properties only because of its relation to the electrode. If after the layer was cut off voltage was applied to the remaining crystal a concentration of potential upon the layer next to the electrode would again be obtained. The inhomogeneity which is active here is not in the material to begin with. It is an inhomogeneity which is produced by the electric current itself. For an understanding of the phenomena in dielectrics, it is not sufficient to treat the dielectric as if it had a simple ohmic conductivity. The nature of the carriers of current must be considered and account taken of the space charges which these carriers produce as a result of the flow of current.

In the absence of evidence other than the voltage-current relationships, the layers of Maxwell, spheres of Wagner, particles of Karapetoff, must be considered as mathematical fictions or conveniences, or simply individual preferences as to the manner of describing the phenomenon that is going on. Personally, I prefer to say that the homogeneous dielectric has its own complex properties rather than to assume a hypothetical complex heterogeneous structure, built up of parts having hypothetically simple dielectric properties.

3. *Theory of Absorption in Solid Dielectrics*, by V. Karapetoff, A. I. E. E. Trans., 1926, p. 124.

Donald Bratt: In regard to the physical conditions of the problem, it is well to remember that Maxwell's idea was nothing more than to show that there is no such thing as "absorption" of charge in a dielectric. He did show, that the phenomena known as "absorption" are the result of lack of homogeneity and confined himself to the simple case of two plane condensers in series, subjected to a sudden application of a d-c. voltage. He further indicates, that the nature of these phenomena remains the same even if the dielectrics assume a geometrical shape other than plane. The proof of this statement could, perhaps, be given in strict mathematical language, there is nothing however to make one believe that the phenomena in physics should change their *nature* by changing the geometrical configuration of the boundaries. In all problems where phenomena obey for instance the well-known Laplace differential equation a purely mathematical transformation exists, which will refer any boundary to the cubical dement on which we base our physical laws, as well as our calculus. Maxwell did not, apparently, consider it necessary to emphasize this.

It is not safe to base an extended analysis on Maxwell's work, for the further reason that Maxwell omitted the magnetic permeability from this problem to get a simpler analysis of the initial displacements due to a suddenly impressed d-c. voltage. He found these displacements all equal initially. Had Maxwell wanted to go a little further, it would have been necessary for him to emphasize that there cannot be any such thing as a displacement until the wave starting from one end of the dielectric has had time to reach the other end.

The idea of a wave does not, of course, occur unless magnetic permeability is introduced.

The term "dielectric absorption" is doubtless derived from a supposed analogy with heat. It was this idea Maxwell tried to refute by showing how different were the laws governing dielectric phenomena from those governing the flow of heat. On page 458 (Vol. I) in his work Maxwell says (referring to his above-mentioned analysis): "The object of the investigation is merely to point out the true mathematical character of the so-called electric absorption and to show how fundamentally it differs from the phenomena of heat which seem at first sight analogous."

To give a general solution of a stratified condenser, consider first the conventional picture of a dielectric: a non-inductive resistance in parallel with an ideal condenser. Should a d-c. voltage be suddenly impressed on such a condenser, the initial rush of current would be infinite. The same would happen if several such condensers were connected in series. To avoid this difficulty it is necessary to make certain restricting assumptions on the form of the impressed voltage, as will be shown below.

Take, now, Dr. Murnaghan's equation (7)

$$\left[\frac{\alpha_1}{D + b_1} + \cdot \cdot \cdot \cdot \frac{\alpha_n}{D + b_n}\right] u = E$$

which I prefer to solve for the current, writing, symbolically

$$i = \frac{E(t)}{\dfrac{1}{g_1 + p\, c_1} + \dfrac{1}{g_2 + p\, c_2} + \cdot \cdot \dfrac{1}{g_n + p\, c_n}}$$

where i is the total charging current at any time t $E(t)$ is the external voltage impressed, and may for the moment be assumed to be perfectly unrestricted.

g_k and C_k are the conductance and capacity of the kth condenser.

p is the differential operator $\dfrac{d}{d\,t}$ (Heavisides notation)

Re-arranging, we obtain an expression

$$i = \frac{A\,(p)}{B\,(p)}\,E\,(t)$$

where A and B are algebraic polynomials in p; A being 1 degree *higher* than B.

To reduce still further, perform the division $\frac{A\,(p)}{B\,(p)}$; we get

$$\frac{A\,(p)}{B\,(p)} = M\,p + \frac{G\,(p)}{H\,(p)}$$

where M is a constant directly obtained by the division, G and H are polynomials in p of the *same* degree (*i. e.* $(n-1)$ if there are n condensers in series.)

According to the Heaviside Expansion Theorem, we now have

$$\frac{G\,(p)}{H\,(p)} = K_0 + K_1\,\frac{p}{p - p_1} + \ldots\ldots + K_{n-1}\,\frac{p}{p - p_{n-1}}; \text{ where}$$

$$K_0 = \frac{G\,(o)}{H\,(o)}$$

$p_1, p_2 \ldots\ldots p_{n-1}$ are the roots of $H\,(p) = 0$ which are all negative and real, no two roots being alike, by assumption.

$$K_r = \frac{1}{p_r} \cdot \frac{G\,(p_r)}{\left[\frac{\partial}{\partial p}\,H\,(p)\right]_r}$$

so that

$$i = \left[M\,p + K_0 + K_1\,\frac{p}{p - p_1} + \ldots\ldots + K_{n-1}\,\frac{p}{p - p_{n-1}}\right] E\,(t)$$

The operation $\frac{p}{p - p_r}$ performed on $E\,(t)$ gives a solution

$$\frac{p}{p - p_r}\,E\,(t) = E\,(t) + \epsilon^{p_r t}\,p_r \int_0^t \epsilon^{-p_r u}\,E\,(u)\,d\,u$$

Further

$K_0\,E\,(t)$ means nothing but $K_0\,E\,(t)$ since K_0 is a constant

$M\,p\,E\,(t)$ means $M \cdot \frac{d\,E\,(t)}{d\,t}$

so that the solution can be written

$$i = M\,d\,\frac{E\,(t)}{d\,t} + E\,(t)\left[K_0 + \sum_1^{n-1} K_r\right] + \sum_1^{n-1} \epsilon^{p_r t}\,p_r \int_0^t \epsilon^{-p_r u}\,E\,(u)\,d\,u$$

The displacement f_r of the rth condenser would be,

$$f_r = \frac{i}{A\left[\frac{1}{r_r} + p \cdot \frac{1}{4\,\pi\,k_r}\right]}$$

which solves into

$$f_r = \frac{4\,\pi\,k_r}{A}\,\epsilon^{-\frac{4\pi k_r}{r_r}t} \int_0^t \epsilon^{\frac{4\pi k_r}{r_r}t}\,i\,d\,t$$

and can be calculated when i is known.

It should be noticed, that these solutions for i and f_r are perfectly general, inasmuch as the voltage $E\,(t)$ has not been subject to any restrictions.

Our immediate concern, as physicists, would now be to check the theory by experiment. It would then be a question of the best form to adopt for the test voltage $E\,(t)$, and particularly the form of $E\,(t)$ near $t = 0$.

There are three principal forms that may occur:

(1) D-c. voltage is entirely inadmissable, as it would introduce wave motion that has not been considered above.

(2) Alternative (sine-wave) voltage is better, but gives a finite value of current for $t = 0$ in the formula above, and is therefore not recommended.

(3) Voltage, possessing zero derivative at $t = 0$ should be used, for instance $E\,(t) = E_0\,(1 - \cos\,\omega\,t)$.

In other words: an a-c. voltage super-imposed on a d-c. voltage so as to produce a gradual smooth rise of voltage at the first moments would probably be the best to use when testing the theory.

To sum up: The weak spots in any theory of the dielectric omitting the magnetic permeability will be found around discontinuous points in the external voltage-curve or its first derivative. In particular it seems inadmissible from a physical standpoint to base a general solution on the solution for a suddenly impressed d-c. voltage.

Vladimir Karapetoff: I am glad that Mr. Bratt brought up the question of discontinuity in the current at the first instant. This discontinuity is not confined to Dr. Murnaghan's paper; any problem on a combination of resistances and capacitances leads to a similar inconsistency if you omit the magnetic flux. The system then has no inertia, and theoretically the current rises instantly from zero to a finite value.

W. B. Kouwenhoven: We are carrying on an investigation of Maxwell's theory at Johns Hopkins University under the auspices of the Engineering Foundation. We are endeavoring to obtain two or more perfect dielectrics having no absorption but different conductivities and dielectric constants. We will then make a mixture of these two dielectrics and if Maxwell's theory is correct the resulting mixture will show absorption. This work is still in its early stages and we are not ready to report any results as yet, but simply to say that we are making progress.

A. F. Puchstein: (communicated after adjournment) Dr. Murnaghan uses the concepts of the physicist rather than those of the engineer. Would it not have been easier for the engineering reader if the set-up had been based on the idea of capacitances instead of electric intensities and displacements?

On this basis, the same value of current passes through all of the dielectrics, then for a two-layer arrangement

$$i_1 = i_2 \tag{1}$$

Since each layer may be regarded as a condenser shunted by a resistance we have the relations,

$$i_1 = c_1\,\frac{d\,e_1}{d\,t} + \frac{e_1}{r_1} \tag{2}$$

$$i_2 = c_2\,\frac{d\,e_2}{d\,t} + \frac{e_2}{r_2} \tag{3}$$

in which e_1 and e_2 are the potential drops across the different layers; r_1 and r_2 are the insulation resistances; and c_1 and c_2 are the capacitances of the condensers formed by each layer.

In addition, the total potential drop e is the sum of the several drops, and this sum is at all times equal to the internal voltage E of the supply source minus its internal $i\,r$ drop. It is assumed that the system is initially uncharged. From this we have

$$e = e_1 + e_2 = E - i\,r \tag{4}$$

At this point, the theory here given diverges from that of Dr. Murnaghan in that he assumes the displacements at the first moment to remain finite, with no further restriction, except that initially $\Delta f_1 = \Delta f_2$, while here a limit is set by the $i\,r$ drop in the supply source. The letter f stands for displacement.

There is an obscurity of statement where we read, "* * * the polynomial φ degree $n - 1$ has all its zeros real and negative and that they lie in the intervals between the negative values of

b's. Let us denote these zeros by $(-\beta_1, -\beta_2, \ldots -\beta_{n-1})$***."

This may be correct, but it carries no meaning to one not initiated into its mysteries.

To solve the above equations, equate (2) and (3), combine (2) and (4), use D in place of $\frac{d}{d\,t}$, and solve for e_1 when

$$e_1 = \frac{E}{r} \frac{c_2\,D + \frac{1}{r_2}}{\frac{1}{r}\left(c_1\,D + \frac{1}{r_1}\right) + \left(c_2\,D + \frac{1}{r_2}\right)\left(c_1\,D + \frac{r_1 + r}{r\,r_1}\right)} \tag{5}$$

Equation (5) may be solved by the rules of operational calculus or by the rules for solving simultaneous equations. The latter method is used here. We may solve for both or either e_1 and e_2, and obtain the other by interchanging the subscripts. This last is the simplest and will be used here.

If we put

$$a = r\,c_1\,c_2, \tag{6}$$

$$b = c_1\left(1 + \frac{r}{r_2}\right) + c_2\left(1 + \frac{r}{r_1}\right) \tag{7}$$

$$c = \frac{r + r_1 + r_2}{r_1\,r_2} \tag{8}$$

then equation (5) becomes, since E is independent of time,

$$e_1 = \frac{E/r_2}{a\,d^2 + b\,D + c} \tag{9}$$

The roots of the denominator in (9) are

$$m_1 \text{ and } m_2 = -\frac{b}{a} \pm \sqrt{\left(\frac{b}{2\,a}\right)^2 - \frac{c}{a}} \tag{10}$$

and the solution,

$$e_1 = A\,\epsilon^{m_1 t} + B\,\epsilon^{m_2 t} + \frac{E}{r_2\,c} \tag{11}$$

where A and B are the constants of integration. To determine these, we notice that e_1 is zero when t is zero, then from (11)

$$0 = A + B + \frac{E}{r_2\,c} \tag{12}$$

Also, when t is zero, from (2) and (4),

$$i = i_1 = \frac{E}{r} = c_1 \frac{d\,e_1}{d\,t}. \tag{13}$$

Substituting e_1 from (11) in (13),

$$\frac{E}{c_1\,r} = A\,m_1 + B\,m_2. \tag{14}$$

Solving (12) and (14),

$$A = \frac{E\,(r_2\,c - m_2\,r\,c_1)}{r_1\,r_2\,c\,c_1\,(m_2 - m_1)}. \tag{15}$$

$$B = -\frac{E}{r_2\,c}\left\{\frac{r_2\,c - m_2\,r\,c_1}{r_1\,c_1\,(m_2 - m_1)} + 1\right\} \tag{16}$$

To obtain e_2, interchange all subscripts 1, 2, except those of m_1 and m_2.

This theory is easily extended to the case of n layers and to alternating currents, though the solutions are more complicated.

F. D. Murnaghan: I have been very interested in the various comments on my paper but shall confine myself here to some remarks on Mr. Puchstein's communication since it is almost entirely mathematical in character. His idea of allowing for the internal resistance in the supply source is quite interesting and may be at once cared for by the general method of my paper. The E in equation (7) is now to be replaced by $E - r\,u$ so that our fundamental equation for the current is

$$\left[\frac{\alpha_1}{D + b_1} + \frac{\alpha_2}{D + b_2} + \ldots + \frac{\alpha_n}{D + b_n} + r\right] u = E$$

It is now of the nth order instead of the $(n - 1)$th as before. In the case of two layers the determining equation for the exponents is

$$r\,D^2 + D\left\{r\,(b_1 + b_2) + \alpha_1 + \alpha_2\right\} + r\,b_1\,b_2 + \alpha_1\,b_2 + \alpha_2\,b_1 = 0$$

Our α's are the reciprocals of Mr. Puchstein's c's while our b's are the reciprocals of the product of his c's and r's, *i. e.*, $b_1 = \frac{1}{c_1\,r_1}$ etc. This equation checks, on substitution of these values, with his results (6), (7), (8). The same method takes care of the general case of n layers.

Space Charge and Current in Alternating Corona

BY C. H. WILLIS[1]

Associate, A. I. E. E.

Synopsis.—1. The physical nature of ionization in a corona discharge in air is studied; by means of the corona spectrum, the saturation current in air around the corona voltage, and the influence of the material of the wire on the saturation current. The results indicate that nitrogen only is ionized in a corona discharge in air; that the ionization of the nitrogen results in the separation of an electron from the nitrogen molecule; and that the electron quickly attaches to a molecule or group of molecules, probably water or oxygen, to form an ion.

2. The free charge in the neighborhood of the wire called the space charge, is found to be alternating in character and to have a definite boundary. The space charge formed on any half-wave returns to the wire on the next succeeding half-wave.

3. The mobility of the ions is calculated from the boundary of the space charge. A limiting value of about 10 cm./sec. per volt/cm. is indicated for the positive ions. The negative ions show no sign of a limiting value and the mobility varies from about 1.6 to 10 cm./sec. per volt/cm. as the maximum impressed voltage rises from the corona voltage to twice the corona voltage.

4. Ionization is found to occur at lower voltages on the positive half-waves than on the negative half-waves and the ionization on the positive half-waves becomes much more copious with the beginning of ionization on the negative half-waves.

5. A formula for the corona current based on theoretical considerations, is developed by the aid of certain empirical assumptions. This formula gives excellent agreement with the observed currents measured in large cylinders. A calculation of the corona current for a 100-mile three-phase transmission line gives a satisfactory agreement with the values of current as measured by W. W. Lewis.

* * * * *

Introduction

In 1913 J. S. Towsend published an explanation of corona on the basis of ionization by collision,[20] which has been widely accepted. In developing this theory Towsend assumed ionization by collision for both electrons and ions. However, recent work on the ionizing ability of charged molecules [31, 32, 49] has led to considerable doubt as to the possibility of any action by the positive ions in corona. Also recent studies of corona[40] have developed a number of anomalies in the behavior of gases under corona conditions. Among these anomalies may be mentioned the facts that: *a*, oxygen forms corona at a gradient below that required by nitrogen, but in the air the oxygen takes no part in the corona discharge,[42, 46] *b*, no simple relation seems to exist between the ionizing potential and the corona gradient. For instance, helium with an ionizing potential of 24.5 volts forms corona at a gradient much below that required by nitrogen with an ionizing potential of 17.0 volts.[44, 46] (The ionizing potential is the voltage through which an electron must drop unimpeded to gain sufficient energy to produce ionization.) A number of such instances can be pointed out and the results are no more rational if ionization is assumed to take place in two stages, first excitation and then ionizing the excited molecules.

It is the purpose of this investigation† to obtain further experimental evidence about the physical nature of the breakdown of the gases in corona and to obtain information about the space charges formed by the corona which may lead to analytical expressions for the corona current, corona loss, and extra capacity due to corona.

Description of Apparatus

The electrode arrangement chosen was a wire and large plane, as this gives a representation of half of a two wire transmission line, and permits an easy adjustment of the distance between electrodes. See Fig. 1. *P P* represents a plane 270 cm. by 420 cm. made of copper screen wire, number 16 mesh. *E E* represents a copper electrode 30 cm. by 91.5 cm. and about 0.2 cm. back of the plane. *W W* represents the corona wire 355 cm. long. The sizes of wire used and the distances used between the wire and plane, which are represented by *c*, are given in the corresponding data.

The potential source was a 5-kv-a. 60-cycle, 125-volt motor-driven generator, connected to a 10-kv-a., 120/240-100,000-volt, 25-cycle transformer. The diagram of connections is shown in Fig. 2. The transformer was used only in the 240-100,000 volt connection.

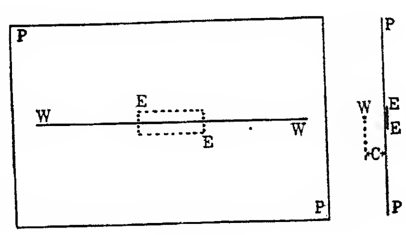

Fig. 1

The electrode *E E* is connected to a battery through a galvanometer *G* and a protective resistance *R*. By making *E E* positive with respect to the grounded plane *P P*, a portion of any negative ionic charge arriving at the plane will be drawn through the meshes of the wire to the electrode, and cause a deflection of the galvanometer *G*. By reversing the potential of the electrode *E E*, a portion of the positive ions arriving at the screen will be drawn to the electrode *E E* and cause a deflection of the galvanometer *G* in the opposite direction. This is essentially the same method for detecting the corona charges as that described by Whitehead in 1912.[13]

The potential on the wire was regulated by resistance

in the generator field. This method may cause variations in the wave form but these were not serious over the range of voltage used as shown by oscillograms. In order to maintain constant voltage the field and driving motor of the generator were supplied from a storage battery.

The high-tension voltage was in most cases determined by measuring the primary voltage. The ratio of transformation was determined by a potential transformer, and as the load was small and almost constant this ratio was assumed to hold for all measurements.

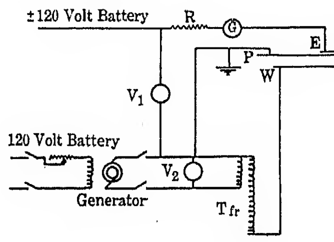

FIG. 2

All voltmeters used were of the dynamometer type and were calibrated on direct-current by a potentiometer and standard cell. The galvanometer was a Leeds and Northrup type N instrument with a period of 20 seconds and a sensitivity of 370 megohms with the scale as used.

THEORY OF SPACE CHARGE

(Wire and Concentric Cylinder)

It is generally accepted that the region of ionization in corona is a thin layer of the gas around the corona wire. Under this condition the ions formed of the same sign as the potential of the wire are driven out while the ions formed of the opposite sign to the potential on the wire will be drawn in to the wire at once. On reaching the wire the charge of these ions flows immediately through the conductor of the potential source to the opposite electrode. It is the flow of this charge that constitutes the corona current.

During the time that the charge of opposite sign to the potential of the wire is passing from the region of ionization to the wire and then to the opposite electrode the charge of the same sign as the potential of the wire moves very little because the charges move much more slowly through air than through a conductor. The charge of the same sign as the potential of the wire is then left as a space charge immediately surrounding the wire when the charge of the opposite sign reaches the opposite electrode. The energy represented by the corona current flowing through the high tension circuit is now stored as an electric displacement between the space charge and the charge on the opposite electrode. See Fig. 3A.

So far the corona wire and the opposite electrode have behaved just as a condenser but there is this important difference; the space charge is free to move under the action of the electric field, and, as the space charge does move out, the energy stored in it is dissipated, reappearing in other forms.

If the source of potential is continuous this space charge will reach the opposite electrode and all of the energy will be dissipated. However, if the source of potential is alternating the space charge may or may not have time to reach the opposite electrode, before the potential reverses, depending on the frequency and the distance between the electrodes.

Under these conditions the behavior of the space charge may be accurately represented by a circuit composed of a resistance in series with a capacity. Fig. 3A represents the condition just after a layer of space charge has been formed, and Fig. 3B represents the condition after this layer has moved out a distance from the wire. It must not be assumed that the entire space charge is formed instantly and in one layer for its formation starts when the voltage passes the corona voltage and continues certainly past the crest of the voltage wave. Figs. 3A and 3B refer to any particular layer of the space charge.

An ion formed at any point on a voltage wave will

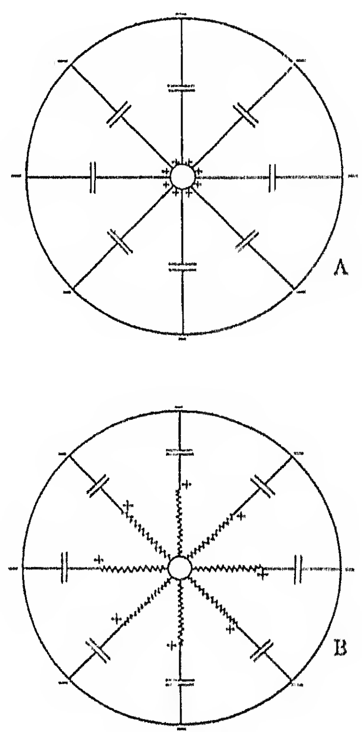

FIG. 3

have the time of the remainder of that wave for its outward journey, and the entire succeeding wave in which to return. All ions will therefore have more time in which to return to the wire than they have for their outward path, since ionization does not begin until the instantaneous voltage has risen to the corona voltage. If then we neglect diffusion and the slowing down of ions due to the formation of molecular aggregates, all of the space charge which does not

reach the opposite electrode before the voltage reverses should return to the wire at which it was formed during the voltage half-wave succeeding that on which it was formed.

The returning space charge of course meets the outgoing space charge and any recombination between these two is equivalent to a return of the space charge to the wire. Recombination therefore increases the probability of the return of all of the space charge to the wire.

The corona loss is due to the movement of the space charge through the electric field surrounding the wire. We may concentrate our attention on any average ion, of the space charge. Beginning just after its formation at the surface of the wire, and assuming that the ion has the average velocity of thermal agitation this ion will be accelerated by a force due to the electric field. As the ion moves through a free path its velocity increases due to the acceleration. At the first collision between the ion under consideration and a neutral molecule, the ion imparts to the neutral molecule, a portion of the energy gained from the electric field, even though the collision be perfectly elastic. However, the ion will start its second free path with a velocity greater than the average velocity of thermal agitation and therefore will have a higher velocity at the end of its second free path than at the end of its first free path. It will therefore lose more energy in the second collision. In this manner the velocity of the ion rises above the mean velocity of thermal agitation, to a value, called the terminal velocity,[30] such that the ion loses as much energy at a collision as it gains during a free path. (The ion requires a number of collisions to reach this terminal velocity, and the terminal velocity of course varies with the field in which the ion travels.)

If the terminal velocity of the ion attains a value sufficient to ionize a neutral molecule, ionization occurs and the ion loses practically all of its energy, and must then start the process of building up its terminal velocity again. From this it is evident that as the space charge moves through the electric field, the energy stored in the space charge is converted into heat in the elastic collisions between ions and molecules, or in case of an inelastic collision may produce a disturbance of the atomic structure resulting in ionization, or sometimes only the radiation of light. This conversion of electric energy into heat, light, and free charge constitutes the corona loss.

In the case the space charge does not reach the opposite electrode, some of the energy stored in the space charge is not dissipated because the ions do not travel through the entire potential difference. The energy stored in the space charge and not dissipated by the ions as they travel out is returned to the system and results in the extra capacity effect observed in corona.

Spectrum of Corona

The spectrum of the corona light was photographed by means of a sensitive spectroscope through the courtesy of Dr. R. W. Wood. The spectrum showed the band spectrum of nitrogen but no trace of the oxygen spectrum even at a voltage twice the corona voltage. These spectrograms were unfortunately destroyed by a fire in the Physics Laboratory. However, the results were in accord with the spectra of the arc in nitrogen as studied by K. T. Compton[39] and the point discharge in air as studied by U. Yoshida and H. Hirata.[42] They have therefore not been repeated.

It has been found by K. T. Compton[39] that the the dissociation of nitrogen occurs at a much higher voltage than that required for ionization and that the dissociation is accompanied by the appearance of the line spectrum. The corona spectrum, a band spectrum, therefore indicates that the ionization in corona is the breaking off of electrons from the neutral molecule and not a dissociation of nitrogen molecules. The results of the corona ionization are electrons and charged nitrogen molecules. The absence of the oxygen spectrum indicates that the nitrogen alone is ionized, or

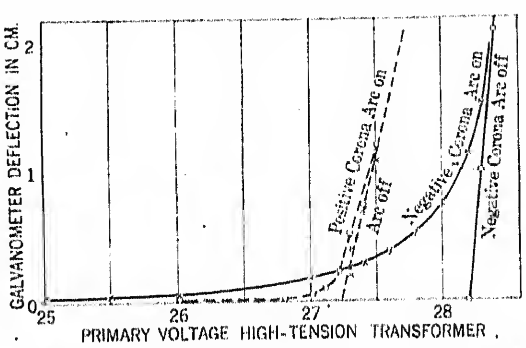

FIG. 4—MAGNESIUM WIRE MERCURY ARC 15 CM. ABOVE WIRE, TEMPERATURE 26 DEG. CENT., BAROMETER 76 CM., WIRE DIAMETER 1.14 MM. DISTANCE FROM WIRE TO PLANE 4.0 CM. TRANSFORMER RATIO 401.

that the oxygen does not play any appreciable part in the corona ionization.

Saturation Current in Air Near the Corona Voltage

In order to obtain further information on the physical nature of the ionization in corona, the saturation current of the air was measured as the voltage approaches the corona value. Whitehead,[11] and Lee and Kurrelmeyer[16] found no effect on the corona voltage due to ionization of the air by external means. A quartz mercury arc was therefore used to increase the conductivity of the air and give an appreciable saturation current.

It was found that a quartz arc placed about 10 cm. from the wire and in a position central to the electrode $E\,E$ would cause sufficient ionization to give an appreciable deflection of the galvanometer due to the charge drawn through the plane. With the electrode $E\,E$ positive and the wire close to the plane, the alternating high-tension voltage was raised by small steps past the corona voltage, and the galvanometer deflections observed at each step. These galvanometer deflections give a measure of the space charge formed on the voltage half-

waves when the wire is negative. These observations were repeated with the mercury arc illuminated, care being taken to have the arc illuminate the side of the wire nearest the plane. A typical set of observations on a magnesium wire are shown in Fig. 4. In a similar manner observations were made on the space charge produced during the half waves when the wire was positive. These results are also shown in Fig. 4.

A measurement of the lower portions of the current

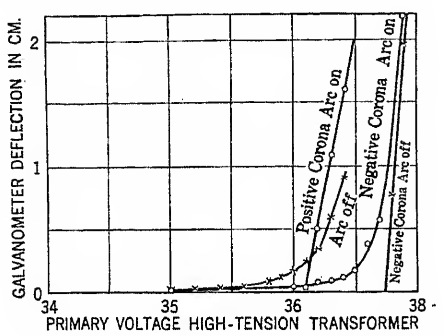

Fig. 5—Copper Wire Mercury Arc 10 Cm. from Wire. Temperature 15.1 Deg. Cent., Barometer 77.0 Cm., Wire Diameter 1.583 Mm. Distance from Wire to Plane 6.0 Cm. Transformer Ratio 401.

curve with the arc on showed the typical saturation curve for gases discussed by Towsend (34, page 2). These curves show that the corona voltage coincides approximately with the sharp rise in the saturation curve due to the ionization by collision for both the positive and negative corona voltages.

However, the curve with a negative wire starts to rise

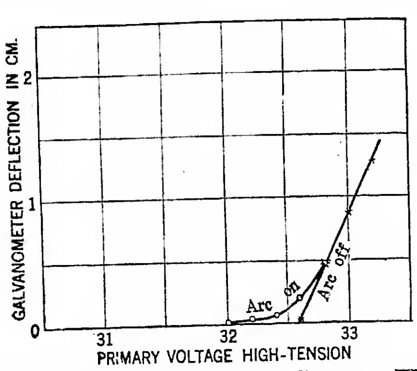

Fig. 6—Negative Corona on Copper Wire. Wire Screened from Arc. Arc 10 Cm. from Wire. Temperature 16.9 Deg. Cent., Barometer 76.1 Cm., Diameter of Wire Mm. 1.583 Distance from Wire to Plane 4 Cm. Transformer Ratio 401

at much lower voltages than the curve with a positive wire. This has been interpreted as indicating that with the wire negative the photoelectrons emitted by the wire cause ionization but with the wire positive the action is due to the charges coming in from the ionized gas. These incoming charges come from a lower gradient and have attached to molecules, forming ions. They, therefore, do not cause ionization at such low gradients nor so copiously as the electrons. This conclusion is substantiated by the following observations.

In Fig. 5 we have curves taken on a copper wire with the arc directly in front of the wire so that it did not shine on the side of the wire nearest the plane. The crossing of the curves for positive wire with the arc on and arc off is probably due to the fact that the arc caused the brass wires in the plane between the wire and electrode (see Fig. 1), to emit negative electrons and therefore reduced the number of positive ions drawn through the plane to the electrode. In the other cases shown the arc did not shine directly at the plane behind the wire and this effect was therefore greatly reduced so that it became inappreciable.

The two curves with the arc on, shown in Fig. 5, are quite similar and indicate that the ionizing agent was the same type of carrier in both cases. Since there is no positive carrier of the dimensions of an electron we must either assume that ionization in both cases was due to ions of molecular dimensions, or that we have

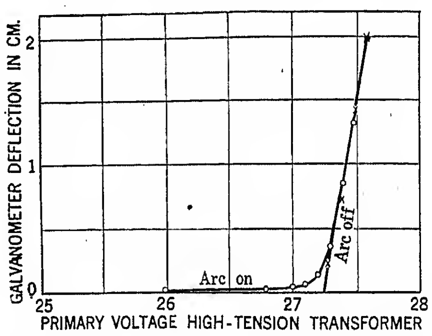

Fig. 7—Negative Corona on Magnesium Wire. Wire Screened from Arc. Arc 10 Cm. from Wire. Temperature 26 Deg. Cent., Barometer 76.0 Cm., Diameter of Wire 1.14 Mm. Distance from Wire to Plane 4.1 Cm. Transformer Ratio 401

electrons liberated from the metallic surface in the case of the negative wire. Recent experiments on the ionizing ability of molecular ions have not shown any evidence of ionization by charged molecules.[32, 49] However, Horton and Davies[31] have shown that the action attributed to the positive ions may be due, in some cases, to the emission of electrons by the metal electrodes under the bombardment of the positive ions. If this be the case in corona the saturation curve should rise much more rapidly for a magnesium wire than for a copper wire when the wire is not illuminated by the arc. To test this conclusion curves 6 and 7 were taken for negative corona on copper and magnesium wires respectively.

In addition to having the arc behind the wires so it did not illuminate the side of the wire next to the plane, the wires were screened from the rays of the arc by a glass tube one cm. in diameter and with a two-mm. wall. These results are shown in Figs. 6 and 7.

The ordinates for the curve on magnesium wire are not materially different from those on copper. While this evidence is negative and may not be considered

incontrovertible, it seems highly probable that the corona gradient is a field intensity where the positive molecular carriers become active ionizing agents as Towsend has assumed. The ionizing action of molecular carriers is quite unknown and probably entirely different in nature from the action of electrons. This is a possible cause of the anomalies in the behavior of the different gases.

Break in the Discharge Curve for Positive Corona

As previously shown, when corona forms at the crest of the voltage wave, the ions produced have a

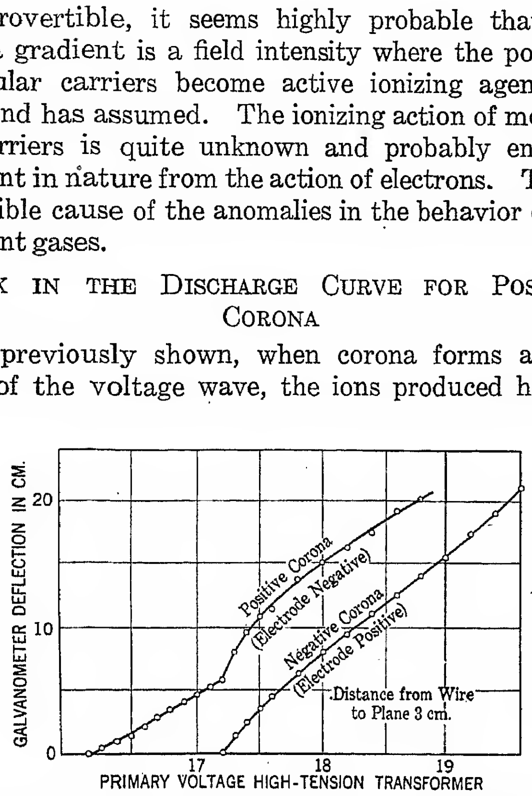

Fig. 8—Corona Discharge Curves. Temperature 21.6 Deg. Cent., Barometer 75.4 Cm., Frequency 59.5 Cycles. Wire Diameter 0.440 Mm. Transformer Ratio 401

quarter period for their outward journey and the next succeeding half period in which to return. Under these conditions all of the space charge produced in any half wave returns during the next half wave and there is a

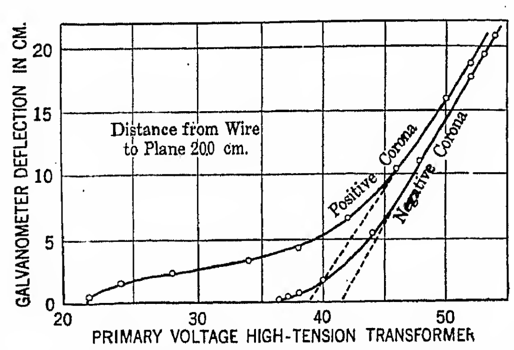

Fig. 9—Corona Discharge Curves. Temperature 24.4 Deg. Cent., Barometer 75.4 Cm., Frequency 59.5 Cycles, Wire Diameter 0.440 Mm. Transformer Ratio 401

definite boundary beyond which none of the space charge is found. (See Figs. 14 and 15.) Typical curves of the galvanometer deflections (proportional to the charge reaching the plane) against voltage are shown in Figs. 8 and 9. Fig. 8 gives the type of curves found when the wire is close to the plane. Fig. 9 shows the curves found when the wire is distant from the plane.

The break in the curves for the positive corona shown in Fig. 8 is due to the start of negative corona on the opposite half waves. In order to establish this point definitely a battery was connected in series with the high voltage winding of the transformer. In this way the a-c. voltage may be given either a positive or a negative bias.

The start of the positive corona appears at a constant value of the positive gradient, while the break of the positive corona appears at an approximately constant value of the negative gradient coinciding with the start of the negative corona, as shown in Table I.

An inspection of the curves shown in Fig. 10 (for

TABLE I

	Positive gradient at start of positive corona	Negative gradient at break of positive corona

positive corona with varying distances between wire and plane) shows that the portion of the positive discharge curve previous to the break is found only at distances from the wire to plane less than 8 cm. for a one-mm. wire. With greater distances than this the

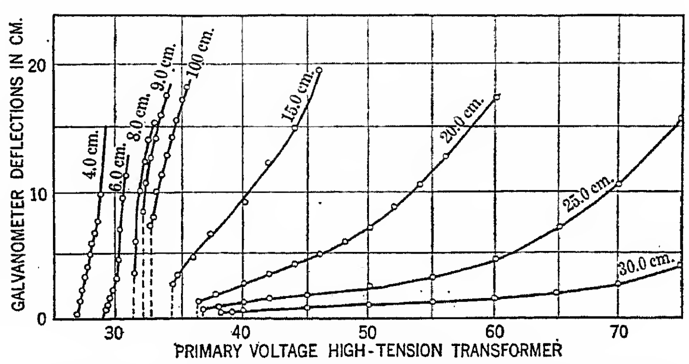

Fig. 10—Galvanometer Deflections vs. Primary Voltage for Corona on Positive Half-Waves. Temperature 18.9 Deg. Cent., Barometer 76.9., Diameter Wire 1.00 Mm. Ratio of Transformer 401

first appearance of the positive corona is not detected but the point determined corresponds to the break in the positive discharge curve at which point the positive discharge becomes much more copious and also much more mobile.

This break in the discharge curve for positive corona is of considerable interest in view of the fact that other observers have found only one voltage for alternating corona, but different voltages for the positive and negative continuous corona. Whitehead and Brown[30] using the free charge in the air to detect the corona found the alternating corona to coincide with the negative continuous corona or the higher value. This is unquestionably due to the fact that their device for detecting free charges was not sufficiently sensitive to detect the first appearance of positive corona. Those observers using visual and aural methods to detect corona undoubtedly determined the voltage for negative corona, because the volume of the discharge

becomes much more copious at this voltage. We were unable to detect any sound or light with the first appearance of positive corona. It seems probable that Whitehead and Isshiki[33] determined the voltage at which positive corona first formed but this is not certain. The size of their apparatus put them very near the boundary of the positive space charge at atmospheric pressure. So far we have made no observations under conditions which should give negative corona at the lower voltage.

Corona Gradients

The positive and negative corona gradients as determined by a wire and parallel plane on alternating current are given in Table II.

The extreme constancy of the gradients for positive

corona is worthy of especial attention here. In no case does the maximum deviation from the mean represent as great a deviation in voltage as one-tenth of the smallest scale division on the meter as used. There are two factors entering into this. The first is that the galvanometer deflections for positive corona before the break lie quite accurately on a straight line. Therefore several readings above the corona voltage can be taken with the voltmeter needle coinciding with a line on the scale and the corona voltage determined by extrapolating these values back to the axis. This gives an exceedingly accurate determination of the point at which the positive corona starts. The second factor influencing the relative constancy of the positive corona is the fact that the negative corona gradient seems to change with varying distances from the plane. The gradient for the wire nearest the plane is in every case about 2 per cent higher than the value a few centimeters further out. This may be due either to the distortion of the field due to returning positive charge or it may be due to the fact that the negative gradient is higher with a more rapidly divergent field.

In support of this latter explanation it may be mentioned: *a*, that with large wires (less divergent fields) in concentric cylinders the negative gradient drops below the positive gradient;[33] *b*, with the wire screened with a glass tube it was found that the gradient for negative corona was reduced until it coincided approximately with the gradient for positive corona, while the positive gradient was not appreciably affected. These facts seem to confirm K. T. Compton's[40] explanation of the increased strength of the air around small wires. Compton shows that the terminal velocity of an electron

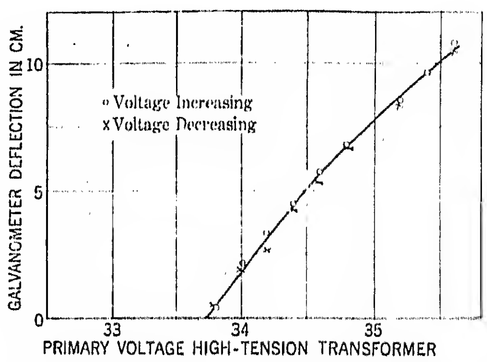

FIG. 11—POSITIVE CORONA. DISTANCE FROM WIRE TO PLANE 4.0 CM.

builds up through a number of elastic collisions thus requiring a voltage distance relation to produce ionization. His calculations seem to be of the proper order of magnitude but a quantitative check is hardly to be expected until more is known about the ionizing action of ions and electrons.

Distortion of the Electrostatic Field due to Returning Space Charge

It is to be expected that the space charge of a previous half wave will distort the electrostatic field as it returns

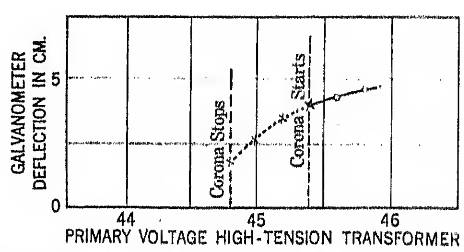

FIG. 12—NEGATIVE CORONA. DISTANCE FROM WIRE TO PLANE 16.0 CM.

to the wire. Evidence of this is found in the fact that the negative corona ceases at a lower value of the effective voltage than that at which it starts, when the wire is far enough from the plane to permit the return of of the positive space charge. However, when the wire is so close that the positive space charge reaches the plane and does not return, the voltage for the start and stop of corona coincides.

This effect is shown in Figs. 11 and 12. Fig. 11 with the wire four cm. from the plane, shows that the curve of positive discharge for increasing voltage coincides with the curve for decreasing voltage. The same was

found true for the negative corona at this distance. Fig. 12 with the wire 16 cm. from the plane shows that the curve for negative corona with decreasing voltages extends below the start of the curve for increasing voltages. The first appearance of positive corona cannot be detected at this distance, and the break in the positive corona curve due to the negative corona, which can be detected behaves just as the curve for negative corona, shown in Fig. 12.

Boundary of the Space Charge

The curves shown in Figs. 10 and 13 give galvanometer deflections against voltage for a number of

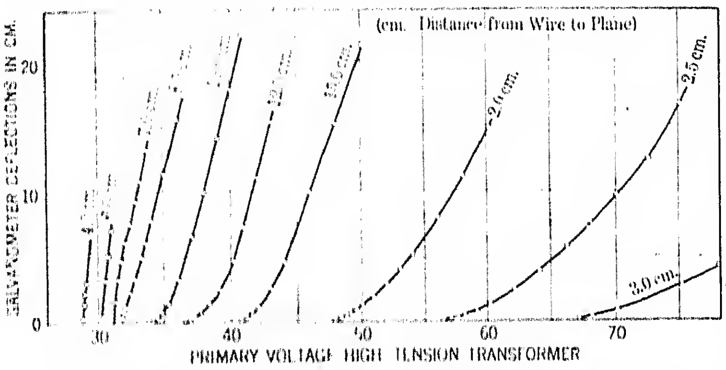

Fig. 13 Galvanometer Deflection vs. Primary Voltage for Corona on Negative Half-Waves. Temperature 18.9 Deg. Cent., Barometer 76.9 Cm., Diameter Wire 1.00 Mm. Ratio of Transformer 401

distances between the wire and plane. The start of positive corona for distances below seven cm. is given by the intersection of the discharge curve with the axis. Calculating the gradient for the start of positive corona, we find this constant, and using this value of the gradient we can calculate the voltage for the start of positive corona for greater distances between the wire and plane. In this manner the primary voltage for the start of positive corona with 15 cm. between the wire and plane was calculated to be 33.6 primary volts. At a high-tension voltage 400 effective volts above the corona voltage the primary voltage would be 34.6 volts. At this voltage the galvanometer deflection was three cm. (See Fig. 10.) In a similar manner we can find the galvanometer deflection at 400 effective volts above the corona voltage for all distances between the wire and plane. We thus obtain the relation between galvanometer deflections (or space charge reaching the plane) and the distance between wire and plane for a given rise in voltage above the corona voltage. Curves of this type for positive corona are shown in Fig. 14. However, they refer to a different size of wire from that used for the curves in Figs. 10 and 13.

The three small curves shown in the lower left hand corner of Fig. 14 give the charge reaching the plane for voltage increments insufficient to cause negative corona. These curves intersect sharply with the axis and this intersection is the boundary of the space charge at that voltage. Thus with a voltage 100 volts above the positive corona voltage no ions can be detected at a distance greater than 5.2 cm. from a 0.1-cm. wire. If the voltage rises 200 effective volts above the positive corona voltage the boundary of the positive space charge is 5.6 cm. from the wire. A few readings were taken at 40 and 80 cycles showing that the boundary of the space charge depends on the frequency. However, the machine used was not suited to these speeds. The results shown all refer to 60 cycles.

If the voltage rises 400 volts above the positive corona voltage, negative corona also forms. The start of negative corona influences the quantity of the positive discharge greatly and it also greatly increases the mobility of the charge as shown by the fact that the sharp drop in the curve comes at a much greater distance from the wire. Above the negative corona voltage the discharge curves for positive charge do not cut the axis sharply but approach asymtotically. This is believed to be due to diffusion. With the great increase in the density of the charge the effect of diffusion would be more important. Also as the voltage is carried higher and higher above the corona value, the time during which the first charges can travel out approaches nearer and nearer to the time they have to return, that is a half wave. Therefore we would expect more and more charge to be carried out by diffusion as

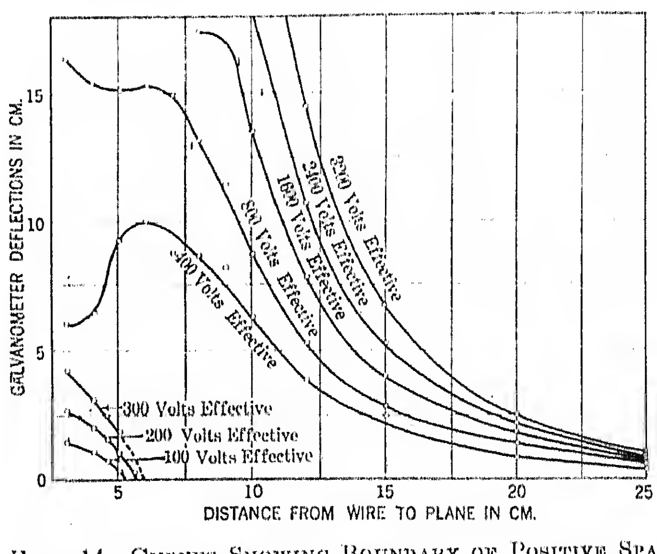

Fig. 14—Curves Showing Boundary of Positive Space Charge as Voltage Increases above Corona. Temperature 24 Deg. Cent., Barometer 75.5 Cm., Diameter Wire 0.440 Mm.

the voltage rises above the corona value. However, the discharge curves descend quite rapidly in every case and this marks the practical boundary of the space charge.

The maximum shown in the curves for 400 and 800 volts above the corona value is probably due to the fact that with a very small distance between the wire and plane most of the negative charge reaches the plane and therefore the effect on the positive charge is less important with small distances. This maximum should become less prominent as the voltage is raised because in that case the last charges formed will have a shorter time to

travel out and therefore the amount of charge returning to the wire will be greater as the voltage is raised.

The curves shown in Fig. 15 are constructed in a similar manner for the negative charge, except that in the case of the negative charge the start of negative corona can be detected at any distance from the wire to plane by the break in the discharge curve for the positive corona. At great distances from the wire to plane, this is the first appearance of positive charge. These curves for negative charge all show a sharp intersection with the axis and a definite boundary of the negative space charge. Since the positive charge is more mobile than the negative charge (except for very high voltages) and since the positive corona starts at lower voltages for the wires used, the negative ions which fail to return to the wire are probably destroyed by recombination. This prevents the curves for negative corona from becoming asymtotic to the axis.

Mobility of Ions in Corona Discharge

Ions moving through a gas under the action of an electric field obey the laws for bodies moving in a

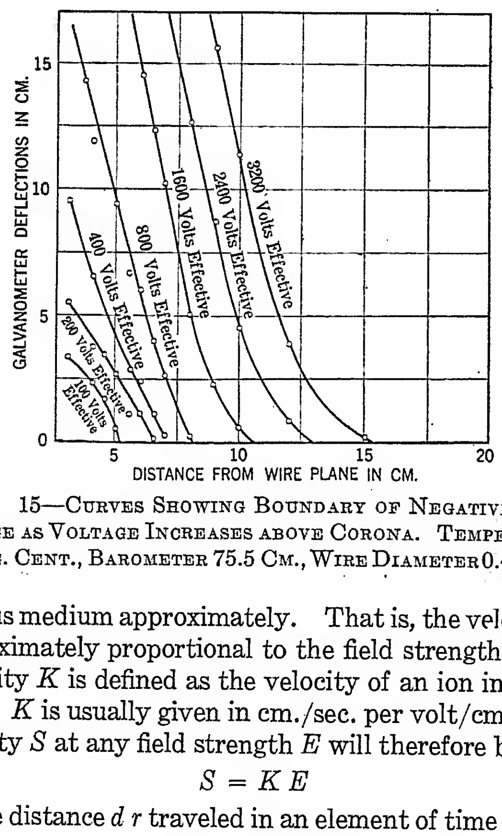

Fig. 15—Curves Showing Boundary of Negative Space Charge as Voltage Increases above Corona. Temperature 24 Deg. Cent., Barometer 75.5 Cm., Wire Diameter 0.440 Mm.

viscous medium approximately. That is, the velocity is approximately proportional to the field strength. The mobility K is defined as the velocity of an ion in a unit field. K is usually given in cm./sec. per volt/cm. The velocity S at any field strength E will therefore be,

$$S = K E$$

The distance $d\,r$ traveled in an element of time $d\,t$ is

$$d r = K E\, d t$$

If now we consider the ions which travel along the shortest path from the wire to the plane, the field along this path, neglecting the distortion due to the ions themselves, is approximately

$$E = 2\, c\, V/r\,(2\,c - r) \log 2\, c/a \qquad \text{Since } \frac{c}{a} >> 1$$

where c is the distance from the axis of the wire to the plane, a is the radius of the wire, r is the variable distance measured from the axis of the wire, and V is the potential difference between the wire and plane. (See Russell, Alternating Currents, Vol. I, p. 99.) Therefore

$$d\,r/d\,t = K\, c\, V/r\,(2\,c - r) \log 2\, c/a \qquad \textbf{(3)}$$

If now we assume V to be an alternating voltage

$$V = V'' \sin w\, t$$

and let V' be the voltage necessary to produce corona such that

$$V' = V'' \sin \theta'$$

The time which the first charges formed will have for their outward path will be

$$t = \frac{\pi - \theta'}{w}$$

If now V'' and E'', the maximum voltage and gradient be so chosen that the space charge just reaches the plane it can be easily shown by integrating equation (3) and substituting limits that approximately

$$K = \frac{2\,\pi\, f\, c^2}{3\, E''\, a\,(1 + \cos \theta')} \qquad (4)$$

Where
- K = mobility of ions
- c = distance from wire to plane
- a = radius of wire
- f = frequency
- E'' = electrostatic gradient at the surface of the wire for the voltage V''
- V'' = maximum voltage necessary to just drive the space charge to the plane
- θ' = angle whose sine is V'/V''
- V' = maximum voltage necessary to start corona.

The quantities which must be determined experimentally are a, f, c, V', and V''. a, c, and f can be measured directly. V' can be calculated, for any distance between wire and plane, from the maximum gradient for corona when the wire is near the plane. (In the case of negative corona, V' is the observed voltage for the break in the discharge curve for positive corona which can be measured for any distance between wire and plane.) V'' is the quantity most difficult to determine experimentally. This is due to the fact mentioned above that the boundary of the space charge is not very distinct on account of diffusion. However, it will be noticed that the upper part of the discharge curves becomes fairly straight for all distances between the wire and plane. This is shown well in Fig. 9. It is assumed that the straight portion of those curves represents the passage of charge to the plane on the same wave on which it is formed and without the aid of diffusion. Therefore the straight portion has been extrapolated back to the axis, and the voltage at which it intersects the axis taken as the voltage V'' at which the charge begins to reach the plane on the same wave on which it is formed.

The mobilities of the positive ions calculated in the

manner outlined above are given in Table III. The corresponding mobilities for the negative ions are given in Table IV.

The curves in Fig. 16 show the variation of the mobility of positive ions plotted against the difference between corona voltage and the voltage at which the mobility was calculated. The corresponding curves for negative ions are shown in Fig. 17.

The initial values of the mobility check very well with

the values given by the physicists, varying from 1.3 to 1.8 cm./sec. per volt/cm. for the positive ions and from 1.6 to 2.2 cm./sec. per volt/cm. for the negative ions. The mobility of the positive ions rises quite rapidly with the appearance of negative corona and then becomes fairly constant at a value around 10 cm./sec. per volt/cm. Loeb[48] calculates from Langevin's equation that the mobility of a charged nitrogen molecule at atmospheric pressure would be 9.85 cm./sec. per volt/cm. The value here found is a surprisingly good check of this predicted value. The error is much below the probable error in our values of the mobility.

No explanation can be offered of the lower values found for the larger wire. However, it must be borne in mind that there are several approximations under-

lying these calculations. The most serious of these are: *a*, the fact that a sine wave voltage was assumed for the calculations whereas the oscillograms showed a ratio of maximum to effective value of 1.52; *b*, the fact that an electrostatic distribution of gradient has been assumed for the calculations whereas the actual gradient differs far from that, when the voltage rises considerably above the corona value, as will be shown later. Both of these errors would cause the calculated value of the mobility to be lower than the value actually possessed by the ions however. The lowered values for the large wire cannot be considered as due to a greater humidity on the day when this run was taken for the humidity was somewhat less that day than for the day when the values were determined for the small wires. The effect of the

humidity could not be studied because there was no means of controlling the humidity and the normal variations in the room were not great.

A few measurements were made with 40 and 80 cycles to determine the aging of the ions but any

variation due to this cause was masked by the variation due to the voltage increase above corona.

The sharp rise in the mobility curve for the positive ions just above the voltage for negative corona suggests that the ions, as they become much more copious are washing out some impurity from the air such as moisture, and that when there are enough ions to wash out the impurity the remaining ions travel as simple molecular carriers. If we calculate the current necessary to carry out all of the water molecules in a cylinder of one cm. radius around the wire, assuming a vapor pressure for the water vapor of 7.6 mm. of mercury; that each molecule requires one electronic charge; and that the water vapor must be carried out each half cycle, we find that current of the order of 10 amperes per cm. length of wire would be required. If the water vapor is carried out it must be a process extending over a number of cycles, but even this does not seem probable.

The curves for the mobility of negative ions do not show a sharp break as found for the positive ions. However, the curves continue to rise more steeply than the curves for positive ions and there seems less evidence of a final maximum value. This is to be expected as the mobility of an electron as predicted by Loeb[17] for atmospheric pressure is of the order of 1500 cm./sec. per volt/cm. The electrons evidently do not travel a very great portion of their paths before attaching to form ions, even in the high field around a corona wire. This is to be expected from the work done on electrons in moist air at low pressures.

At a voltage practically twice the corona voltage the mobility of the positive and negative ions is the same and around 10 cm./sec. per volt/cm. as calculated from the boundary of the space charge.

Theory of Corona Current

In explaining corona on the basis of ionization by collision it must not be assumed that ionization by collision starts at the corona voltage or that it starts so sharply as does corona. An inspection of the saturation curves of air around the corona voltage, Figs. 4 to 7 inclusive, shows that ionization by collision is present below the corona voltage. The corona voltage is determined rather by the condition that the ionization by collision has become cumulative in such a way as to lead to an unstable condition.

This may be illustrated by assuming that the potential gradient around the wire draws to the wire ions due to the ambient ionization of the atmosphere. As these ions pass through the layer in which corona will form some of the ions will cause ionization by collision if the potential gradient is high enough. Also some of these newly formed ions due to the ionization by collision, in their turn will produce further ionization by collision, and any group of ions will in this way tend to reproduce itself indefinitely.

However, if the new ions formed by any group are less numerous than the original group, the descendants of this group will soon disappear and the current will be approximately the saturation current of the air. On the other hand if the new ions formed by any group are more numerous than the original group the descendants of this group will increase indefinitely and the saturation current of the air will be similarly magnified.

This serves to show that a small increase in the gradient just at the corona voltage would lead to an infinite current or a short-circuit condition; provided the gradient remained at the increased value. (The exposition of the current given above is not rigid because of the assumptions for the average value. However, the rigid treatment given by Towsend[11] shows the same characteristics for the current but in more complicated mathematical language.) In the case of corona, the gradient does not remain constant at the wire when ionization begins, for the space charge driven out from

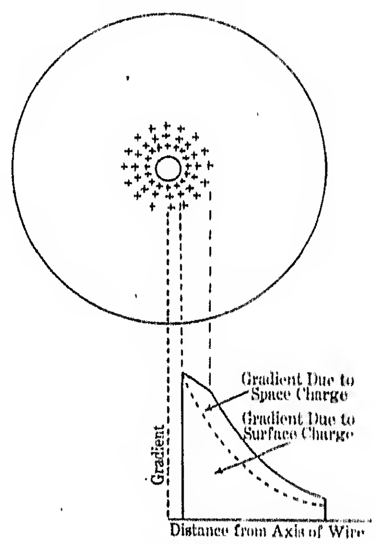

Fig. 18

the wire increases the gradient at a distance from the wire, where the gradient is low. Thus the space charge absorbs a part of the impressed voltage when ionization is taking place, as shown below.

Consider a wire inside a concentric cylinder as shown in Fig. 18. When ionization begins the charge of the same sign as the wire is driven out into space. This layer of charge raises the gradient at all points outside the layer and thus absorbs a part of the impressed voltage and reduces the gradient at the wire, where ionization is taking place. Thus there is established a condition of equilibrium between the space charge around the wire and the rate of formation of new charge, for any voltage. The space charge serves to shield the wire so that the gradient at the wire never rises above the critical value at which corona starts. In the alternating case the conditions are further complicated by the return of the space charge formed on any previous half-wave.

In order to obtain some idea of the nature of the

corona current with an alternating electromotive force we will consider a wire of radius a inside a large cylinder of radius b with an impressed voltage.

$$v = V'' \sin w\,t$$

When any transient conditions have passed, and the instantaneous voltage is above the corona voltage there are three charges that must be considered. First, there is the surface charge on the wire which has a limiting value q and is constant for all values of voltage above the corona voltage (because the gradient at the surface of the wire is limited to the corona gradient by the formation of new space charge); second, there is the space charge Q' formed on this same voltage half-wave and moving out from the wire; third, there is the space charge Q'' which was formed on the previous voltage half-wave and is now returning to the wire.

For simplicity we will assume that the charge Q', instead of being distributed through space is concentrated in a cylindrical layer of radius L', such that its effect on the gradient in the ionizing layer around the wire is equivalent to the actual distribution, and that similarly Q'' is concentrated on an equivalent layer of radius L''.

We may now divide the impressed voltage into three parts. First, a component v''' which is supported by the surface charge q' on the wire; second, a component v' which is supported by the space charge Q' which has just formed and is now traveling out from the wire; third, a component v'' due to the space charge Q'' which is now returning to the wire. This last component is negative in sign.

We have then

$$v''' = 2\,q \log b/a \tag{8}$$

$$v' = 2\,Q' \log b/L' \tag{9}$$

$$v'' = 2\,Q'' \log b/L'' \tag{10}$$

and also that

$$v = v''' + v' - v'' = V'' \sin w\,t \tag{11}$$

Substituting the values of v''', v', and v'' in equation (11) and differentiating with respect to time we have

$$\frac{d\,v}{d\,t} = -\frac{2\,Q'}{L'} \times \frac{d\,L'}{d\,t} + \frac{d\,Q'}{d\,t}\,2 \text{ Log } .\ b/a$$

$$+\frac{2\,Q''}{L''}\,\frac{d\,L''}{d\,t} - \frac{d\,Q''}{d\,t}\,2 \text{ Log } .\ b/a = w\,V'' \cos w\,t$$

(The derivatives of the charge with respect to time are multiplied by log b/a because the charge is formed and absorbed at the surface of the wire and not on the equivalent cylinder.)

The current i is

$$i = \frac{d\,Q'}{d\,t} - \frac{d\,Q''}{d\,t} \tag{12}$$

Transposing and substituting we obtain

$$i = \frac{1}{2 \text{ Log } b/a}\left[\frac{2\,Q'}{L'}\,\frac{d\,L'}{d\,t} - \frac{2\,Q''}{L''}\,\frac{d\,L''}{d\,t} + w\,V'' \cos w\,t\right] \tag{13}$$

A solution of this equation when the proper values are substituted for the Q's and L's seems at present impossible. However, some information about the corona current can be obtained from a discussion of the different terms.

The first term in the expression for the corona current, namely:

$$\frac{Q'}{L' \log b/a} \times \frac{d\,L'}{d\,t}$$

represents the rate at which new space charge must be formed to compensate for the outward movement of the space charge already formed. This term does not change sign during a given voltage half-wave and is of the same sign as the voltage half-wave.

The second term in the expression for the corona current,

$$\frac{Q''}{L'' \log b/a} \times \frac{d\,L''}{d\,t}$$

represents the rate at which space charge must be formed to compensate for the return motion of the space charge formed on the previous voltage half-wave. The motion of this charge is opposite to that of the outgoing charge so that the current required by this term is in the same direction as that required by the previous term and these two terms add their effects as shown by the negative sign before this term.

The third term in the expression for the current

$$\frac{w\,V'' \cos w\,t}{2 \text{ Log } b/a}$$

represents the current due to variation in the impressed voltage, and is the current due to electrostatic capacity. This term is of the same sign as the voltage wave on the rising part of the wave but reverses in sign at the crest of the voltage wave.

We see therefore that on the rising portion of the voltage half-wave all terms in the current relation add their effects, but when the voltage is decreasing the last term reverses in sign and tends to cancel the first two terms. The current will then decrease rapidly past the crest of the voltage wave and will probably reach zero slightly past the crest of the voltage wave. The maximum value of the corona current should come ahead of the crest of the voltage. If the frequency be high, the current will reach zero just past the crest of the voltage wave; if the frequency be low the outward motion of the space charge may produce a greater effect than the fall in the voltage and the current may continue down to the corona voltage, on the decreasing side of the voltage wave. Any recombination between the outgoing and

returning space charges tends to reduce the terms representing the motion of these charges and causes the current to reverse nearer the crest of the voltage wave.

These facts suggest the possibility of expressing the total space charge and therefore the current in terms of the charge necessary to support the maximum voltage. This is attempted in the next section. Holm[42] has also devised a method for doing this. However, we think the approximation given below represents more closely the theoretical conditions than Holm's method.

Some precautions necessary in an experimental study of alternating corona are also evident from the discussion of equation (**13**). When the outer cylinder is too small some of the space charge will reach it. In this case the returning space charge is reduced in value and the current is therefore reduced in magnitude. If the cylinder be further reduced in size the outgoing space charge may begin to reach the cylinder before the crest of the voltage wave. In this case the current is increased again and we are approaching the conditions found in d-c. corona. It seems therefore, that there should be some size of cylinder which would give a minimum current for a given rise of voltage above the corona voltage. For a somewhat larger cylinder there should be a maximum current and then any further increase in the size of the cylinder would lead to a reduction in the current. No attempt has been made to check this experimentally.

In taking oscillograms of the corona current care should be taken to allow sufficient room for the space charge, if its full effect is desired. The oscillograms of Bennett[19] were taken in a cylinder so small that the effect of the space charge is almost if not entirely lost. They do not, therefore, represent the normal alternating condition. It will be seen later that when the space charge returns the average current on the opposite half-waves must be equal. This is far from true in most of Bennett's oscillograms.

The corona current curves of Whitehead and Inouye[38] were also taken in a cylinder too small to allow the full effect of the space charge. There is evidence in some of these curves that a part of the space charge was returning but it is also certain that a part of it did not return. It is impossible to know how nearly these curves represent the normal alternating condition.

The curves taken on transmission lines,[15,16] are the only ones allowing sufficient room for the full effect of the space charge and in these the corona current is a very small part of the total current, so that its true shape is difficult to determine. It would be very interesting to see the changes in the wave form of the current as the effect of the space charge is reduced by the size of the cylinder. Also the ratio of the average to the effective value of the corona current is of practical value.

Approximate Formula for Corona Currents

As seen above, an exact solution of equation (13) for the corona current seems impossible. However, an approximate solution may be obtained by assuming that all of the space charge is formed previous to the crest of the voltage wave and that it is just sufficient to support the rise in voltage above the corona voltage at the crest of the voltage wave. In order to make the calculations possible we must also assume that at the crest of the voltage wave this space charge is concentrated on a layer of equivalent radius L' as was previously done. (The method used for approximating L' will be given later.)

As shown above, the surface charge per unit length of the corona wire never exceeds the value q which it attains just at the corona voltage V'. Any increase in the voltage causes ionization and the formation of a space charge around the wire which absorbs the excess of the voltage above the corona value.

If we measure the current into a wire from zero voltage up to a voltage above the corona voltage we observe a current relation as shown in Fig. 19. There is a sharp break in the current curve at the corona voltage V'. At any voltage V above the corona voltage the

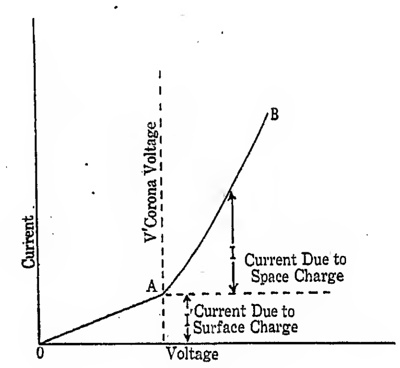

Fig. 19

current may be resolved into two parts; I' a constant part due to the surface charge on the wire and I due to the space charge around the wire. This part due to the space charge we will call the corona current. Let Q represent the maximum value of the space charge per unit length of wire in statcoulombs, l the length of the wire in cm., and f the frequency in cycles per second. We have then that the corona current (average value) is

$$I_{av} = 4\,Q\,f\,l \quad \text{(Statamperes)} \tag{14}$$

Since the space charge Q must support the excess of the voltage above the corona voltage, (by our assumption above) we have, if we assume Q concentrated on a cylinder of radius L',

$$Q = \frac{V'' - V'}{2 \log b/L'} \tag{15}$$

where V'' and V' represent the maximum values of the impressed and the corona voltages respectively in statvolts, b is the radius of the outside cylinder in cm., and L' is the radius of the equivalent space charge layer in cm. See Fig. 20.

We may determine L' as follows. Let the impressed voltage be,

$$v = V'' \sin w\, t,$$

and let θ' be the value of $w\, t$ when the instantaneous voltage has risen to the corona value such that,

$$V' = V'' \sin \theta'$$

We have then

$$\cos \theta' = \sqrt{\frac{V''^2 - V'^2}{V''^2}} \qquad (16)$$

We will now assume that the entire space charge is formed at an equivalent instant t''' such that

$$\cos w\, t''' = \frac{\cos \theta'}{4} = \frac{1}{4\, V''} \sqrt{V''^2 - V'^2} \qquad (17)$$

See Fig. 21. (The introduction of the factor 4 must be considered as a purely arbitrary assumption. However, it is justified by the fact that the first charge formed will tend to neutralize the returning space charge. Therefore the center of the formation of the space charge will be displaced toward the crest of the voltage wave. The introduction of the factor 4 is nearly equivalent to assuming that the formation of the space charge is due to the rise in the impressed voltage with the assumption

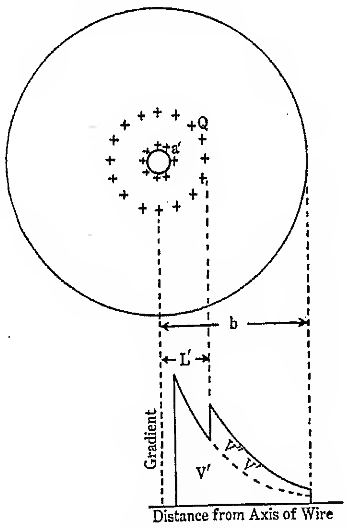

FIG. 20

that the first half of the space charge formed neutralizes the returning space charge and that therefore the center of formation of the useful space charge is at the point where three-quarters of the entire charge has been formed. Oscillograms would be of little use in determining the center of formation of the space charge because there is no way of distinguishing between the current due to the return of the previous space charge and the formation of new space charge.)

Calculating now by equation (4) the distance L' that the charge formed at the equivalent instant t''' will travel by the time the voltage reaches the crest value, we have

$$L' = \sqrt{\frac{K}{2\, w \log b/a}}\ \sqrt[4]{V''^2 - V'^2} \qquad (18)$$

where K is the mobility of the ions, and the other symbols have the values assigned to them above. K is practically an arbitrary constant and the value of 4 cm./sec. per volts/cm. was adopted because it gave the best agreement with the observed values. However, this value for the average mobility of the positive and negative ions agrees well with what might be expected

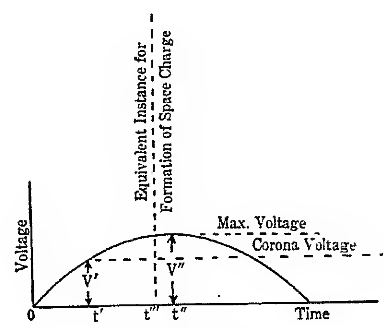

FIG. 21

from the measurement of the maximum mobility in the first part.

It must also be noted that the value of K is dependent on the arbitrary factor 4 introduced above. We might combine these two arbitrary constants but we would then lose sight of the theoretical significance of the two parts of the arbitrary constant. From theoretical considerations the first constant was thought to be approximately 4 and having introduced this, a value of K was chosen to give the best agreement with the observations.

Our formula for the corona current in practical units is now,

$$I_{av} = \frac{f\, l (V'' - V')}{4.5 \log b/L'} \times 10^{-11} \qquad (19)$$

and L' has the value

$$L' = \sqrt{\frac{1}{\pi\, f \log b/a}}\ \sqrt[4]{V''^2 - V'^2} \qquad (20)$$

I_{av} = average value of the corona current in amperes
f = frequency in cycles per second
l = length of the corona wire in cm.
V'' = maximum value of the impressed voltage in volts
V' = maximum value of the corona voltage in volts
b = radius of outer cylinder in cm.
a = radius of corona wire in cm.

In order to apply this to a two-wire transmission line we have the following changes:

V'' = maximum value of impressed voltage to mid-point between wires (ground)
b = distance between wires, in cm.

This formula is not applicable unless all of the space charge formed on one half-wave returns on the next.

When a wire and concentric cylinder are used the cylinder should be so large that the space charge does not reach the cylinder. The size of cylinder required of course depends on the frequency, size of wire, and the rise of the voltage above the corona voltage. The radius required in any case can be determined by calculating the distance traveled on any half-wave, by the ions formed just as the instantaneous voltage reaches the corona voltage. This distance may be calculated by assuming the ions to have a mobility of 10 cm./sec. per volt/cm. For 60 cycles on a No. 10 wire with a

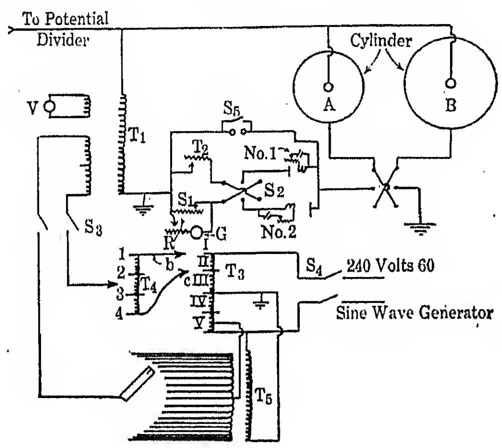

FIG. 22

voltage twice the corona voltage the radius of the cylinders should be about 30 cm. This was checked experimentally.

In case parallel wires are used the space charge should not go more than half way between the wires for it will then meet the space charge from the opposite wire. The necessary distance between the wires may be calculated by using the gradient along the line joining the wires and assuming a mobility for the ions of 10 cm./sec. per volt/cm. as above. For No. 10 wires with a 60-cycle impressed voltage twice the corona voltage, the distance between the wires should be about 60 cm. This value was also checked experimentally.

MEASUREMENT OF CORONA CURRENTS

Corona currents were measured in two large cylinders by rectifying the charging current to a central section of the cylinder through three-electrode vacuum tubes with grid connected to plate. The current was measured by a calibrated D'Arsonval galvanometer which could be connected to measure either the positive or negative waves. A diagram of connections is shown in Fig. 22.

Power was supplied by a 50-kv-a. 60-cycle motor-driven generator. The voltage was maintained by a Tirrill regulator. However, the speed was subject to fluctuations of about 1 per cent. By means of the tap-changing transformer and auto-transformers shown, the voltage could be varied by steps of one volt from zero to 240 volts. This arrangement was used to avoid wave distortion at varying voltages. The voltage was measured from a calibrated tertiary coil on the 10-kv-a. 120/240 to 100,000-volt high-tension transformer. The transformer was used only on the 240-volt connection.

The galvanometer G was shunted by the combination of resistances R and S for varying its range. It was calibrated by connecting a known e. m. f. and a known R' in series with the galvanometer and its shunt. The opposite side of the circuit was balanced by a resistance T equal to the resulting resistance of the galvanometer and its shunt. By means of the switch S 2 the galvanometer could be thrown in series with tube 1 or tube 2. A reversing switch in the galvanometer circuit was provided (not shown in figure) to keep the galvanometer deflection in the same direction for both tubes.

Switch 1 permitted the rectifying and measuring device to be thrown in series with either cylinder A or cylinder B. Cylinder A was 61 cm. inside diameter and composed of a central section 62 cm. long and a guard ring on each end of approximately the same length. The central section in which the current was measured was screened from stray fields by a gauze wire

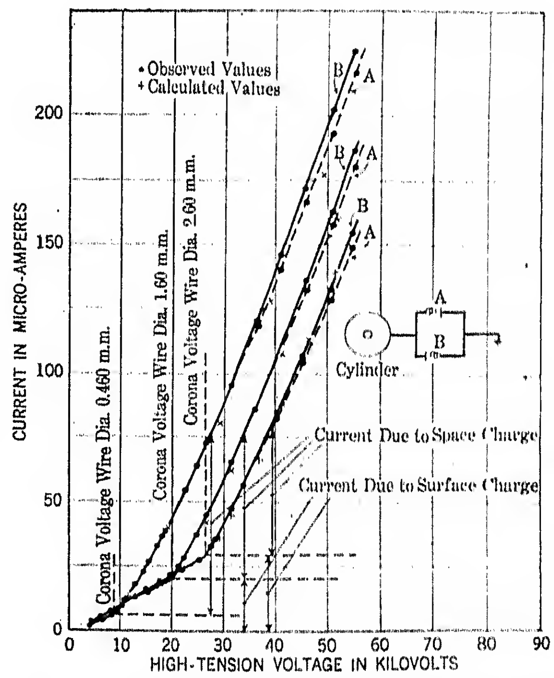

FIG. 23—CORONA CURRENT CURVES. AVERAGE VALUE OF HALF-WAVES. DIAMETER CYLINDER 61 CM. ACTIVE LENGTH OF WIRE 62 CM. FREQUENCY 64 CYCLES.

around the outside. The separation between the central and end sections was about five mm.

Cylinder B was 155 cm. in diameter. It was composed of a central section 154 cm. long and guard rings on each end of approximately the same length. As in cylinder A, the central section in which the current was measured was carefully screened. The separation between the central and end sections was about five mm. as in cylinder A.

Measurement of the insulation resistance and

capacity to ground of the central sections of cylinders A and B, and of the plate voltage required for the rectifying tubes, showed that the error caused by the admittance to ground of the central sections of the cylinders was less than 0.5 per cent.

The charging current of the central section of each cylinder was measured for three sizes of wire, up to a voltage at least twice the corona voltage. These values are shown in Figs. 23 and 24. The currents plotted are rectified half waves, and therefore represent half of the total current expressed in average values.

The readings of the positive and negative half waves were equal except when the space charge began to reach the cylinder. The symmetry of the current waves is no indication that the positive and negative space charges are equal because any half wave measures the outgoing charge of one sign and the returning charge of opposite

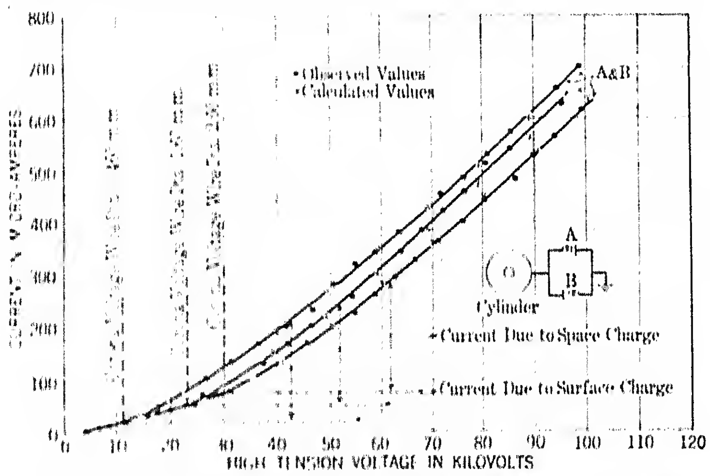

FIG. 24—CORONA CURRENT CURVES. AVERAGE VALUE OF HALF-WAVES. DIAMETER OF CYLINDER 155 CM. EFFECTIVE LENGTH OF WIRE 154 CM. FREQUENCY 64 CYCLES

sign. This is not true when the cylinder is small. With small distances between the wire and cylinder the current corresponding to the formation of negative space charge exceeds the current corresponding to the formation of positive space charge. This may be explained as due to a decrease in the return of the negative space charge or an increase in the formation of the negative space charge. The voltage corresponds roughly to the voltage at which the negative charge should reach the cylinder and it seems most probable that this difference is due to a decrease in the return of the negative space charge. This indicates that the negative space charge reaches the cylinder first, which is in accord with our previous determinations of the mobility of the negative space charge for this voltage. For the large cylinder it was not possible to raise the voltage to such a value that the positive and negative current half waves became unequal.

CALCULATION OF CORONA CURRENTS

In the calculation of the corona currents the corona voltage is determined experimentally from the break in the current curves. A comparison of the observed values of the corona voltage with the values calculated from the formula of Whitehead and Brown, Peek, and Whitehead and Isshiki are given in Table V.

The ratio of the maximum voltage to the effective voltage at 240 volts for the generator used had been previously determined by oscillograms to be 1.46. This value is used in the calculations of the corona current. The calculated values are shown by crosses

TABLE V

Cylinder dia. Cm.	Wire dia. cm.	Observed kv. eff.	Corona voltage calculated by formula of: White-head and Brown kv. eff.	Peek kv. eff.	White-head and Isshiki kv. eff.	Eq. 2 kv. eff.
61	0.046	8.7	10.27	9.93	9.92	9.35
61	0.160	20.0	20.6	19.8	20.2	18.7
61	0.260	26.5	27.6	26.0	26.8	24.7
155	0.046	10.5	11.95	11.55	11.53	10.88
155	0.160	23.0	24.5	23.2	23.7	22.0
155	0.260	30.0	33.5	31.6	32.6	30.1

on the curves of the observed corona current Figs. 23 and 24.

The agreement is entirely satisfactory in all cases. Any differences between observed and calculated currents are of the order of the probable experimental error. The agreement is even more impressive when

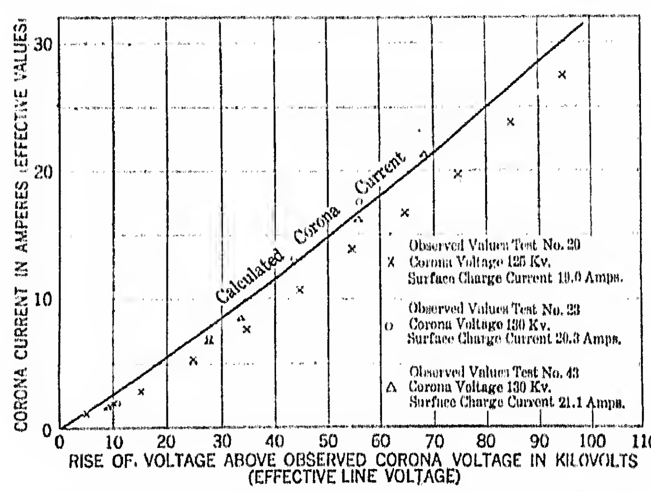

FIG. 25—CORONA CURRENT CALCULATION. TESTS OF W. W. LEWIS, A. I. E. E. TRANS., VOL. 40, P. 1059. THREE PHASE LINE WIRES IN VERTICAL PLANE. LENGTH 101.5 MI. SPACING 12 FT. CONDUCTORS NO. 0, SEVEN STRAND. DIAMETER 0.19 IN. FREQUENCY 30 CYCLES

we notice that the voltage range is quite wide. In Fig. 23 the voltage was raised to nine times the corona voltage for the small wire. This indicates that the corona current formula is of the correct mathematical form.

The corona currents are also calculated for the three-phase transmission line studied by W. W. Lewis.[37] This line consisted of three 110,000-cir. mil, seven-strand conductors spaced 12 ft. in a vertical plane. The length was 101.5 miles, and the radius of the conductors was 0.19 in. The corona voltage is here again deter-

mined by the break in the charging current curves given by Lewis. In calculating the corona current, voltages to neutral are employed. The measured currents are in effective amperes. In order to convert the corona current from average to effective values the factor 1.11 is used—(the ratio for a sine wave.) This is open to criticism but no better method presented itself. A comparison of the observed and calculated values for this transmission line is given in Fig. 25.

The agreement is surprising when we consider the possible causes for discrepancy. Among these causes may be mentioned; 1, the fact that the voltage rose about 10 per cent along the line so that different parts of the line were at different stages of corona formation; 2, the space charge around the wire with corona on it distorted the electric field and therefore the neutral of the system (this may cause a shift of the voltage away from the corona wire); 3, the ratio of the effective to the average value of the current is probably not 1.11 as assumed; 4, the frequency of these tests was 30 cycles while the formula fcr corona current was developed for 60 cycles.

Summary

1. The spectrum of corona shows the band spectrum of nitrogen indicating that only the nitrogen breaks down in a corona discharge in air and that the ionization produces electrons and positively charged nitrogen molecules rather than a dissociation of nitrogen molecules into atoms. The electrons even in the high electric field around corona wires almost immediately attach themselves to molecules (probably of water vapor or oxygen), forming ions as seen from the mobility below.

2. The air was rendered more conducting by a quartz mercury arc and the saturation current measured as the voltage approached the corona voltage. The corona voltage lies somewhat above the first rise of the saturation current due to ionization by collision. Saturation curves taken on copper and magnesium wires show no influence due to the material of the conductor. This indicates that the positive ions are active ionizing agents as Towsend has assumed.

3. Corona forms on the positive half-waves of an alternating impressed voltage about 2 per cent below the voltage required to form corona on the negative half-waves. (This has been tested only at atmospheric pressure for wires between No. 25 and No. 10 B. & S. gage.) The first appearance of positive corona does not give appreciable sound nor light, and ions due to this corona do not penetrate the air to a distance greater than about 8 cm. (for a No. 10 wire at atmospheric pressure).

4. The amount of ionization on the positive half-wave becomes very much more copious with the appearance of corona on the negative half waves.

5. The observed voltage for positive corona was found to be much less subject to errors due to surface irregularities and the divergence of the field, than the observed voltage for negative corona. This is to be expected from similar work on the continuous corona.

6. The ions formed around a corona wire, during any half-wave, which are of the same sign as the potential of the wire, are driven out from the wire forming a space charge. This space charge moves out from the wire until the voltage reverses. It then returns to the wire. Thus the space charge is able to penetrate the air around the wire only to a definite distance, or may be said to have a boundary. This boundary of the space charge varies with the corona voltage, the rise in voltage above the corona voltage, and the frequency. Diffusion reduces the sharpness of the boundary of the space charge. (See Figs. 14 and 15.)

Since the space charge formed on any half-wave returns to the wire on the next succeeding half-wave, we must consider during a half-wave two approximately equal space charges, one space charge of the same sign as the potential on the wire traveling out, and the other space charge of the opposite sign to the instantaneous potential of the wire and returning.

7. The mobility of the ions formed in the corona discharge was calculated from the boundaries of the space charges. The mobility of the positive ions was found to increase with the rise of the voltage above the corona voltage from about 1.3 to 10 cm./sec. per volt/cm. The mobility of the negative ions was found to rise with the increase of the voltage above the corona voltage from about 1.6 to 10. cm. sec. per volt/cm.

The curves of mobility of positive ions plotted against rise in voltage above the corona voltage indicate a limiting value of the mobility of about 10 cm./sec. per volt/cm. This is in good agreement with the value 9.85 calculated by Loeb[48] from Langevin's equation. The curves for the mobility of negative ions do not indicate that a limiting maximum value is probable.

8. An analysis of the conditions of corona formation indicate that the gradient near the surface of the wire can never rise above the value it has at the corona voltage. This requires that the surface charge on the wire be constant for all voltages above the corona voltage and that the space charge support any rise in the voltage above the corona voltage. The differential equation of the corona current based on these conditions does not admit of a simple solution.

9. An approximate formula for the average current due to the space charge has been derived by the aid of certain empirical assumptions. This formula gives a good agreement for the corona currents measured in two large cylinders. The corona currents were calculated by this formula for a 101.5-mile three-phase transmission line and the agreement is reasonable, with the measurements made on this line by W. W. Lewis.[37]

The author wishes to express his appreciation of the facilities provided by the Johns Hopkins University, and the assistance given by members of the faculty. He is particularly indebted to Dean J. B. Whitehead for his valuable suggestions and criticisms, and to Dr. W. B. Kouwenhoven for his advice on problems of measurement. The author also wishes to express his appreciation of the assistance given by Mr. S. K. Waldorf, graduate student in Engineering, in the measurement of corona current.

Discussion

Joseph Slepian: One thing that Mr. Willis brings out and which is worth emphasizing is that the beginning of corona is not the point where ionization by collision begins. This is important because very frequently in the past it has been assumed that the beginning of ionization by collision is also the beginning of breakdown or of corona under various conditions. Mr. Willis has shown by his experiments here that the corona comes at a higher gradient than that at which appreciable ionization by collision occurs and that corona sets in when a sufficiently great cumulative reaction takes place between the ionization produced by collisions of the negative ions and that produced by collisions

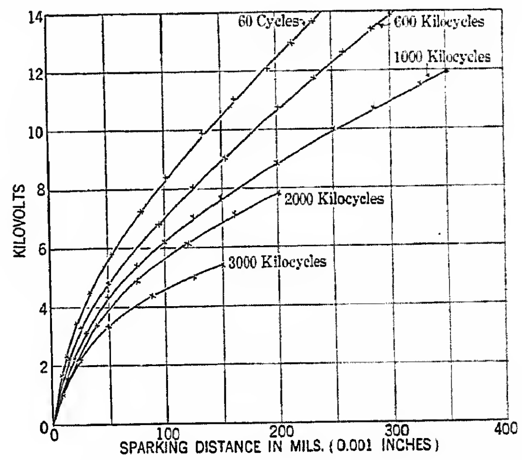

Fig. 1—Two-c. m. Sphere-Gap Sparking Voltage at Various Frequencies

of the positive ions. Hence the gradient at which the corona begins is not a constant of the gas but also depends upon the geometrical configuration of the electrodes; that is, it depends also upon the radius of the wire and the distance to the other electrode.

Alexander Nyman: I should very much like to see this work extended to include operation at high frequency.

Probably many people are familiar with the fact that at high frequency the corona begins to appear at much lower voltage than at 60 cycles; in fact, perhaps two or three times lower at frequencies as high as 1,000,000 cycles. At frequencies as high as 5,000,000 or 10,000,000 cycles, corona begins even at lower voltages than this; it is possible to observe a corona on sharp points at 1000 or 1500 volts. This fact became apparent in the first place during the measurement of voltage on static condensers and on insulators for condensers for use on power transmitting stations. A sphere-gap calibrated at high frequency showed values as illustrated in the accompanying figure, from which it is evident that the sparking voltage at 1,000,000 or 2,000,000 cycles is considerably lower than at 60 cycles. At 10,000,000 cycles these voltages are lower yet.

Now, it is evident that the discharge between sphere-gaps is not of the nature of corona, but the reduction between the sphere-gaps brought to the attention a similar reduction of discharge voltage between sharp points and it was then even more conspicuous.

With the spacing of ½ in. and a frequency of 10,000,000 cycles, a sparking distance of 4000 or 5000 volts is quite usual between

edges which are not strictly sharp. Of course, with sharper edges this voltage is considerably lower. The question will arise "How do we know that this is a correct voltage measurement?" The process to ascertain this fact is rather lengthy, but consists in general of the following:

A static condenser, which remains constant at different frequencies, and a measurement of current and frequency gives a measurement of voltage.

The measurement of current may be again in doubt, but can be assured by a proper design of an ammeter, suitable for this specific purpose.

W. A. Del Mar: On the third page of Mr. Willis' paper there is this statement: "The results of the corona ionization are electrons and charged nitrogen molecules. The absence of the oxygen spectrum indicates that the nitrogen alone is ionized, or that the oxygen does not play any appreciable part in the corona ionization." On the sixteenth page there is something which appears to be contradictory. Under "Summary," paragraph one it says: "The electrons, even in the high electric field around corona wires, almost immediately attach themselves to molecules, (probably of water vapor or oxygen), forming ions as seen from the mobility below." Oxygen is here mentioned as one of the types of ions, whereas in the preceding paragraph it is said to have practically no part. I should appreciate an explanation.

H. J. Ryan and J. S. Carroll: (communicated after adjournment) Three papers have been presented to the Institute, heretofore, that deal largely with the space charges which surround conductors in alternating corona [a,b,c]. These papers are not mentioned in the bibliography given at the end of the paper and no reference is made to their conclusions, which are quite different from those here presented. The facts presented in the preceeding papers were obtained by quantitative studies of the *whole* space charge that surrounds a conductor in corona due to high voltages at low frequencies,—generally 60 cycles. The studies reported in the papers presented at Seattle, [b] 1925, and Salt Lake City, [c] 1926, included the cyclic time element and the radial positions of the space charges.

The electrodynamic behavior of the ions in the alternating corona cycle is far too complex and too little understood, as yet, to enable anyone to formulate a theory of the space charge such as attempted in this paper. The author is apparently convinced that the integrity of his theory is ample to warrant him in setting forth the complete *quantitative* behavior of the space charge from *qualitative* observations of diffuse remnants of alternating space charges with the determinations of the radial positions incomplete and the cyclic time elements wholly omitted.

We submit that one cannot inform himself reliably about these space charges by that sort of procedure and that he certainly cannot help others. Surely knowledge of all facts that it is possible to obtain must come first; the facts must be studied thoroughly to develop an understanding of their mutual relation and then only can a theory be formulated and put forth to assist others to acquire, with economic effort, such understanding.

Dependable knowledge as to these space charges is of undoubted importance in high-voltage engineering. We regret that Mr. Willis has made it so difficult for us to join in a more hearty welcome to him with his results, as a worker in this field in which we hope we can all continue to work unremittingly. We earnestly trust that we will soon be able to resolve our differences with understanding, so that we can present the facts about these space charges, without confusion, to the membership of the Institute.

C. H. Willis: I appreciate Dr. Slepian's emphasis of the fact that the corona gradient is not the beginning of ionization by collision. In ionization by collision we are measuring average effects, but the probability of ionization at any particular collision between an ion and a molecule depends on the actual free path which the ion has just traversed and also on the type of collision. The saturation current in the gas increases as the voltage rises and the explanation of this increase is ionization by collision. We cannot, however, pick any particular voltage as the point where ionization by collision begins.

In corona, the current rises abruptly at a certain voltage. The explanation is that at this voltage the ionization has become cumulative to such an extent that it would lead to a short circuit, but for the action of the space charge.

Mr. Nyman speaks of the lowering of the voltage at high frequency. His remarks were quite interesting to me. The only work I know of in this regard is the work by Gorton and Whitehead, in which they found the corona gradient to be affected to about two or three per cent at frequencies up to 3600 cycles per second. I should be very much interested in seeing further work if it has been published.

In regard to Mr. Del Mar's question, I believe my statement was that the nitrogen played the main role in ionization by collision. We have in the air a mixture of N_2 molecules and O_2 molecules. There are, of course, two ways in which we may produce ionization. We can dissociate the molecules into N plus and N minus. This would give a line spectrum. Therefore, this is not the form of ionization which occurs in corona, nor does that occur except at very much higher gradients than the corona gradient. But the band spectrum indicates that the N_2 molecule breaks up into a positively charged N_2 molecule and an electron. We must remember that the electron has a mass of $^1/_{18}$ hundredth of the hydrogen molecule and therefore, is very much smaller than a nitrogen molecule. The probable mobility of the nitrogen molecule is around 10 cm./sec. per volt/cm. I had expected in this work to find that the negative space charge would have a very high mobility and would penetrate the air to a very much greater distance than the positive space charge. To my surprise, I found that the two charges penetrated to practically the same distance, and the conclusion which follows is that the electron attaches itself to a molecule very quickly forming an ion.

The nitrogen molecule is ionized and the electron then attaches itself either to a water or oxygen molecule to produce an ionic carrier rather than an electronic carrier. The reason that I conclude that the electron attaches to water vapor or oxygen is the fact that water vapor and oxygen have a very much higher electron affinity than nitrogen. We would expect that the nitrogen would not attract the electrons, from the work done by physicists.

The author wishes to apologize for the omission of the paper by Messrs. Ryan and Henline, from his bibliography. The bibliography however is by no means complete, as only those papers are given which seemed to have a direct bearing on our work. The other papers mentioned by Messrs. Ryan and Carroll were published after this work was planned and the bibliography prepared.

We feel that the criticism of Messrs. Ryan and Carroll that our work was qualitative is hardly justified. The method of determining the total space charge by measuring the rectified current is probably the most accurate method, and is certainly not subject to the very serious criticisms which may be made against the other methods which have been employed, (*i. e.*, that these methods either limit the space charge or distort the field or both.)

We also feel that any serious criticism of our generalizations in regard to the space charge, which are used in developing the expression for the average value of the corona current, should include a demonstration of the inaccuracy of the expression for the corona current.

Tests on High- and Low-Voltage Oil Circuit Breakers

BY PHILIP SPORN[1] and HARRY P. ST. CLAIR[1]
Associate, A. I. E. E. Associate, A. I. E. E.

Synopsis. *Data from a large number of tests on several types of oil circuit breakers are given in this paper. The tests were made on breakers with the following ratings: (a) 150 kv., 1,500,000 kv-a.; (b) 35 kv., 250,000 kv-a.; (c) 7000 volts, 7500 kv-a.; (d) 132 kv., 1,250,000 kv-a., and (e) 132 kv., 750,000 kv-a. These tests were made on power systems having sufficient connected capacity to make the tests conclusive. Complete data are tabulated and oscillograms are shown. Some valuable conclusions resulted from the tests.*

INTRODUCTION

THE American Gas and Electric Company has carried out a number of tests on high- and low-voltage oil circuit breakers, these tests falling into three principal groups which are as follows:

1. The first group of tests was brought about by the purchase from the Brown Boveri Company of a number of 150-kv. and 35-kv. breakers, the acceptance of which was made conditional upon the results of rupturing capacity tests. The 150-kv. breaker, described and illustrated more fully in later paragraphs, is of the round tank multiple break type equipped with oil filled 150-kv. bushings. A total of 10 breaks per pole is employed using simple ball type butt contacts.

Although it was not possible to obtain sufficient short-circuit current at any point on the interconnected 132-kv. system of the American Gas and Electric Company to test the breaker at its full rated interrupting capacity of 1,500,000 kv-a., it was felt, nevertheless, that a series of tests at the maximum capacity available, approximately 750,000 kv-a., would serve to indicate whether the breaker would be acceptable for the intended service. The Sunnyside Substation of the Ohio Power Company at Canton, Ohio, was selected as

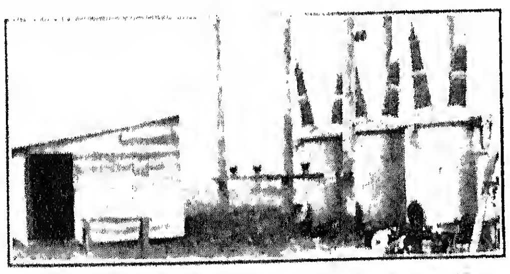

FIG. 1—BROWN BOVERI 150-KV. BREAKER IN POSITION FOR TEST WITH SHELTER FOR CURRENT TRANSFORMERS AND TRIPPING RELAYS

the logical place to carry out the tests, since not only was it possible to obtain a maximum concentration of short-circuit capacity at that point, but also because the particular point being a substation, any short circuit placed on the system there would be divided between the various generating stations on the interconnected system through the intervening lines between Sunnyside Substation and the generating stations.

The 35-kv. breaker was of the plain break type, two breaks per pole, with all three poles in one rectangular tank. Several of these switches had been purchased subject to the results of tests to be made at 22 kv. (the only voltage of that class available at Sunnyside Substation) and carried to the full breaker rating of 250,000 kv-a.

2. The second group of tests, conducted at Schenectady, using the regular testing equipment of the General Electric Company, was made on one unit of the Reyrolle compound filled switchgear, type C-1-ORD, rated at 7000 volts, 400 amperes, and having a guaranteed rupturing capacity of 75,000 kv-a. As in the case of the Brown Boveri breakers a number of these units had been purchased subject to satisfactory performance under short-circuit tests. These tests, more fully described later, were made first at 2300 volts beginning with less than rated duty and carried to a point considerably beyond the rating, and later at 6600 volts at more than full rating.

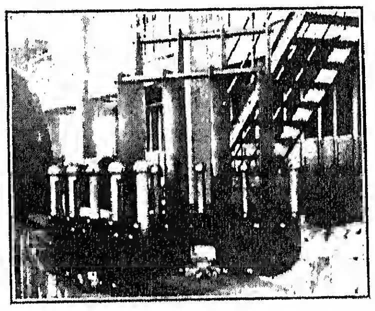

FIG. 2—UPPER RIGID CONTACTS (INVERTED) AND ONE SET OF BARRIERS

3. The third group of tests was made on two General Electric Company breakers, the breakers selected being two 132-kv. breakers, one of them an FHKO-39-B and the other an FHKO-136-B. The first, that is, the FHKO-39-B, had a rated rupturing capacity of 1,250,000 kv-a. This breaker, as is well known, is of the round tank, explosion chamber type. The other, the FHKO-136-B, is rated at 750,000 kv-a. and is of the oval tank explosion chamber type. It was felt that a short-circuit test on this breaker at the Sunny-

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

side Substation, where a capacity practically equal to the breaker rating was available, would serve as an excellent check on the design principles embodied in other high-voltage breakers of the same type.

Tests on the Brown Boveri Type[2] A F 24/1 A 150,000-Volt Oil Circuit Breakers

The general appearance of the 150-kv. Brown Boveri breaker is shown in Fig. 1. This illustration

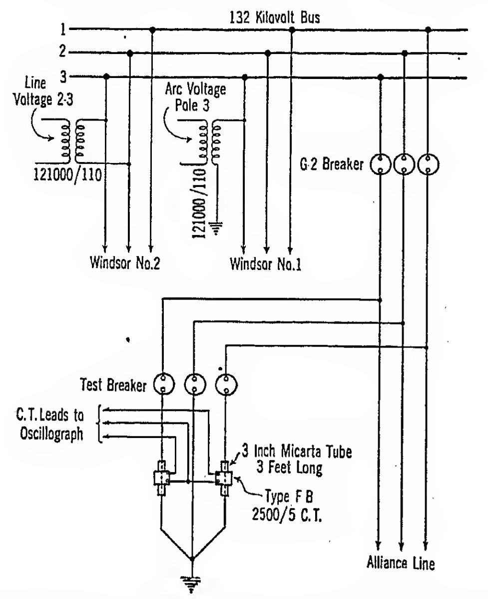

Fig. 3—Diagram of Test Connections for the Brown Boveri 150-Kv. Breaker Tests at Sunnyside Substation

also shows the method of mounting the breaker and of bringing the leads on the short-circuit side to a small shelter in which were placed the 2500-ampere current transformers and the relays used in tripping the breaker. The foundation for the breaker consisted of heavy timbers placed directly on the ground as shown.

The breaker tanks have a diameter of 65½ in. and a height of 8 ft. 10 in. from the truck wheel to the center line of the horizontal operating shaft. The ball type contacts are shown in Fig. 2, which is a view of the upper stationary contacts in an inverted position. The upper contacts are rigidly attached to the lower end of the bushing. Fig. 2 also shows an assembly of flash barriers placed between the contacts.

Diagram Fig. 3 shows the test connections and relative location of equipment. The test breaker was connected solidly to the Alliance 132-kv. circuit at the first tower outside of the substation yard, the G-2 switch on this line serving as a back-up breaker. The current transformers used for obtaining current records were Westinghouse type FB 2500 amperes, 2300 volts indoor busbar type with the insulation reinforced by adding a micarta tube three in. in diameter, three ft. long, with a ⅜-in. wall, and wrapping the bare 4/0 conductor with varnished cambric to a thickness of approximately ½-in. before placing the tube and current transformer over it. It was felt that this insulation would withstand any voltage that could be built up on the grounded side of the switch even though the

	Philo-Canton 336,400-cm. ACSR, 16.6 ft. effective spacing.

ground connection was not of particularly low resistance. The breaker tanks were grounded to separate ground pipes driven near the tanks and not tied in with the short-circuit ground connection.

Professor H. E. Dyche who, assisted by Professor E. R. Rath, both of the University of Pittsburgh, was engaged to take oscillographic records and to furnish

2. See also *Electrical World* of May 9, 1925.

the necessary equipment, had added to an original Siemens and Halske oscillograph a number of automatic features making it possible to start the film at an exact predetermined time delay after the actual closing of the test breaker control circuit, and to automatically stop the film after a predetermined travel. This feature made it possible to record as many as four shots on one film without reloading the instrument even though the shots were made in rapid succession. A film taken in this manner is shown in Fig. 6.

Complete results of all tests including data on the system set-up are summarized in Table I. The system data given will be sufficient, when combined with the system diagram Fig. 4, to show the set-up for each test.

Beginning with a standard duty cycle of 2-O C O shots with a two-minute interval and with a system set-up calculated to give approximately 225,000 kv-a., the duty on this breaker was increased by steps until on Tests No. 16 to No. 26 the full system capacity available was applied.

After Test No. 5 the oil was drained from one tank in

*Estimated from current and voltage record.

†Estimated, record cut off.

order to permit examining the contacts. Finding the contacts only slightly burned and the oil only slightly discolored, it was decided to go ahead with the tests without any change of oil in the other two tanks and without dressing the contacts.

The series of eight shots comprising Tests No. 6 to No. 13 inclusive, presents an unusual and interesting test in that the eight shots were given as rapidly as the breaker could be closed, the interval averaging approximately 10 sec. The short-circuit kv-a. opened on this series averaged approximately 330,000 or approximately one-fourth of the rated capacity of the breaker. The oscillograms for this series of tests are not reproduced here but are of the same general form as those shown in Fig. 6. The first two shots were intentionally not recorded on the oscillograph, but the last six were all recorded on one film. The voltage element on the oscillograph was burned out at the beginning of this series of tests, but the current record was obtained in each case.

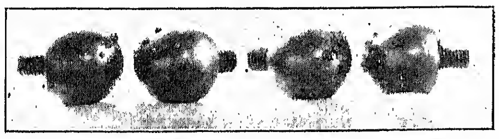

FIG. 5—BALL TYPE CONTACTS OF BROWN BOVERI 150-KV. BREAKER AFTER TEST NO. 15

Oil samples taken after this series tested 27 kv. as compared with a test of 28 kv. on the oil originally supplied to the breakers, and showed only slight discoloration.

It might be of interest to note that considerable trouble was experienced in recording the two currents on the oscillograph apparently due to stray currents in the secondary leads. The difficulty was not overcome until an entirely separate ground consisting of a single ground pipe had been made and the test current transformers completely isolated from the station ground.

Tests No. 14 and No. 15 represent a standard 2-OCO duty cycle to which was applied the full system capacity as shown on Fig. 4 with the exception that Cleveland was not connected and at Akron there was connected one 22,000-kv-a. generator only. This set-up was calculated to give a short circuit of approximately 525,000 kv-a. Fig. 5 shows the burning of the contacts which were removed for inspection after Test No. 15. Oil samples taken at this time showed slightly more discoloration than those taken after Test No. 5, but the oil was in very good condition and tested an average of 24 kv.

In an attempt to obtain a record of the internal pressure on this breaker during the tests, engine type pressure indicators were connected to the tanks through a fitting in the center of the manhole cover at the bottom of the tank. This method of obtaining a pressure record, however, was very inadequate as the pressure in the tanks was insufficient to cause any appreciable deflection. As near as could be determined, the indicators registered a pressure of approximately 10 lb. per sq. in. on all tests.

During the interval between Test No. 15, the final test on March 8, and Test No. 16, the contacts were removed and dressed and fresh oil supplied to the breaker.

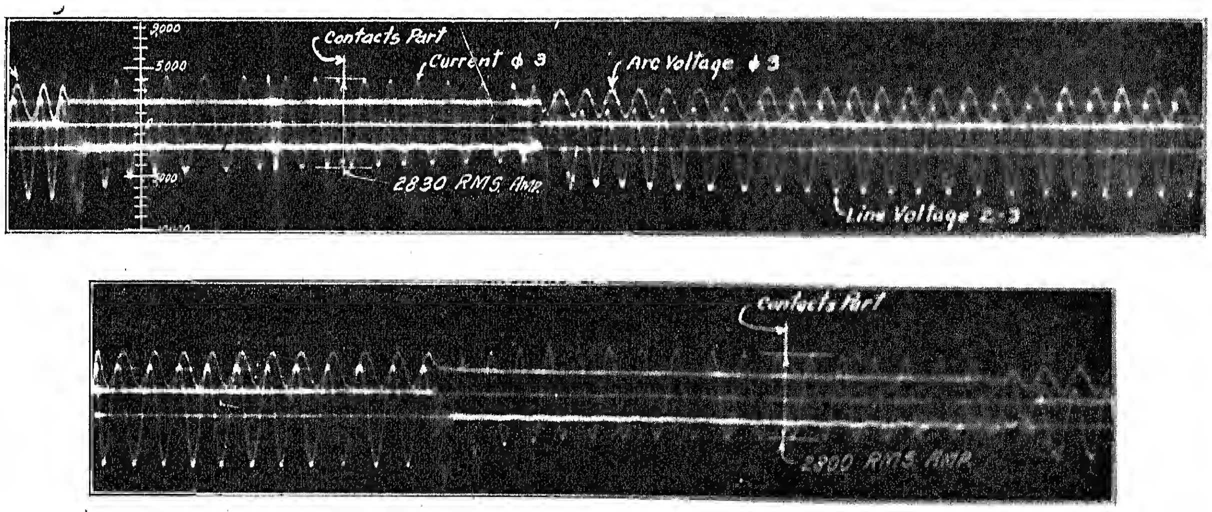

FIG. 6—OSCILLOGRAMS FOR TESTS 20 AND 21

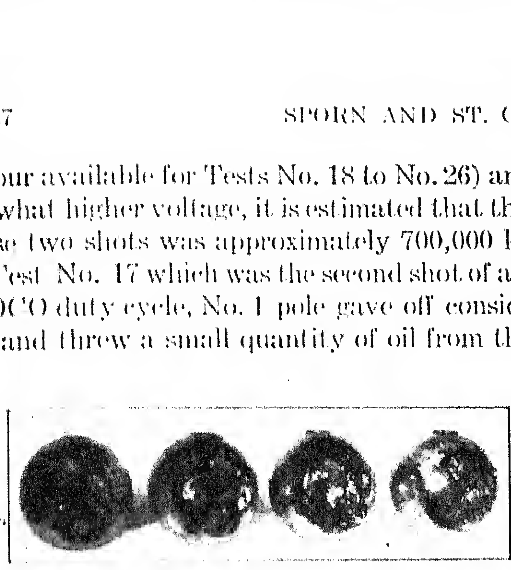
For Tests No. 16 to No. 26 inclusive, the full system capacity shown in Fig. 4 was applied with the exception that the 22,000-kv-a. generator at Akron was omitted and that after Test No. 17 only four generators were available at Windsor instead of the original five. This set-up was calculated to give approximately 745,000 kv-a. with five generators at Windsor and approximately 725,000 kv-a. with four generators at Windsor.

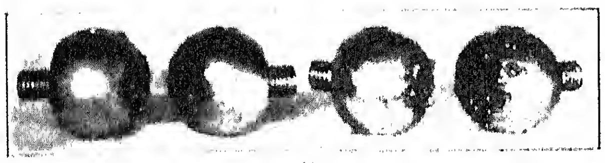
While no current records were obtained on Tests No. 16 and No. 17, so that the exact value of ruptured kv-a. cannot be given, with the five generators at Windsor

(only four available for Tests No. 18 to No. 26) and with a somewhat higher voltage, it is estimated that the duty on these two shots was approximately 700,000 kv-a.

On Test No. 17 which was the second shot of a standard 2-OCO duty cycle, No. 1 pole gave off considerable smoke and threw a small quantity of oil from the vent



A



B

FIG. 7 (A) CONTACTS OF BROWN BOVERI 150-KV. BREAKER AFTER COMPLETION OF TESTS
(B) SIDE VIEW OF SAME CONTACTS

indicating more distress than on any of the other shots during the entire series. Nine shots at full system capacity were applied after this test without any repetition of this apparent distress so that the reason for it on this shot is not at all clear. An examination of the barrier between the individual breaks in tank No. 1 after the completion of the tests showed that one of them had been somewhat charred on both sides opposite the breaks. This barrier was of a material

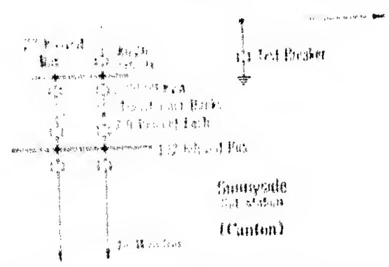


FIG. 8 CONNECTIONS FOR TEST ON 35-KV. BROWN BOVERI BREAKER

different from that furnished with the original breaker, as it had been obtained locally and placed in the breaker to replace one of the originals which had become broken in assembly. Subsequent examination failed to reveal any puncture, however, so that the distress shown is still unexplained unless it was simply due to the generation of more than the usual amount of gas and smoke caused by the burning of this barrier.

After Tests No. 18 and No. 19, which comprised another standard duty cycle of 2-OCO shots, a final series of 7-OCO shots at one-minute intervals was applied. The oscillographic records of Tests 20 and 21 are shown in Fig. 6. On all of the shots at the higher values of kv-a. a considerable movement of the tanks was observable due, it is believed, at least partly to the resilient character of the timber foundations. This last series was intended to consist of eight shots instead of seven, but, on account of the instability of the timber foundations causing considerable movement each time the breaker opened, it was agreed that between each of the shots the test breaker would be given a blind shot; that is, it would be closed and opened with the back-up

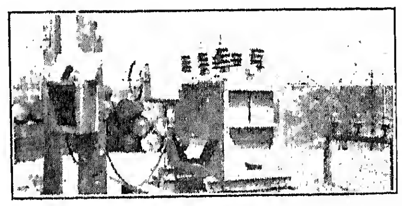

FIG. 9—BROWN BOVERI 35-KV. TYPE *A F* 12/36 OIL CIRCUIT BREAKER AS SET UP FOR 22-KV. TEST

breaker open so as to make sure that the tanks had not been thrown out of alignment to such an extent as to prevent tripping. This proved to be a wise precaution as the breaker failed to trip on the blind shot made after Test No. 26 and no further tests were made.

The contacts taken from this breaker after Test No. 26 are shown in Fig. 7. Although considerably burned, there was nothing, in the authors' opinion, in the condition of these contacts which would prevent the breaker from continuing in service even without any dressing of the contacts. The oil was considerably

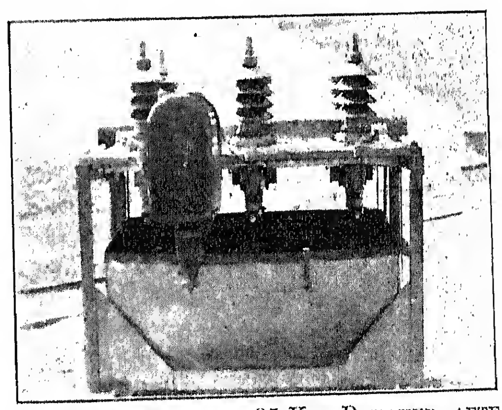

FIG. 10—FRONT VIEW OF 35-KV. BREAKER AFTER TEST. NOTE CRACK IN COVER AND RIVETS SHEARED OFF AROUND TOP OF TANK

discolored, but tested an average of 25 kv. as compared with 30 kv. for the fresh oil supplied to the breaker before Test No. 16.

TESTS ON THE 35-KV. BROWN BOVERI TYPE A F 12/36 OIL CIRCUIT BREAKER

The general appearance of this breaker and the location and arrangement for test are shown in Fig. 9. As shown on Fig. 8, the breaker was connected tempor-

arily to one of the 22-kv. circuits radiating from the main 22-kv. bus at Sunnyside Substation.

The 132-kv. bus was supplied only from four generators at Windsor with two 132-kv. lines and two transformer banks at Windsor in service.

The contacts on this breaker are of the plain break type with spring mounted arcing contacts and are shown in Figs. 10 and 11. The most distinctive feature of this breaker of course is the fact that all three poles are placed in one rectangular tank and separated only by internal barriers.

It was planned to give this breaker an initial standard

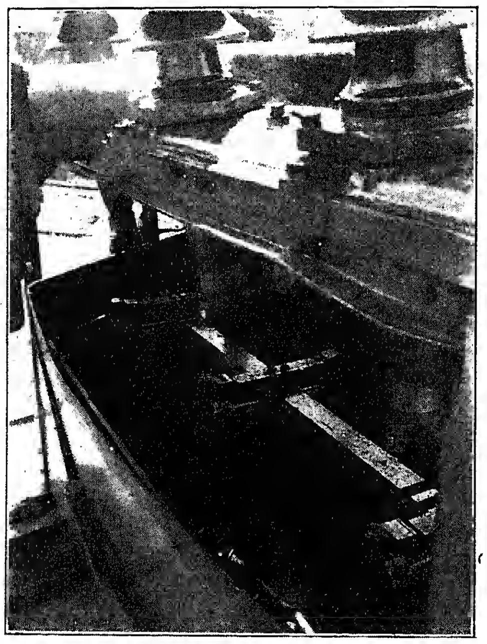

Fig. 11—Interior of 35-Kv. Breaker after Test. Showing Contacts and Broken Barriers

duty cycle at about 175,000 to 200,000 kv-a. and then increase in one or two steps to the full rating of 250,000 kv-a. The short-circuit kv-a. for the first test as calculated from the system set-up was approximately 180,000 kv-a. at 0.2 seconds and approximately 200,000 kv-a. at 0.1 sec. Tests on the over-all time required to trip the breaker from the closing of the trip circuit until the breaker contacts separated indicated that the duration of the short circuit would be between 0.1 and 0.2 sec. Arrangements were made for taking oscillographic records of current, line voltage, and arc voltage the same as on previous tests on 150-kv. breakers.

The planned series of tests was carried out, however, only to the extent of the first shot, as this resulted in a failure accompanied by the oil catching fire. Unfortunately, due to a mishap on the oscillograph, no record was obtained of the current and voltage values on this shot. As stated above, however, calculations indicate that the short circuit was probably in the neighborhood of 190,000 kv-a. Fig. 10 shows how the breaker tank was dropped on this shot, leaving the contacts exposed to the air. In this view is also shown the break in the cover casting as well as the two halves of the rivets which hold the tank to the angle iron ring at the top and which were sheared off, thus allowing the tank to drop. The arcing at the exposed contacts of course immediately turned into a short circuit, igniting the oil and causing the back-up breaker to open. Although not visible in the pictures the lower half of one of the bushings was stripped of porcelain by the arc. Fig. 11 is a close-up view of the contacts and the interior of the tank showing the manner in which the tank lining and barriers were displaced.

It is regrettable that no determination was possible as to the amount of capacity the breaker could actually interrupt or as to whether the design could be reinforced sufficiently within economic limits to give it a rupturing capacity of 250,000 kv-a. It was definitely determined, however, that the breaker was not up to its rating.

Tests on Reyrolle Type C 1-Ord-7000-Volt Oil Circuit Breaker

The Reyrolle armor clad compound filled switchgear, the circuit breaker portion of which was tested with the results given below, is shown very clearly in Fig. 16. The upper enclosed compartment contains the bus while the lower compartment just beneath the bus contains

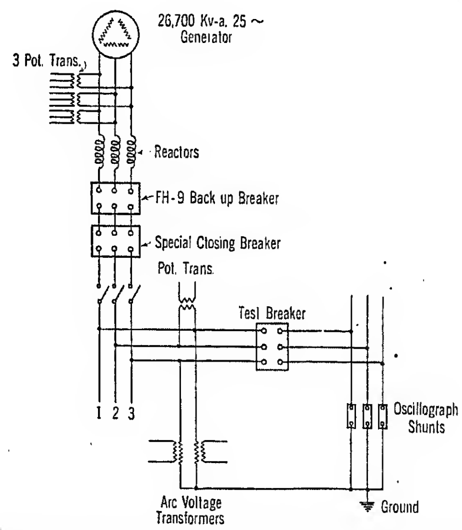

Fig. 12—Diagram of Test Connections for Reyrolle Switchgear

the built-in current transformers designed to take care of the individual feeder controlled by the switch. Fig. 16 shows the breaker racked completely out in which position hinged covers automatically close the busbar openings.

This breaker was purchased subject to the breaker being able to meet the guaranteed rupturing capacity of 75,000 kv-a. at 2300 volts. To determine this, arrangements were made to test one of these units at the factory of the General Electric Company at Schenectady using the regular testing equipment consisting of the 26700-kv-a., 25-cycle test generator and auxiliary equipment.

Fig. 12 shows the arrangement of equipment and connections for this test including the current and potential transformers used for obtaining voltage and current records. The tests were carried out under the supervision of American Gas and Electric Company representatives, the actual testing personnel of course being the regular staff of men employed by the General Electric Company for carrying out their own tests.

The complete results of the tests on the Reyrolle breaker are summarized in Table II. In connection with this table it is well, perhaps, to point out the method employed in obtaining from the oscillographic records the total r. m. s. value of interrupted kv-a. when the current wave is not symmetrical; particularly so in view of the fact that the method employed by the authors, and the one they believe is standard in this country, is apparently different from the method employed in England. The method employed to obtain the values shown in Table II consists of resolving the displaced wave into its a-c. and d-c. components and taking the r. m. s. of these two components as the total r. m. s. value of current interrupted. The d-c. component is equal to the distance from the normal zero line to the actual center line of the displaced a-c. wave at any particular point. For example, in the case of a displaced current wave having a major ordinate of 20 mm. and a minor ordinate of 10 mm., the d-c. component is the difference between the major ordinate and half the sum of the two ordinates, or five mm. To carry this example further, the r. m. s. total current for the wave in question would be $\sqrt{\left(\frac{15}{\sqrt{2}}\right)^2 + 5^2}$ which is equal to 11.7 mm. As to the method of calculating the total kv-a. interrupted, since the three poles were all in one tank, the average of the three measured current values was used instead of the highest value which of course is used in the case of the individual tank breaker.

It was planned to give this breaker 2300-volt tests consisting of standard duty cycles at 40,000 kv-a., 60,000 kv-a., and 75,000 kv-a., followed by 6600-volt tests at 75,000 kv-a. and 100,000 kv-a. On the first duty cycle in which the breaker opened 39,200 kv-a. no distress was evident beyond the hissing sound of escaping oil and gas. Approximate figures as to the loss of oil and other data are recorded under Table II.

The second duty cycle on which 58,000 kv-a. and 45,700 kv-a. respectively were obtained on the two shots, was handled by the breaker apparently as easily as the first duty cycle. Upon lowering the tank, however, it was found that the wooden barriers separating the three poles were broken from their fastenings and displaced, the screws fastening these barriers to the tank lining at the side and at the bottom having been

torn out of the wood. Also considerable burning was disclosed on this test, both on the arcing contacts and somewhat on the main contacts.

It will be noted that the kv-a. interrupted on test No. 4 was considerably less than that on test No. 3. This is due to the difference in the total duration of short circuit which is evidenced by the oscillograms shown in Fig. 13. It will also be noted that there was a six-minute interval between tests No. 3 and No. 4.

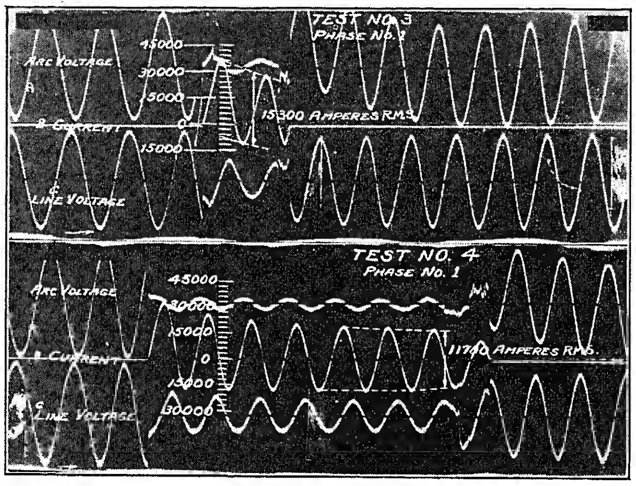

Fig. 13—Oscillograms taken on Tests Nos. 3 and 4

The reason for this interval was the accidental jarring out of the manual trip lever of the breaker on test No. 3, preventing the closing of the second shot until the lever had been reset. Furthermore, this jarring out of the trip lever is responsible for the short duration of only two cycles in the short circuit on the first shot,

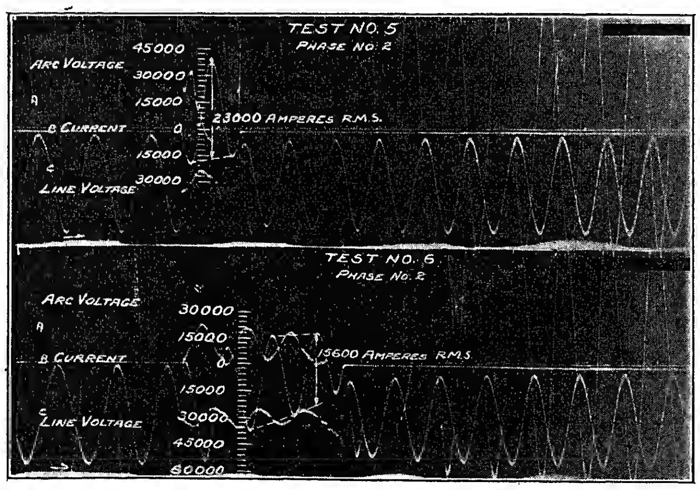

Fig. 14—Oscillograms taken on Tests Nos. 5 and 6

thus accounting for the large difference in value, the decrement on the first shot being much smaller than on the second.

On the final duty cycle at 2300 volts the breaker successfully cleared a short circuit of 100,000 kv-a. on the first shot and 64,300 kv-a. on the second shot. Before these two tests were made the wooden barriers, found broken after the last test, were repaired and replaced and new oil was supplied to the breaker. The oscillograms for this duty cycle (Fig. 14) show that on test No. 5 the total duration of current was only about 1⅛ cycles as against 3½ cycles for test No. 6. The reason for the short duration and consequent high value of current on test No. 5 was the fact that the d-c. time delay relay used as part of the regular station testing equipment for tripping the test breaker was not reset after the last test, resulting in energizing the trip circuit of the test breaker as soon as the auxiliary

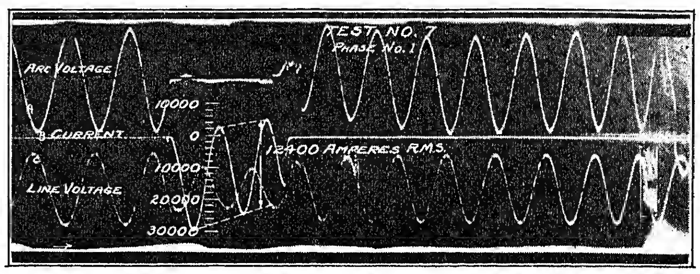

Fig. 15—Oscillograms taken on Test No. 7

contacts closed. This relay was properly reset before test No. 6 so that the normal duration of short circuit and the smaller value of current were obtained.

The wooden barriers found broken after test No. 4 and repaired prior to test No. 5 were again found completely broken from their fastenings and displaced after

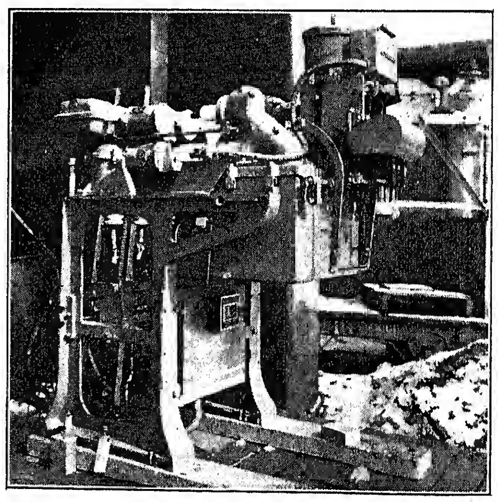

Fig. 16—Reyrolle Type C1-ORD—7000-Volt Compound Filled Switchgear Set-up for Test. Switch Racked Out

test No. 6. As before, the arcing contacts, both upper and lower, were quite badly burned and considerable burning was also evident on both the upper main contacts and on the lower contact bar.

Before proceeding with the test at 6600 volts it was decided, due to the badly burned condition of the arcing contacts after the preceding six shots at 2300 volts, that new arcing contacts, both upper and lower, should be made up and installed, that the main contacts should

be carefully dressed, and that new wooden baffles should be made up and fastened in the tank. New oil of course was supplied.

Based on a duration of short circuit of seven or eight cycles for which it was intended that the time delay relay should be set, the generator circuits were arranged to give a calculated value of 75,000 kv-a. for test No. 7. For some unknown reason the short circuit lasted only 2½ cycles instead of seven or eight, and the kv-a. which the breaker attempted to open was 122,000. The oscillogram shown in Fig. 15 bears evidence that the

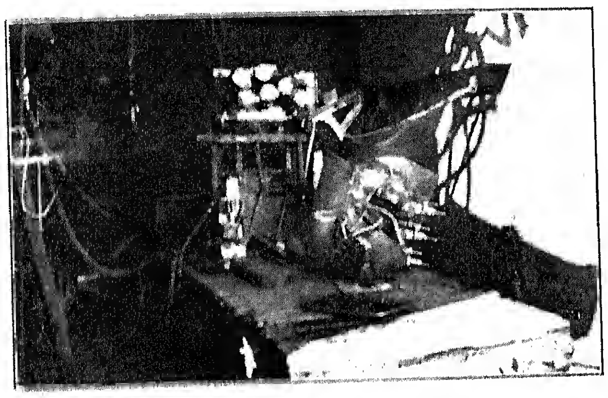

FIG. 17 REYROLLE SWITCHGEAR AFTER TEST NO. 7

short circuit actually was cleared for a period of seven cycles after which complete failure and blow-up of the breaker took place. Apparently the breaker cleared the short circuit but the gas pressure was so great that the tank was completely ruptured, one side being thrown against the exposed 6600-volt temporary terminals underneath the current transformer chamber causing a short circuit which immediately set fire to the oil. The appearance of the breaker after the fire had been put out is shown in Fig. 17. The force of the explosion which ruptured the tank was so great that the tank was split not only along the welded seams but on two edges where the steel had been bent but not welded.

As will be noted from the table, the rupturing capacity of this switch was exceeded by more than 60 per cent on test No. 7 at which value the result obtained might well have been expected. On test No. 5, on the other hand, the breaker successfully opened 100,000 kv-a. at 2300 volts, which, aside from the breaking of the barriers and rather extensive burning of the arcing contacts (the contacts tested were not designed for 2300 volt service), ought certainly to be considered a creditable performance.

Although the breaker more than met its guaranteed rupturing capacity, certain design features which were standard with the manufacturers on breakers of heavy duty were incorporated in the breakers actually installed, the principal ones being those of increasing the thickness of the tank from ¼ in. to 5/16 in., increasing the depth of the tank two in., and the substitution of a much heavier butt type-arcing contact and the employment of steel barriers over which is placed a wooden lining instead of wooden barriers fastened to the tank lining. The authors have no doubt but that the breaker as finally obtained has a rupturing capacity considerably in excess of the originally guaranteed capacity.

TESTS ON GENERAL ELECTRIC 132-KV. OIL CIRCUIT BREAKERS

Due to the large number of 132-kv. breakers that are employed on the system of the American Gas and Electric Company, the question of rupturing capacity of different types of breakers, particularly of 132-kv. rating, is naturally a very vital one to us and it takes a test to make the final check on rupturing capacity. This was one reason for the third series of tests. Another reason was the desire already mentioned to carry out tests close to the rupturing capacity of the breaker and thus determine if possible the correctness of some of the fundamental design principles and therefore whether designs based on these principles for rupturing capacities beyond any possible test values could be relied upon with a certain degree of safety. Still another reason was to determine experimentally whether a cycle more strenuous than the standard duty cycle on the breaker was too dangerous or whether it could be employed safely.

Tests on the FHKO-39-B 132-kv. Breaker. Arrange-

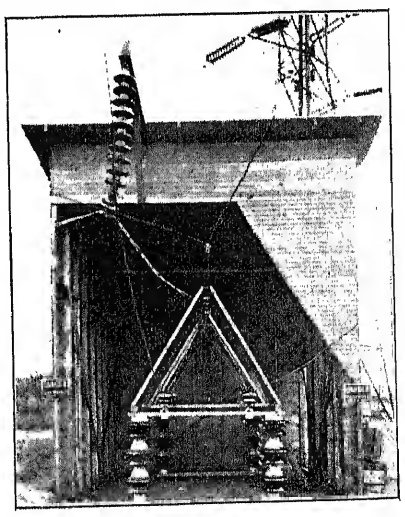

FIG. 18—HOUSE BUILT FOR SHELTERING THE GENERAL ELECTRIC OSCILLOGRAPH SHUNTS AND PROF. DYCHE'S CURRENT TRANSFORMER

ments for the test included, among other things, first, tapping the Alliance Line at the first tower the same as for the Brown Boveri 132-kv. test, and running this tap through the FHKO-39-B and FHKO-136-B breakers which were connected in series to the short-circuit point; second, building a temporary house with dark room for the oscillograph equipment, including in this house a platform insulated for 132,000 volts to carry one of the General Electric oscillographs used for measuring currents by means of shunts placed

§"Full System" means the set-up shown in Fig. 4 minus the 22,000-kv-a. generator at Akron.

directly in the short circuit leads; and third, the building of a special insulated triangular framework support for mounting the shunts, together with the shelter, all of which is shown in Fig. 18. In addition to the three oscillographs supplied by the General Electric Company, a fourth machine, Professor Dyche's, was provided in order to obtain parallel records of voltages and current, the latter by means of the same current transformer used in the previous Brown Boveri test. The system set-up for these tests was that shown in Fig. 4 with the omission of the 22,000-kv-a. generator at Akron.

Since it was planned on these tests to take a number of shots with the short-circuit point ungrounded, it was fourth the rating of the breaker, a standard duty cycle at full system capacity, a special duty cycle consisting of 2-CO shots with two-minute interval to obtain a shorter duration of short-circuit current, and finally several special duty cycles including a series of 7-OCO shots, also with full system capacity. Most of these tests were to be made with the short-circuit point grounded, permitting the taking of records both on the shunts and on the current transformer with its limited insulation. After these it was planned to take a number of shots with the short circuit ungrounded and with the current transformer disconnected from the circuit.

Table III gives a complete summary of the results of all of the tests on the 39-B breaker including the data

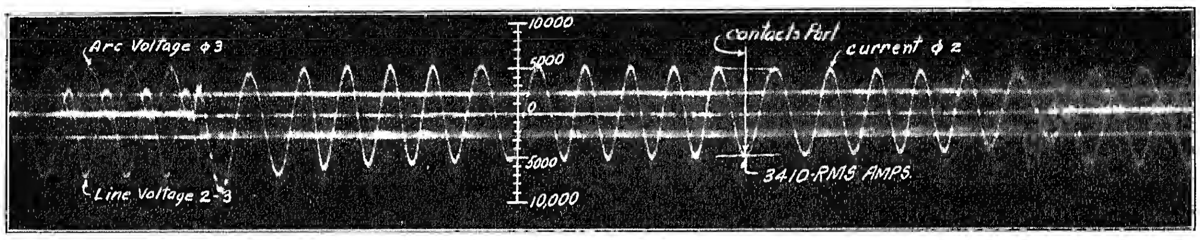

Fig. 19—Oscillograms of Test No. 10 on FHKO-39B Breaker (Prof. Dyche)

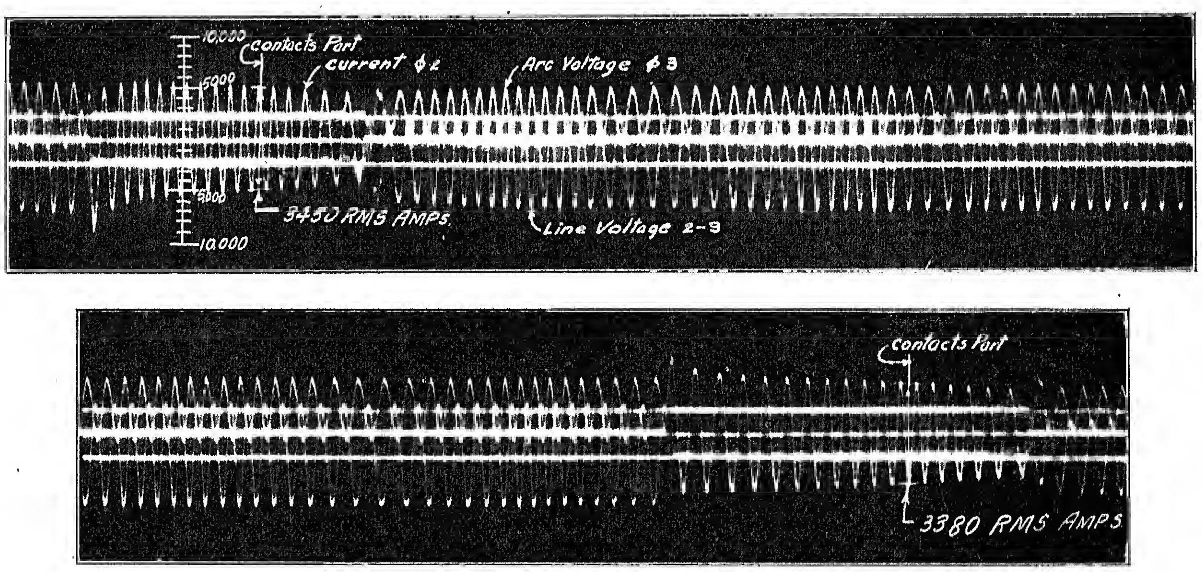

Fig. 20—Oscillograms of Test Nos. 18 and 19 (Taken on One Film by Prof. Dyche)

necessary to carry the leads from the shunts on 132,000-volt insulators to the oscillograph house and, as stated above, mount the oscillograph on an insulated platform. It was also necessary to carry a 132,000-volt insulated connection from one terminal of one of the permanently installed Windsor line potential transformers located in the 132-kv. yard, back to the short-circuit side of the 136-B breaker.

In an attempt to duplicate as nearly as possible on the FHKO-39-B the tests carried out on the Brown Boveri 150-kv. breaker, the program for testing consisted of a preliminary trial shot followed by a series of eight shots in rapid succession at approximately one- from both the General Electric Company oscillographic equipment and Professor Dyche's equipment. Using the data given in Table III on the system set-up for each test and by referring to Fig. 4, the exact system connections for any test may be obtained, omitting of course the 22,000-kv-a. generator at Akron, shown on Fig. 4.

During all of the tests on this breaker no inspections of the contacts were made at any time. Typical oscillograms of these tests are shown, both those obtained by the General Electric Company and those from Professor Dyche's oscillograph. Of the latter, Fig. 19 shows the first shot of the standard 2-OCO duty cycle comprising tests 10 and 11 which were

the first tests using the full capacity of the system.

After the completion of this duty cycle oil samples were drawn from the middle of each tank and from the bottom of tank No. 1. Dielectric tests on these samples gave for tank No. 1, 24.5 kv. average; for tank No. 2, 21.3 kv.; for tank No. 3, 27.6 kv; and for the oil drawn from the botton of tank No. 1, 11 kv. No change was made in the oil.

The special duty cycle represented by tests 12 and 13 at one-minute intervals was not made intentionally as such but was supposed to be the beginning of the series of seven shots at one-minute intervals. Due to trouble with the oscillographs it was necessary to interrupt this series after the second shot.

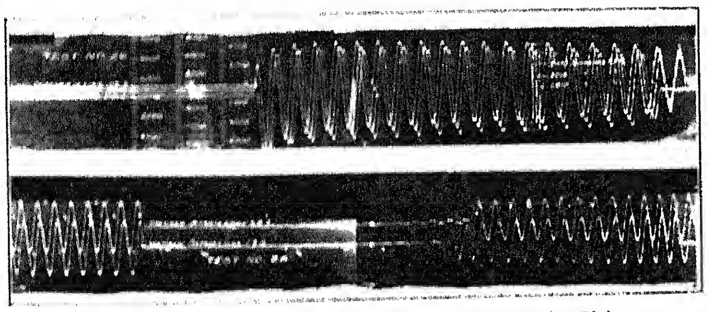

FIG. 21 OSCILLOGRAMS OF TEST NO. 26 (G. E.)

The special duty cycle of seven shots at one-minute intervals was then successfully carried out as shown under test Nos. 14 to 20 inclusive in the table. Due to the number of shots and the short interval between shots, it was not possible to record each shot on a separate film, although records were obtained on all but one of these shots from either one or the other of the oscillographic equipments. Fig. 20, which shows Professor Dyche's record of tests 18 and 19, is a reproduction of only a portion of the original film on which five shots were recorded. All of the shots were cleared by the test breaker with no evidence of distress, with no throwing of oil, and with very little smoke visible except on test No. 17 when No. 3 tank gave off quite a puff of smoke. This tank, however, as well as the other two tanks, did not give off more than a small amount of smoke on any other tests and the inspection following the completion of the tests did not reveal any unusual condition in No. 3 tank or anything different from that in the other two tanks.

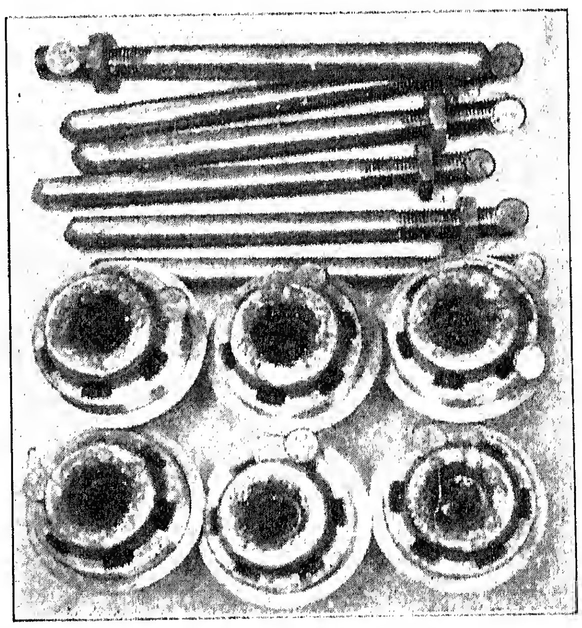

FIG. 22—FULL SET OF CONTACTS FROM FHKO-39B BREAKER AFTER COMPLETION OF TEST NOS. 1 TO 26

In order to obtain a higher value of current by decreasing the total duration of the short circuit, a duty cycle consisting of 2-CO shots was made as covered by test Nos. 21 and 22. While this type of duty cycle did decrease the total duration of short circuit to approximately 30 one-half cycles, the increase in ruptured kv-a. as shown in Table III was not very large.

All of the shots up to and including test No. 22 were made with the short circuit grounded. The remaining four shots, tests 23 to 26 inclusive, were then made with the short circuit ungrounded, so that it was necessary to disconnect the current transformer supplying Professor Dyche's oscillograph and confine further oscillographic records to the General Electric equipment, the current recording oscillograph as stated

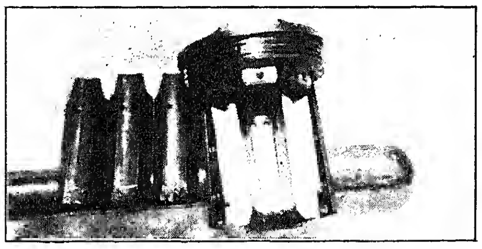

Fig. A

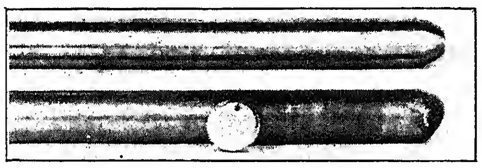

Fig. B

Fig. 23—(a) Rod and Contact Segments from One Pole of 39 B Breaker after Test No. 26

(b) Comparison of New Rod with Rod from 39B Breaker after Test No. 26

above being mounted on a platform insulated for 132,000 volts. Fig. 21 shows oscillograms obtained by the General Electric equipment on test No. 26 of this series.

At the conclusion of the tests the oil was immediately drained from the tanks and the contacts from phase 3, which had given off the puff of smoke on test No. 17, were removed from the tank. It was found that the burning was confined almost entirely to the arcing ring below the current-carrying segments and that the burning of the rod was confined to the arcing tip and was such that no beads or pits were left which might cause the rod to stick in the contacts. It was quite evident that the contacts were in sufficiently good condition so that without any dressing at all the breaker could be kept in service and carry its rated current even though 26 short circuits had been interrupted, 17 of them at full system capacity.

Fig. 22 shows all six contacts and contact rods taken from the FHKO-39 breaker after the completion of the tests while one of the contacts and contact rods with part of the segments removed to give a better view of the burning are shown in Fig. 23A. Fig. 23B, a comparison between a new contact rod and one of the rods taken from this breaker after the test, also shows the extent and character of the burning which was fairly smooth and without beads. The average test on the oil taken from this breaker after the completion of the tests was 19.25 kv.

An examination of Table III will reveal a comparatively large discrepancy between the values of current as recorded by the General Electric oscillographs and by Professor Dyche. The maximum discrepancy occurs on test No. 22 in which Professor Dyche obtains a value of 3610 amperes for the initial r. m. s. current in the arc as against a value of 3020 for the same phase on the General Electric oscillograms. Differences of somewhat lesser magnitude will be found in most of the other tests, particularly on the full system capacity shots.

In order to discover whether one or the other of the equipments was in error or whether the observed discrepancy was merely the possible error inherent in the oscillographic method of recording currents, a calibration check was made using the set-up in Fig. 24. A heavy current transformer for stepping down from 220 volts to three volts was obtained, together with a 2000-ampere instrument type current transformer and an ammeter calibrated with the current transformer, both of General Electric make. With this set-up, a current was passed through the circuit, first approximately 1000 amperes and then 2000 amperes and simultaneous readings were obtained on both oscillographic equipments as well as the calibrated ammeter. The results of these tests made under steady state conditions which are shown complete in Table IIIa give a maximum variation between Professor Dyche's record and that of the General Electric oscillographs of 13 per cent,

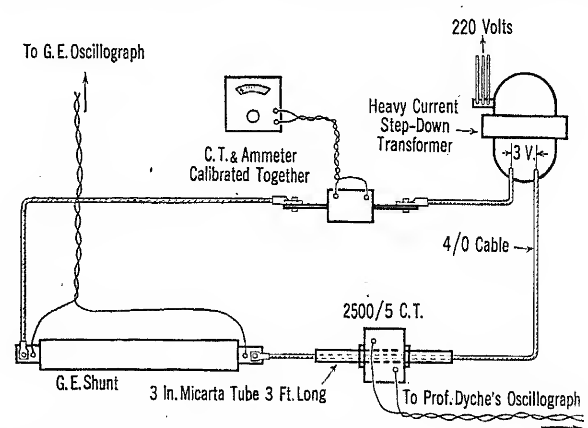

Fig. 24—Set-up for Checking G. E. Shunts and Prof. Dyche's Current Transformer

which is nearly as large as the discrepancy found on the actual short-circuit test.

Since check tests (with special current transformer and its own meter) showed the two oscillograph equipments to read within a very few per cent, it is difficult to explain what caused the discrepancy of some 15 per cent on test No. 22 and a smaller percentage on certain other tests. A great deal of study was given to circuit set-ups in the endeavor to locate the cause of this discrepancy but nothing definite was found. It is

probably fair to assume that some condition peculiar to the particular set-up was the real cause, although unfortunately nothing definite was determined.

Plotting of the readings of the two oscillographs against the readings of the standard current transformer showed that the discrepancy was not consistent, one equipment reading high over part of the current range, then showing low results over another part; while the other equipment read low, then high over the same ranges. In view of the fact, however, that a certain amount of difference in calculated results is to be expected from such causes as differences in inaccuracy of

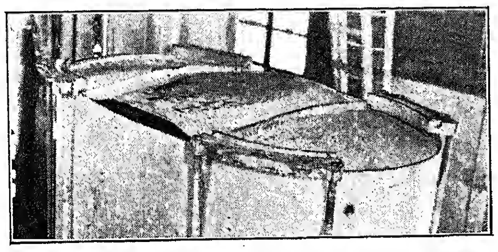

Fig. 25—Middle Tank of 136 B after Test No. 31 showing Actual Opening Where Welded Seam Failed

reading waves of different heights and lengths, different methods of calibrating instruments, etc., a reasonably close agreement between results was shown. With these various considerations, therefore, it is probably not far from correct to assume that the true current values were represented by the mean of the two values indicated by the General Electric Company and Professor Dyche's equipments.

Since the records in the case of the Brown Boveri 150-kv. circuit breaker tests, however, were taken with the same set-up as that used by Professor Dyche on the present tests, it is believed that the values obtained by Professor Dyche may be used as a fair comparison with the results obtained on the Brown Boveri breaker.

Tests on the FHKO-136B 132-kv. Breaker. After the completion of the tests on the FHKO-39B breaker, tests were made on the 136B which, as previously mentioned, was connected in series with the 39B, the latter then being used as a back-up breaker.

On account of the difficulties encountered in testing the 136 breaker, these tests were spread out over a considerable period of time and divided into three series, the first taking place on December 6, 1925, the second on January 10, 1926, and the third on May 23, 1926.

It was planned to subject this breaker to a series of eight OCO shots in rapid succession at approximately one-fourth of the breaker rating followed by one or more standard duty cycles at the full system capacity, and then to carry out one or more special duty cycles, such as four shots at full system capacity with one-minute intervals.

The first attempt to carry out the above tests on this breaker was made on December 6, 1925. Complete results of the tests made on this date, as well as of the tests made on the following January 10, 1926, are given in Table IV. As will be noted in this table, after subjecting the breaker to a trial shot and three of the proposed series of eight shots at approximately one-fourth of the breaker rating, the breaker failed by splitting open along the welded seam at the bottom of the middle tank, permitting the oil in that tank to escape. The character of this failure is clearly shown in Fig. 25 in which the tank is suspended and the view is from below. The tests were discontinued of course for that day and the tanks opened to permit examination of the contacts.

It was found that one of the insulating cylinders normally surrounding the explosion chambers had broken from its fastenings and was lodged on the cross-head. The other insulating cylinder in this pole had

not fallen down but was partially broken from its fastening. It was apparent also that the explosion chamber insulation had failed, permitting the arc to cut through the throat bushing to the lower edge of the steel explosion chamber. Fig. 26A shows the broken throat with insulating collars in place. Marks on one of the fibre rings show evidence of burning by the arc. Fig. 26B shows the same throat bushing with one collar removed, revealing the place where the arc punctured through.

*Tests 32 to 35 inclusive made on January 10, 1926.

†Closed short-circuit kv-a. from Dyche Films.

Another throat bushing also bearing evidence of puncture is shown in Fig. 26c. The steel explosion chamber itself showed marks of the arcing on the inside edge of the bottom opening, and retained the imbedded half of the six fibre screws which were broken off and which, together with the explosion chamber throat bushing, were used to support the insulating cylinder around the explosion chamber. The contacts taken from this breaker, two of which are shown in Fig. 27, indicated by the small amount of pitting that the actual short-circuit duty was very light.

On the trial shot an accident occurred to the General Electric oscillographic equipment which may be of interest to describe. On all of the tests made on the 39B the oscillograph mounted on the insulated platform was kept entirely separate from the other equipment, using a separate 125-volt battery for motor control, etc. At the beginning of these tests through some delay the separate 125-volt battery was not available so that on the first shot the necessary current for operating the oscillograph motor and arc was taken from the battery connected to the other oscillographs. This was done partly through an oversight as it was fully realized that considerable voltage might be built up on the short-circuit side of the breaker due to the resistance drop of any momentary unbalanced current which might flow throught the ground connection. This was definitely proved on the first shot taken under these conditions. As soon as the circuit was closed, considerable fireworks ensued with resultant serious damage to the General Electric equipment, all of the elements being burnt out in the insulated oscillograph and some of the elements in the other two oscillographs, a total of six out of nine being completely burned out. This burning was not only confined to the vibrators proper but in some cases the field coils too were burned out. Naturally, no records were obtained on the General Electric oscillographic equipment in this series.

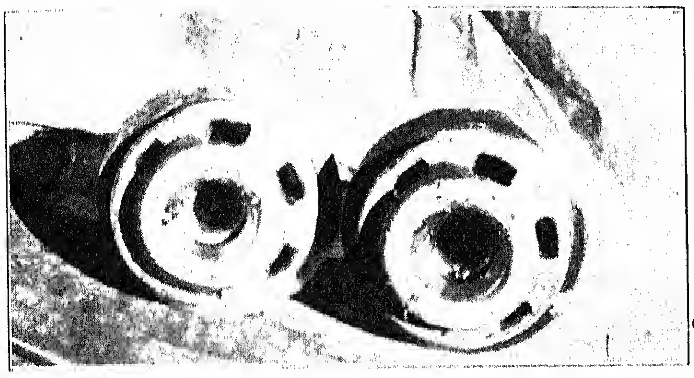

Fig. 27—Contacts from 136B Breaker after Test No. 31

In going over such evidence as was available as to the cause of the breaker failure, two things were apparently certain; first, it seemed established beyond a doubt that material used in the throat bushing was inadequate from the standpoint of dielectric strength and perhaps also from a mechanical standpoint; and second, the tank, and particularly the weld, seemed to be weak. The first, that is, the faulty bushing, through its electrical breakdown, probably caused the mechanical breakdown which in turn ruined the explosion chamber assembly and at the same time allowed open arcing with the result that there was created a pressure sufficiently high to open a weld which was none too strong in the first place.

The tanks were returned to the factory and rewelded, a stronger weld being employed in the new set-up. New types of throat bushings slightly different in design but principally different in the employment of new material, supposedly stronger from a mechanical and electrical standpoint, were also supplied. The breaker, embodying these changes, but no others, was submitted to a second series of tests on January 10, 1926.

The set-up for this second series of tests on the 136B breaker was the same as on the first series with the exception that the 39B back-up breaker instead of being connected directly to the Alliance line was connected by means of a short temporary 132-kv. line to the end of the 132-kv. station bus. The results of this series of tests, which along with the first series are summarized in Table IV, proved to be almost an exact repetition of the results obtained on the previous series, with the exception that the failure on the third shot of the proposed series of eight was evidenced by the breaking of a 132-kv. bushing on the high side of the breaker, permitting oil to leak out, and by a sharp report with fire issuing from the vents on pole 3.

The second series of tests being thus ended, the oil was immediately drained from the tanks and the interior examined. As in the case of the failure on December 6, it was found that the insulating cylinders on both the explosion chambers in No. 3 tank (the one on which the bushing was broken) were broken from their fastenings and both were down on the cross head. It was noted also that this tank showed considerably more bulging than the other two. Upon removing the explosion chambers from all of the tanks it was found that throat bushings were again broken in both No. 2 and No. 3 tanks. In this case, however, the breaks were such that it did not seem possible that they were caused by electrical puncture. These broken bushings are shown in Fig. 28. The manner in which the high-voltage bushing was broken is illustrated in Figs. 29 and 30, the break at the lower end of the bushing not being discovered until the bushing was taken apart.

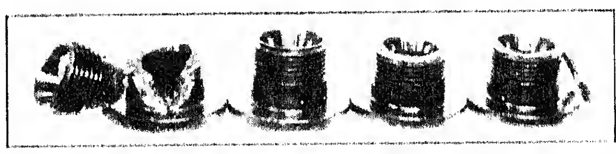

Fig. 28—Throat Bushings from 136B Breaker after Test No. 35 (Second Failure)

The final explanation adopted as the reason for the failures of December 6 and January 10, and the one which served as the basis for the changes that were made prior to the tests of May 23, was as follows:

The fairly long insulated cylinder placed over each explosion chamber was supported only and entirely at the bottom, partly by means of a number of fibre screws tapped into the bottom of the steel explosion chamber and partly by the explosion chamber throat itself. This assembly is shown in Fig. 31. When the breaker

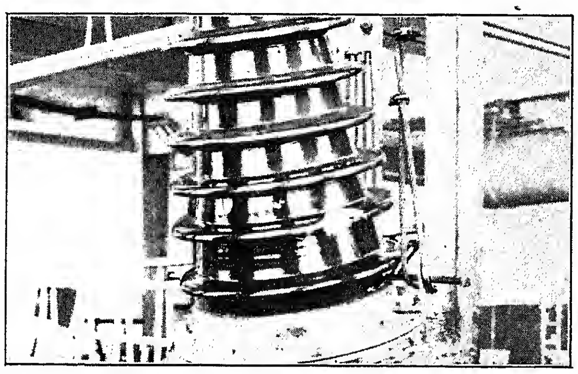

FIG. 29—UPPER HALF OF 132-KV. BUSHING FROM POLE NO. 3 OF 136B BREAKER AFTER TEST NO. 35

opened on short circuit the generation of gas caused some internal pressure, throwing oil against the flat sides of the tank and springing these sides out to a certain extent. On the rebound the oil was made to exert force in the opposite direction causing considerable thrust against the insulating cylinders over the explosion chambers. Since these long insulating tubes were supported only at the bottom, the cantilever strength was insufficient to withstand this shock and the supports

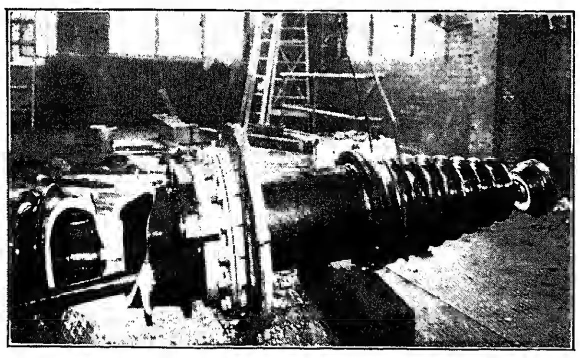

FIG. 30—BUSHING FROM POLE NO. 3 OF 136B BREAKER AFTER TEST NO. 35. NOTE BREAK AT LOWER END

had to give way, thus breaking the explosion chamber throat and allowing the cylinder to drop.

While there was no conclusive evidence to show whether the electrical puncture encountered on the throat bushings during the test of December 6 was caused by mechanical failure or was the cause of the mechanical failure, at the same time there is a slight preponderance of evidence, especially after an analysis of the tests of May 23, that would show that mechanical failure preceded electrical failure. Following out this theory a new assembly for the explosion chamber parts, including the insulating shield, was worked out and is

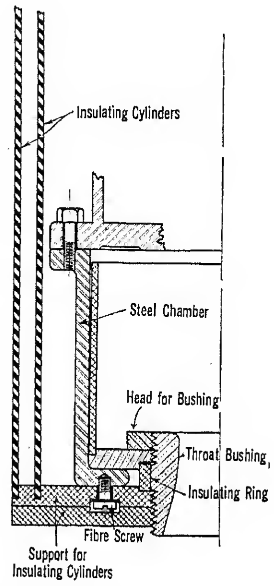

FIG. 31—EXPLOSION CHAMBER ASSEMBLY USED IN 136B BREAKER ON TESTS 27 TO 35 INCLUSIVE (DECEMBER 6 AND JANUARY 10) EXCEPT THAT THROATS USED ON TESTS 32 TO 35 WERE OF THE TYPE SHOWN ON FIG. 48

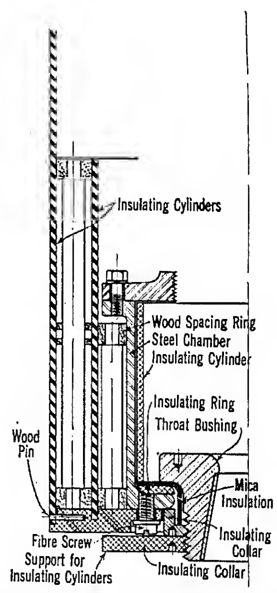

FIG. 32—EXPLOSION CHAMBER ASSEMBLY AS REDESIGNED FOR TESTS 36 TO 65 (MAY 23, 1926)

shown in Fig. 32. It will be noted that this assembly differs in a number of respects from the former, but the principal new features are, first, that the insulating cylinder is supported at the bottom again by means of fibre screws but tapped directly into the steel pot and kept quite separate from the explosion throat. Further, although not shown in the sketch, the number of these

supporting screws was increased from six used originally, to 12 in the new assembly. Second, an entirely new part was installed consisting of two wooden rings, one at the top of the steel pot and the other at the bottom, exactly filling the space between the inner insulating cylinder and the steel at these two points, thus taking all cantilever strain off from the lower end of the cylinder. These two upper and lower wooden rings are joined together by several connecting wooden uprights making a rigid structure.

With these changes carried out the third series of tests on the 136B breaker was arranged for May 23, 1926.

The testing arrangements on this series were the same as on the last, with the exception that the system capacity available was somewhat less, the set-up being in accordance with Fig. 4 with the following changes: first, no generating capacity was available from Akron, and second, at Cleveland the capacity was reduced from seven to five generators with only one transformer bank stepping up from 11 kv., one 66-kv. cable circuit, and one transformer bank stepping up form 66 kv. to 132 kv. at South Akron. With this reduced capacity the calculated value of short circuit available at 0.16 sec. after the beginning of the short circuit was reduced from 775,000 kv-a. to 685,000.

The complete results of this final series of tests on the 136B breaker, made on May 23, 1926, are summarized in Table V. In view of the discrepancies which were found between readings on the General Electric oscillograph and on Professor Dyche's during the 39B tests, arrangements were made in these final tests to have one element of the General Electric oscillograph supplied from the current transformer which was supplying Professor Dyche's oscillograph.

The program for testing was laid out in the same manner as that which had been attempted for the two preceding series. After making the preliminary trial shot to determine whether all oscillographic equipment was functioning properly, the series of 8-OCO shots at approximately one-fourth the breaker rating in rapid succession was begun. A little trouble was experienced at first when the breaker failed to close on the second shot of this series and when, after making slight adjustments on the mechanism, it failed to close again on the third shot of a second attempt to make the series. After this the mechanism was not satisfactorily adjusted, and the 8-OCO shots at approximately 30-sec. intervals were carried out. No distress was apparent on any of the shots, only a slight trace of smoke being visible and no oil being thrown.

The next test was a standard duty cycle of 2-OCO shots with a two-min. interval at the full system capacity available. Following this a duty cycle consisting of 2-CO shots with a two-minute interval was given to the breaker with the idea of obtaining a somewhat higher current due to decreased time between the beginning of the short circuit and the first half cycle of arcing. As will be noted from the value of interrupted kv-a. on both of these duty cycles, this procedure did result in increasing the current from approximately 2300 to approximately 2500 amperes. On both of these duty cycles, which include tests 48 to 51, the short circuit was cleared without signs of distress on the part of the breaker.

As a special duty cycle with a larger number of shots at closer intervals, the breaker was subjected to 4-CO shots at one-min. intervals with the maximum system capacity available. These four shots which averaged 600,000 kv-a. interrupted were handled without any distress by the breaker.

After these tests a number of additional shots were taken with the short circuit ungrounded. Professor Dyche's equipment, of course, was disconnected from the current transformer, which was not insulated for high voltage, and General Electric records only were obtained, taking advantage of the oscillograph mounted on the insulated platform. An attempt was made also to further increase the short-circuit current by means of CO shots on which the test breaker was tripped through an auxiliary switch on the KO.39 back-up breaker, thus decreasing the total duration of the short circuit. The first series made in this manner consisted of 4-CO shots at one-min. intervals, records being obtained only on the first and last shots. It was found, however, that the adjustment of the auxiliary switch trip on the back-up breaker did not speed up the tripping of the test breaker as much as had been anticipated.

The next series of tests consisted of 4-OCO shots at one-min. intervals at full system capacity, the first and last of these being recorded in Table V.

In a final attempt to approach nearer to the rating of the FHKO-136B test breaker a further adjustment was made on the auxiliary switch of the 39B back-up breaker so as to speed up considerably the tripping of the test breaker. With this adjustment and with the system still ungrounded a final duty cycle consisting of 2-CO shots at two-min. intervals was carried out. The attempt to speed up the tripping was quite successful in this case as it will be noted from the table that the total duration of short circuit was reduced to approximately 31 half-cycles and the interrupted kv-a. was increased to 625,000, a larger value than on any of the previous shots. These shots were handled by the breaker with no distress, only a small amount of smoke being given off and no oil being thrown. Oscillograms taken on this duty cycle, tests 64 and 65, are shown in Fig. 33.

After the completion of the tests, samples of oil were drawn from the middle of the tanks and tested for dielectric strength, averaging 15 kv. as against approximately 30 kv. obtained for the original oil. Upon draining the oil and inspecting the interior of the tanks it was found that all of the insulating cylinders around the explosion chambers were in place and that no

damage had been done to any of the throat bushings. The burning of the contacts which is shown in Fig. 34 was found to be confined almost entirely to the arcing tips of the contact rods and to the arcing bell of the explosion chamber, the contact segments themselves being in a very clean condition.

In view of the fact that the breaker handled a total of 30 shots without any inspection or even a change of oil, and that on 18 of these shots the duty was not far below the actual rated interrupting capacity, and further in view of the excellent condition that the breaker

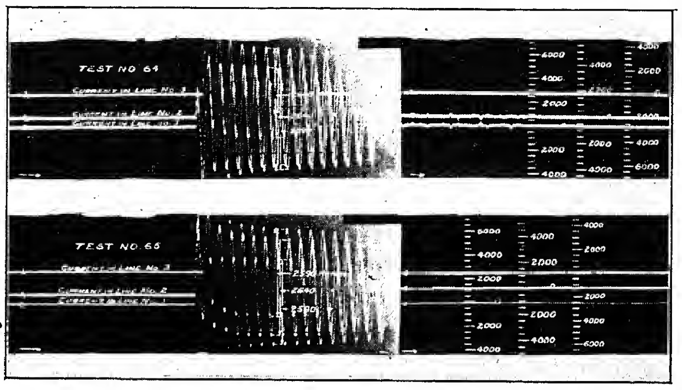

FIG. 33—OSCILLOGRAMS OF TESTS 64 AND 65 (G. E.)

and contacts were in at the end of the tests, it does not appear rash to state definitely that the breaker was fully adequate to meet its guaranteed rupturing capacity and that the troubles in the explosion chamber assembly encountered in the tests of December 6 and January 10 were completely eliminated in the new assembly developed.

VALUE OF THE TESTS

While the carrying out of tests on oil circuit breakers is as a general rule highly interesting, it is at the same time a very expensive affair and further very often results in a considerable upset of the system. Even if no actual physical damage results there is always the damage worked indirectly as a result of the effect of the short circuits on the system voltage and perhaps upon apparatus susceptible to voltage changes or dips. The authors believe therefore that before a test of this sort is undertaken the question should be raised as to the benefits that may be expected from the test and that these benefits should be weighed to make certain that they are sufficient to overbalance the possible harmful effects. Further, the tests having been carried through, it is very vital that the question should be raised again as to what value has actually been obtained.

Reviewing the results of the tests on the Brown Boveri breakers in the light of these data, it can be stated that in the case of the 150-kv. breaker tests the following benefits were obtained:

1. While the question was not definitely determined in the affirmative as to whether a multi-break breaker could be designed and built to handle successfully rupturing capacity in the order of 1,000,000 kv-a., it is believed at the same time that the performance of the breaker when rupturing a short circuit of the order of 75 per cent of that value was such that there appeared no doubt that the limit of the rupturing capacity of the breaker had not been reached.

2. Definite information was obtained as to the ability of the breaker to go through a cycle much more severe than the standard duty cycle. It was shown that for the system in question, if operating conditions called for it, the breaker tested could be plugged in on a short circuit four or five times in rapid succession with perfect safety.

3. In all, 26 short circuits were placed on the 132-kv. system of which 13 were at approximately full system capacity. So far as is known no appreciable damage of any sort resulted to the system. There were minor exceptions. One was that of the breaking of jewels on meters connected in secondaries of current transformers that fed heavily into the short circuit and which, through an oversight in some of the first tests, had not been removed from the circuit. A strain choke coil on the circuit supplying the full short-circuit capacity collapsed, and half of the primary of one of the current transformers on a 132-kv. circuit supplying the short circuit was short-circuited by arcing between turns. But with these exceptions no further damage of any kind was experienced.

When the tests were originally contemplated and the test procedure was being discussed, doubt was expressed by some of the operating people as to the advisability of purposely placing severe short circuits on a healthy system. The view that finally prevailed, however, was that a system such as ours was at all times in danger

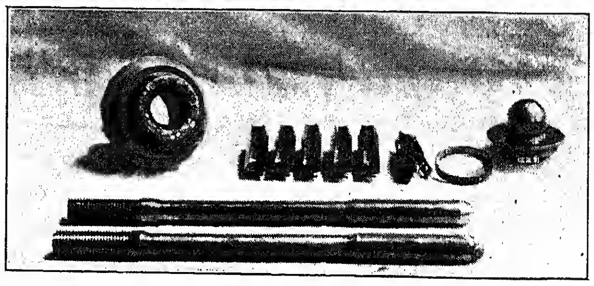

FIG. 34—ARCING BELL COMPARISON OF NEW AND USED CONTACT ROD, AND EXPLODED VIEW OF CONTACT SEGMENTS TAKEN FROM ONE POLE OF 136B BREAKER AFTER TESTS 36 TO 65

of having a short circuit placed on it with the full system capacity and if it was not in a position to stand up under such a short circuit, the sooner that condition was found and remedied the better off the system would be. It was satisfying to find that the system was able to go through all these short circuits without any appreciable damage.

4. Until the carrying out of the tests in question no check was available as to the system short-circuit capacity. Many calculations and much design work

and specification work had been done, however, on the basis of calculated values and it was felt that sooner or later some of these calculations ought to be subjected to test to determine whether the actual values were in agreement within reasonable limits. The tests demonstrated that the system calculations were correct at least to within 10 per cent.

In the case of the 37-kv. breaker of the Brown Boveri type, the principal benefit obtained was, of course, a complete demonstration that the designer of the breaker had completely missed his mark in giving the breaker a guarantee of 250,000 kv-a. Further, it indicated that perhaps under no conditions would it be possible to build economically a single tank type breaker for that voltage and the rupturing capacity in question, namely, 250,000 kv-a. It would be interesting if this point, at some future time, could be definitely established or disproved.

As regards the Reyrolle tests, the benefits that were obtained as a result of the tests can be summarized as follows:

1. It gave confidence in the engineers' original decision to install this equipment although so far as was known no equipment of that type had at that time been placed in service in this country. The equipment, as is well known, however, is widely used on the continent and particularly in England.

2. As regards the design itself, it showed that the system of baffling, such as was originally proposed, which consisted of wooden linings with wooden barriers fastened to the linings, was inherently weak and was not advisable for breakers that were expected to rupture even such a moderate amount of power as 75,000 kv-a.

Coming now to tests of the General Electric Company breakers, it is believed that the following can be listed as distinct benefits resulting from the tests:

1. A further check was obtained on the system short-circuit capacity and on the calculations that had been employed in the past.

2. In all, 64 short circuits were placed on the 132-kv. system of which 35 were at approximately full system capacity. So far as is known, no appreciable damage of any sort resulted to the system. Full advantage, of course, was taken of the experience gained during the Brown Boveri tests, so that the troubles encountered at that time were not met with during these tests. It was highly satisfying to find that the system went through all these 64 tests without any damage.

3. The tests served as a very thorough check on the explosion chamber type of breaker and particularly on the assembly that was standard before the tests were undertaken. It showed the weaknesses of the original assembly and demonstrated the complete efficacy of the remedial measures that were finally applied to overcome these difficulties. This was of great value not only from the standpoint of future breakers but also in connection with some of the breakers that were already in service and that were employing the original explosion chamber assembly. An example of this occurred during the summer following the spring in which the last tests were made when perhaps six or seven 132-kv. breakers of the KO-39-B type failed in operation, the failure consisting of the inability of the breaker to go back in circuit after opening a number of times under short-circuit conditions. An examination of the explosion chamber assembly, which was the cause of the failure, showed that the failure encountered was exactly similar to that which had occurred during the tests on the 136-B breaker. As a direct result, therefore, of the experience that was obtained during the tests the new type of explosion chamber assembly was substituted for the old type and no trouble of any kind has been experienced since.

4. A benefit that must not be overlooked is the fact that a breaker of high rupturing capacity was subjected to a test very close to its rated values and on a cycle which might, on the basis of the present tentatively adopted standard for the derating of breakers for other than a standard duty cycle, be interpreted to have subjected the breaker to a duty considerably in excess of its rating. The test clearly showed that at least for the particular type of breaker in question, after certain changes had been made, the guaranteed limit could be handled by the breakers successfully. If now it is assumed that the design was carried through on a certain rational basis and on the basis of definite empirical and other fundamental data, then it may be safely considered that the tests of the breaker in so far as such data entered into its design, served as a check on it and on other breakers designed on the same principle.

The authors desire to acknowledge the great assistance and cooperation they have received in the carrying out of these tests, and without which the tests would have been impossible, from the Cleveland Electric Illuminating Company, The Northern Ohio Power and Light Company, The Ohio Public Service Company, and the West Penn Power Company whose systems were either tied in with the test circuit or through whose cooperation in carrying a certain portion of the load it was possible to make available the capacity gathered together for the tests.

The authors also wish to acknowledge the great help received from the American Brown Boveri Corporation and from the Reyrolle Company in furnishing the switches and assisting in the tests and to the General Electric Company for their cooperation in the making of the Reyrolle tests and for furnishing the switches, the test equipment and operators, and for other assistance rendered in connection with making the tests on their breakers. Finally, acknowledgment is due to the operating department of The Ohio Power Company and Professors H. E. Dyche and E. R. Rath for their great help in making and recording the tests.

Discussion

J. D. Hilliard: The management of the American Gas and Electric Company, and other companies allied in making the tests, showed real courage in permitting repeated and severe short circuits to be thrown on the system—short circuits of greater magnitude than any to which high-voltage system had hitherto been intentionally subjected,—and they deserve the thanks of the electrical profession. The operating and construction departments also deserve credit for their efforts in carrying out the testing program in an efficient and expeditious manner.

In consenting to the publication of the full details without reserve of the Canton tests made by Messrs. Sporn and St. Clair, the General Electric Company has taken the stand that it believes that the engineers of the power companies of the country should be fully informed regarding circuit-breaker operation. The General Electric Company's engineers realize the value of field tests as supplementing the tests made in its testing laboratory; they realize that the only test which absolutely determines the interrupting capacity of an oil circuit breaker is the test made repeatedly at the full rated capacity, both in current and voltage, and they realize also that the only thing proved by such a test is the interrupting capacity of the breaker upon that particular system and under the particular conditions existing at the time the test was made; that if the test had been made upon another system at the same voltage and current interrupted, results might have been entirely different. The latter remark is not "theorizing," but is based upon years of experience in circuit-breaker testing and is a fact.

In their paper, the authors have drawn certain conclusions which seemed logical to them; they have assumed that because to them, a breaker performed satisfactorily, at part rated current or part rated voltage, it would perform satisfactorily at its full rating. Such a conclusion is illogical and is, in a large number of cases, contrary to the facts. A breaker may interrupt more than its rated kv-a. at a voltage below its maximum rating, and be blown to pieces at a small part of its kv-a. rating at its maximum voltage rating. Many tests have proved the truth of this latter statement and have repeatedly proved it at the first shot of the higher voltage. The explanation is simple. The excessive current at the lower voltage produces a strong electromagnetic blowout effect which instantly ruptures the circuit, while at the higher voltage and much smaller current, the blowout effect is weak, the arc hangs, producing a continuous generation of gas which almost instantly blows off the tank. It is my belief that in reporting tests upon oil circuit breakers, all authors should stick to observed facts in the tests, that speculation is almost sure to mislead and may do a great deal of harm by giving confidence in apparatus which is in fact not the reliable piece it is assumed to be. The immediately proceeding remarks are general and not intended to apply to any particular breaker or make of breaker. It is a statement based on conclusions drawn from observing many tests.

It is not thought necessary to make extended explanations on the happenings in the case of the K-136-B breaker, except to say that the causes of the trouble are known, the remedy has been applied to our full satisfaction and the tests have proved that the explosion-chamber breaker is all we ever claimed it to be.

The tests upon General Electric Company's breakers confirmed the empirical formula upon which the interrupting-capacity rating is based, they confirmed our observations as to the burning of the arcing contacts in our own testing laboratory and it was this latter experience which influenced us to consent to the making of the full number of shots, (26 and 30 respectively), without an examination of contacts until the end of the tests. The tests confirmed also our laboratory tests for oil throw, as not a drop of oil was thrown from any tank during any shot on the K-39-B breaker and the final test on the K-136-B breaker. In short, except for the very slight burning of the arcing contacts, there was nothing to indicate that the breakers had undergone a test.

Evidently through an oversight, a misstatement of fact appears in the test of the Reyrolle breaker. I refer to the statement "For some unknown reason the short circuit lasted only 2½ cycles, etc." As a matter of fact the reason was known at the time of testing and is previously explained as being due to the latch on the breaker not holding. The same thing had happened at previous shots. I believe it is due to the General Electric Company, whose generator and testing organization was used to make the tests that this statement of fact be made.

Since the data are given for the Brown Boveri and General Electric K-39-B and K-136-B breakers, it is possible to make in a way a comparison between them and since Prof. Dycke recorded the Brown Boveri tests, we shall take his records on the K-39-B and K-136-B breakers.

	Brown Boveri	General Electric	
		K-39-B	K-136-B
Rating of breaker	1,500,000 kv-a. at 150,000-volt	1,250,000 kv-a. at 132,000-volt	750,000 kv-a. at 132,000-volt
Break in series	10	2-explosion chamber	2-explosion chamber
Total number of shots made	26	26	30
Maximum load interrupted	70,000 kv-a. (est)	826,000 kv-a.	617,000 kv-a.
Percentage of rated interrupting capacity interrupted	46.6	65.8	81
Ratio max. line voltage before shot, to rated voltage (per cent)	80.5	100	104.5
Half cycles of arc at 2800 to 2900 amperes	13 min. to 17 max.		
Half cycles of arc at 3380 to 3610 amperes		11 min. to 15 max.	
Half cycles of arc at 2280 to 2600 amperes			12.5 min. to 17 max.
Oil throw	some	none	none
Contacts inspected and dressed during tests	yes	no	no
New oil used during tests	yes	no	no
Signs of burning of any part of breaker other than arcing contacts	yes	no	no

While no statement is made as to the speed of operation or arc lengths in the Brown Boveri breaker, it is believed from the arc duration that each of the ten arcs was not substantially shorter than each of the two arcs in the General Electric K-39-B breaker and in any event each of the two arcs of the General Electric K-39-B breaker had a shorter arc duration than each of the ten arcs of the Brown Boveri breaker. No conclusions are drawn from the above facts. I shall state, however, that the above observations agree with test results obtained in our testing laboratory on a breaker of similar design. I believe it should be stated that the observations and conclusions in reference to the General Electric Company breakers as stated in the paper are those of the authors, and do not necessarily express the opinions of the General Electric engineers.

Electrical engineers should understand that in testing oil circuit breakers they are dealing with very erratic phenomena and because of this fact should be slow in drawing conclusions from any series of tests or generally applying such conclusions.

The information gained by means of its present testing generator has been so valuable to the General Electric Company that it is building, and will have in operation in early summer, the

largest testing generator in existence; a generator that will have a sustained short-circuit capacity for circuit-breaker interrupting tests of over 500,000 kv-a., three-phase, with provision for the addition of units of equal or larger capacity as they may be required. The new laboratory will be equipped to test breakers of all voltages and currents and to observe and record phenomena taking place during interruption.

The interruption of a given number of volt-amperes by the breaker for example 100,000 kv-a. does not necessarily impose the same stresses as result from the interruption of the same kv-a. at other times at the same point on the system, at other points on the system or on different systems. In other words, volt amperes are not equally "hot" at all times and places, due to a number of causes. It seems probable that this difference in the difficulty of interruption depends largely upon the magnitude of the voltage "kick" at the end of each half wave of arc, and upon the speed at which each half wave of this transient voltage is built up. The need for making many tests on a device and making them under the most severe operating conditions is clearly indicated.

The Canton tests were very valuable in determining interrupting constants on that particular system and upon the existing conditions, but the "duty" was light as measured by other tests under other conditions. Certainly there are few, if any, other places in the world where so much power is available at 132,000 volts. In concluding my discussion, however, I wish to emphasize again the importance of conservation in drawing conclusions from one set of tests on a given breaker. Until experience is gained under conditions giving a vicious recovery voltage "kick," one is very likely to label a breaker safe which, as a matter of fact, is far from being so.

To give a concrete illustration of what may be expected, I shall cite one particular test in which the length of arc drawn in the same breaker operating with the same kind of oil, at the same speed, on the same system *but a different part thereof*,—at the same voltage and current interrupted, consistently gave an arc nearly three times as long in one case as obtained in the other. In one case, the breaker was safe; in the other, it was severely stressed and if the break distance had not been large, it would have been blown up.

J. B. MacNeill: Looking over the data on the several makes of breakers given for the 132,000-volt tests, the thing that strikes one is that the duration of arcing time is comparable for all designs. For instance, with the 150-kv. Brown Boveri breaker, the average test voltage (so-called, in the paper),—that is, the system voltage prior to the short circuit,—for all the tests is 131,700 volts, the average duration of arcing in the breaker is 14½ half-cycles or 7¼ cycles on a 60-cycle circuit. In other words, the breaker handled approximately 18,600 volts per cycle of arcing.

Now, turning to the final set of tests on the General Electric 136-B breaker, (135-kv.), the average test voltage of 139,000 volts was somewhat higher, the average time of arcing was 16½ half-cycles on 60 cycles, or, the breaker handled 16,800 volts per cycle of arcing.

On the KO 39-B, rated at 132,000 volts, the average test voltage was 132,000 volts and the average time of arcing 13.3 half-cycles. This breaker handled voltage at the average rate of 20,000 volts per cycle of arcing.

So we have these three values for comparison; 18,600 volts per cycle, 16,800 volts per cycle, and 20,000 volts per cycle. They are all of the same order of magnitude. What are the relative dissipations of energy in the two types of breaker? Personally, until I saw the paper, I had expected to see considerably less duration of arcing on the 10-break breaker. While the data on volts handled per cycle are not conclusive regarding the operation of the breaker, in fact, the breaker with 10 breaks made a very successful test, but, looking forward to higher powers, the question naturally arises whether the dissipation of energy on 10 breaks isn't considerably greater than on 2 breaks. The indication from these tests is that 2 breaks will handle voltage about as fast as 10 breaks. Possibly these comparisons don't represent the ultimate development to which the two types may lead, but that is the conclusion that I draw from the data submitted here.

The length of the arcs in the breakers may vary and the dissipation of energy may not be five times in one case what it is in the other. The length of arc, I believe, was given for the General Electric tests but not for the Brown Boveri tests.

Another thing to which I invite attention is this: These tests are quite interesting from the point of view of the type of short circuit placed on the system. Some of the short circuits were grounded and some were made with the short circuit ungrounded. Most data that have been accumulated on previous tests on other voltages has indicated that ungrounded short circuits hang on longer. You get instantaneous conditions in the breaker when one pole has come to a zero of current whereby that pole may be subjected to as high as 87 per cent of line voltage. If the short circuit and the source of power are grounded, that particular pole that is open first cannot be subjected regularly to more than 58 per cent of line voltage. Consequently, we have been led to expect longer durations of arcing with short circuits ungrounded than with short circuits grounded. This is the first series of tests of any magnitude that I have seen in which the indications seem to be that an ungrounded short circuit is no more severe than a grounded short circuit.

Referring to Table V, we see that certain of the tests, (56 to 65), were made with the system ungrounded, and that they were made with different kv-a's ranging from 460,000 to 625,000 arc kv-a. The average duration of arcing on these tests is 16.7 cycles. Referring, now, to similar tests made on grounded short circuits, tests (52 to 55), the duration of arc is 15.4 on the same voltages, 134,000 kv-a.

The conclusion I should draw from this would be that at this voltage there is not much difference between a grounded and an ungrounded short circuit. This is of particular interest to the operating people at this time because of the discussions that have arisen as to the application of breakers on grounded-neutral systems. Several of the large systems have installed great quantities of apparatus for 220-kv. service, using 187-kv. apparatus. So far they have got away with it but there has been a great deal of discussion as to whether they were justified in buying under-rated apparatus. This is the first actual test information brought forward that indicates practically no difference between the two types of short circuit. If this data can be substantiated by further data, it would seem that the operator's practise of using undervoltage apparatus would be pretty well justified and that special apparatus was hardly necessary.

G. A. Burnham: It is possible to draw an entirely erroneous conclusion from witnessing the moving picture of an oil circuit breaker test.

The film of the 6600-volt test on one of our competitor's breakers showed a breaker tested to destruction. In making a judgment on this breaker's ability, one should bear in mind that this picture showed the oil circuit breaker undergoing a test at a value far above its rating.

With reference to Mr. Hilliard's comments on testing, we feel very much as he does. Apparently their vast experience in testing has led them to the conclusion that the variables in circuit-breaker operation are so great that a test on a particular circuit breaker at one place perhaps does not lead to a general conclusion as to how well that breaker may operate under other conditions. From this, we are led to believe that when comparison tests are to be made, (particularly on oil circuit breakers in which so much difficulty is encountered in arriving at analytical results), the test should be made in the same place; as near at the same time as possible; with the same system setup; and, if possible, the tests be run under what might be called a "master

supervisor." It is obvious that exactly the same instruments should be used to record the results.

In making comparison between the Brown Boveri breaker and the General Electric Co.'s breaker in the 132,000-volt class, it is perhaps, as Mr. Hilliard has said, impossible to draw a conclusion without giving the most careful analytical study. The Brown Boveri breaker I believe handled all energy that could be imposed upon it at the time by the American Gas & Electric Co.'s system. It may have had slightly less duty, according to records, than the General Electric Co.'s breaker; nevertheless, we do not know how much more the Brown Boveri breaker would have handled had it been given the opportunity to display its ability. It apparently operated without sign of distress, and no doubt would have handled considerably more energy. Both Mr. MacNeill and Mr. Hilliard have referred to the fact that the duration of arcing was about the same in both breakers. Both gentlemen have therefore concluded that the arc length per arc in the Brown Boveri breaker was as great as the arc length per arc in the General Electric Co.'s breaker. From these statements, it would be a logical deduction to assume that the Brown Boveri breaker would have five times the total length of arc and for that reason would probably generate greater destructive forces. Such a conclusion would be incorrect as it rests upon the false premise that the speed of the moving elements was the same. The fact is that the moving element of the Brown Boveri breaker is slower and calculation shows that the total sum or actual arc length for the Brown Boveri 10 breaks is almost exactly equal to the total sum or actual arc length in the General Electric Co.'s 2 breaks. Furthermore, were Mr. Hilliard's assumptions correct, it is evident that the 10-break breaker would have to be built enormously stronger than the 2-break breaker. Analysis of facts will show that this older design of Brown Boveri breaker, successful as it was, was not of so heavy construction as the General Electric Co.'s breaker.

We believe this special test confirms the very satisfactory actual service results which have been had for some years in the United States with these multiple-break oil circuit breakers. It is our opinion that the multiple-break principle gives a more efficient handling of the arc resulting in less gas evolution, and less evolution results in lower pressures or destructive effects.

Philip Sporn: Mr. Hilliard stated in his discussion that a breaker performing satisfactorily at a low value of current may not perform satisfactorily at the maximum rating. There could be, of course, no argument on this point. What we should like to point out is that the engineer who tests his breaker and finds that it is satisfactory even at half rating is on safer ground than the one who makes no test at all.

Mr. Hilliard further stated that it is dangerous to speculate regarding the ability of a breaker to perform on the higher voltage from results obtained on a lower voltage. With this, again, we are in agreement. On the other hand, if a breaker is going to be used at other than its rated voltage, it should be tested at that voltage as that is the only way of finding out whether it can actually perform satisfactorily under those conditions.

Another statement made by Mr. Hilliard was that the test showed that the explosion chamber is all that it was claimed to be. Here, again, we agree. The explosion-chamber assembly is now all that it was claimed to be.

In connection with the table in which were shown comparisons between Brown Boveri and General Electric Company breakers, statement was made that the Brown Boveri breaker had the oil in it changed whereas the General Electric Company had no change. We should like to point out that this change in the case of the Brown Boveri breaker was made on one pole only, no changes whatever having been made on the other two poles. There was also a statement made to the effect that some burning occurred on the Brown Boveri breaker. Here, again, we should like to point out in fairness to the Brown Boveri Company that the burning in question was a slight amount of charring on a barrier that was made up in the field, out of micarta bought in a local shop. No trouble of any kind was experienced on any of the material that originally was supplied with the breaker.

Mr. MacNeill has raised the question as to whether, in view of the time of arcing being practically the same in the case of the General Electric as in the Brown Boveri breaker, this would not indicate that the relative rate of dissipation of energy was five times as great in the General Electric breaker as in the Brown Boveri breaker. We do not see that the tests have shown this. The fact of the matter is that the Brown Boveri breaker was physically lighter than the General Electric breaker. The above carefully considered may not lead to Mr. MacNeill's conclusions.

Another point brought out by Mr. MacNeill was the fact that previous to our tests it had been generally believed that ungrounded short circuits lasted considerably longer than grounded short circuits, whereas apparently in our tests this was not the case. It seems to us that there were not enough data obtained on this point to warrant any conclusions, nor do we see that this throws any conclusive light on the application of what we term 187-kv. breakers on 220,000-volt systems. For one thing, in a good many cases the breakers that were actually applied had clearances and length of stroke equivalent to 220,000-volt service, but bushings for 187,000-volt service. Such a piece of apparatus is, of course, underrated, but it certainly is not a straight 187-kv. piece of apparatus and the data which we have presented do not, we believe, throw very much light on the advisability or inadvisability of such practise.

Mr. Burnham has brought up a fact in regard to the Reyrolle breaker and motion pictures of the tests which were shown. It will be recalled that considerable fire and smoke ensued when the breaker exploded. We believe it was definitely pointed out in Table II that in the test where the breaker exploded, contacts of the breaker actually opened a short circuit of 122,000-kv-a. or a short circuit 63 per cent in excess of its guaranteed rating. The resulting pressure was enough to wreck the breaker tank. It would appear that little else could be expected under such conditions.

One more point in connection with the Canton tests we should like to bring out further and that is that, in all, we placed something like 90 short circuits on the system without apparently the slightest damage to it. While it may not be desirable in order to test the system to seek short circuits definitely, at the same time it is well to know that the system is so designed and assembled that it can withstand these trials when it may be called upon to withstand them without danger of everything breaking loose. So long as short circuits may occur on a power system it is essential that the system be so built that it can stand up under them and can come out of the short circuit unharmed except for the particular minor portion that can be affected by it. It seems to us that such a knowledge is bound to help the morale of an operating organization; that the less these things are feared the more likely it is that they will be handled properly when they do occur.

Klydonograph Surge Investigations

BY J. H. COX[1]

Synopsis.—*Since its recent development, the klydonograph has been used to investigate surge conditions on a number of transmission systems. Quantitative data, which show the characteristics of the actual surges present on transmission systems, are presented. In addition, these data are discussed in relation to various existing theories and practises regarding the production and the elimination of transient high voltages. The correctness of some of these ideas and the fallacy of others are indicated. The paper is subdivided, according to the nature of individual investigations, as follows:*

I. Open-wire Systems.
II. Cable Systems.
III. Lightning Arresters.

Introduction

The development of the klydonograph[2] in 1924, by Mr. J. F. Peters, gave promise of settling the long-standing question of the prevalence of surges on transmission systems. This instrument and the results of the first few applications were described at the Annual Convention of the Institute in 1925.[3] Data from an extensive investigation on the 220-kv. lines of the Southern California Edison Company were presented by Mr. R. J. C. Wood[4] at the Pacific Coast Convention in the same year. Since the spring of 1925, 26 three-terminal klydonographs have been in almost continuous operation on many systems of widely varying characteristics. Work has been concentrated on open-wire systems during the lightning seasons and on cable systems at other times. This paper is presented to place the information obtained, before the engineering public.

In most cases, the klydonographs were connected and calibrated to measure the crest values of surges between conductors and ground. Therefore, the surge voltages have been referred to the "normal operating crest voltage to neutral." Where the term "times normal" is used, it refers to the magnitude of the surge, on this basis. In addition to measuring magnitude, the klydonograph indicates the polarity of a transient voltage; that is, whether it is positive, negative, or oscillatory, where these terms have their usual meaning. When an oscillatory voltage is recorded, a superposition of positive and negative figures is obtained on the klydonograph record. The number of cycles, if few, or the approximate duration of oscillatory surges may be estimated from the appearance of the figures.

The klydonograph figure resulting from a negative voltage, is less than half the size of that produced by a positive voltage of the same magnitude. It has been the practise to adjust the potentiometers, through which the klydonograph is connected to a system, so the operating voltage gives a potential of approximately three kilovolts crest at the instrument terminals. This produces a normal voltage line on the klydonograph film. Thus negative surges, up to about 2.5 times normal, are obscured beyond detection by this normal voltage line. However, since surges of this voltage class are not of great importance, it is considered preferable to continue this method of connecting the klydonograph, even at the sacrifice of these low-value negative surges. This arrangement permits the measurement of voltages of from seven to 10 times normal. Beyond this, the magnitude is estimated from the degree of spreading of the figure, or from the violence of the instrument flashover.

In addition to the investigations for the purpose of measuring transient voltages, arrangements were made to record the performance of lightning arresters on certain systems. The arrester-discharge current and the surge voltages to ground at the arrester terminals were the quantities measured.

The data have been divided into three parts, according to the nature of individual investigations:

I. Open-wire systems,
II. Cable systems,
III. Lightning arresters.

Each section is complete in itself. Of course, the surge condition found on open-wire lines are closely related to the subject of lightning arresters.

I. Open-Wire Systems

Surges on open-wire transmission systems are of interest to the operating engineer, chiefly on account of the flashovers and consequent interruptions which follow. Although high voltages have a deteriorative effect on apparatus insulation, and although the life of this insulation probably is shortened by such surges, the effect on continuity of service usually is regarded as the more important point. The comparative freedom of high-voltage apparatus from failures justifies this opinion.

Consequently, in summarizing the data, the number of surges, rather than the number of indications, has been considered. For example, if high voltages appeared on more than one conductor, or at more than one point of a line simultaneously, they have been regarded as one surge. Obviously, such a surge could cause only one interruption, regardless of the voltages

existing on individual phases or at various points. The maximum value and its polarity have been used in classifying the magnitude and the polarity of each surge; in the tables.

Surges on transmission lines are usually due to one of three causes, lightning, switching, and short circuits due to mechanical reasons. However, it will be noticed that the causes of many surges are listed in the tables as unknown. No doubt, these were also due to lightning storms and switching operations, but incomplete operating records and discrepancies in recorded times of occurrence prevented the detection of many of these causes. However, the great majority were low in magnitude and, therefore, not of great importance.

All surges identified as due to lightning are listed in Table I, those to switching in Table II, and those to other causes, including unknown, in Table III. The tables show the relations between frequency of occurrence, cause, and magnitude, for each system investigated. In addition, the principal line characteristics, which are likely to have affected surge conditions, are included in Table I. A given system is designated by the same number in all Tables. Aggregate data for all systems are classified according to surge causes in Table IV.

In order to facilitate comparison of the results from various systems, all data have been brought to a common basis. This basis is ten years operation of one three-terminal klydonograph at one point of each system. The relatively long period of ten years was chosen to avoid fractions for high-magnitude surges, which were of infrequent occurrence. Thus, the actual number of surges of each classification, recorded on any given system, has been multiplied by the necessary constant. Since the lightning season usually is regarded as six months, the constant used where lightning surges were involved is one-half the value applied to all other surges. Although many investigations lasted only a few months, and although some were conducted at such times that no lightning data were obtained, the tests were sufficiently extensive to warrant some important conclusions.

Lightning. As shown by Table I, the majority of lightning surges were positive. However, all the highest surges were negative, but they were infrequent. The only positive surges over 10 times normal occurred on systems 4 and 21. These only slightly exceeded 10 times normal, while negative surges sometimes were considerably beyond this value. In three cases, direct strokes were known definitely to have caused the large negative records. In view of the fact that an induced surge is of opposite polarity, and that a surge, due to a direct stroke, is of similar polarity to the charged cloud, it is concluded that those clouds, which cause surges, are of negative polarity[5].

The occurrence of a flashover following a surge depends upon the wave-front, as well as upon the magnitude, of the transient voltage. The maximum possible potential, induced by lightning, is the product of the field gradient destroyed by the stroke, and the height of the line. It has been estimated that gradients as high as 100 kv. per foot (330 kv. per meter) are reached near the earth's surface; 60 kv. per foot (200 kv. per meter) has been measured. It is universally assumed that cloud-field gradients are constant for the height of a transmission line. Thus, extremely high induced potentials are possible. However, the extreme voltages are induced only near the discharge path. From this point to the boundary of the field, the gradient decreases rapidly.[6] The rate of rise of potential, on that part of the line directly in the cloud field, is equivalent to the rate of collapse of this field. Where negative clouds are concerned, it is believed that the collapse takes place in a time of the order of three microseconds. Upon the release of the bound charge, it divides and travels along the line in both directions. On points of the line outside the cloud field, the rate of rise of potential is determined by the front of the traveling wave. With the rates of discharge mentioned above, the front of this traveling wave is determined chiefly by the space configuration of the charge. Klydonograph data indicated that lightning surges have wave-fronts varying from a few to 200 microseconds. The higher-voltage surges had the steeper wave fronts. This conforms with the above discussion. Also, it is well known that the potential, which can be applied to any insulation, increases with the rate of application of the voltage. However, the time lag of the flashover of insulators decreases as the potential, in excess of the 60-cycle flashover voltage, is increased. Thus the potential, that can be applied at any given rate of application, is limited, and similarly the maximum voltages, reached by lightning surges of even the steepest wave fronts, are limited by insulator flashovers. These flashovers permit the charge to pass to ground. The limitation of voltage is indicated by the fact that, on systems of widely different voltages, the maximum surges were approximately the same number of times the operating voltages. However, the data are not conclusive on this point, owing to the limitations of range of the klydonograph. More definite information was obtained on a 55-volt signal circuit. Since this circuit was only 2.5 miles (4.0 km.) long, any surge induced upon it would have been detected. This line flashed over repeatedly during lightning storms, but the potentials never exceeded 10 kv.

In this connection, it is believed that the flashover voltage of 220 kv. transmission-line insulation, at the steepnesses of wave-front of lightning surges, is comparable to the maximum potential ordinarily induced by lightning. Thus, lines of this voltage should be practically immune to lightning, with the exception of direct strokes.

*P = Positive. N = Negative. O = Oscillatory.

The number of important surges which appear at a given point of a line during one lightning storm, was found to be low. More than two surges in excess of seven times normal voltage seldom were recorded at one klydonograph station. Also, many apparently severe storms were experienced without recording these higher voltages. Of course, their presence on a line depends, to a certain extent, on its length; the greater the exposure, the greater is the probability of lightning voltages at some point. The distance, from the point of origin, over which a surge maintains a magnitude of several times normal, is not definitely known. However, this appears to be of the order of a very few miles. It is hoped that accurate information on this point will be secured in the near future. In the meantime, the fact that only about two surges per storm occur, has considerable significance in connection with the application and operation of protective equipment.

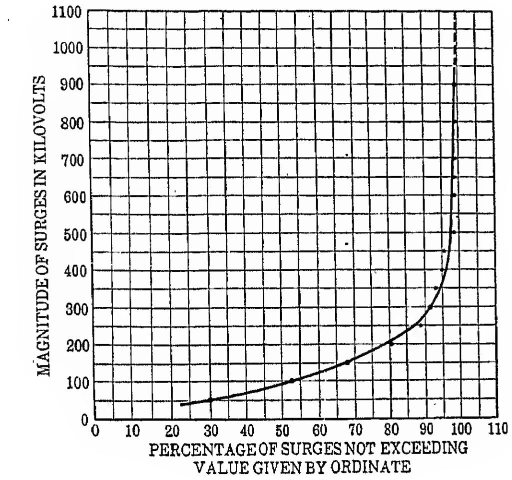
Table I shows a rather striking freedom from surges on the lower voltage lines, which operating statistics hardly verify. Higher, and more frequent surges, since lower induced-voltages must be considered, would be expected. For example, a lightning surge of 100 kv. would be 1.8 times normal on a 66-kv. line, but 5.4 times normal on a 22-kv. line. It is true that low-voltage lines are better protected from the field of influence of the cloud, because they are invariably nearer the ground than high-voltage lines. Consequently, lower induced voltages are to be expected, but this factor is not great enough to account for the results mentioned above. A number of possible explanations has been considered but, to warrant definite conclusions, further investigation is necessary.

Certain localities are nearly immune from lightning. Sometimes these are found even adjacent to regions where lightning is severe. On a system with lines extending in opposite directions from the same station, lightning conditions were found to be severe on one of these lines, and mild on the other. The freedom from trouble of the latter had been attributed to certain features which had been incorporated in its construction. This illustrates the error of drawing conclusions regarding the efficiency of protective devices from an individual application.

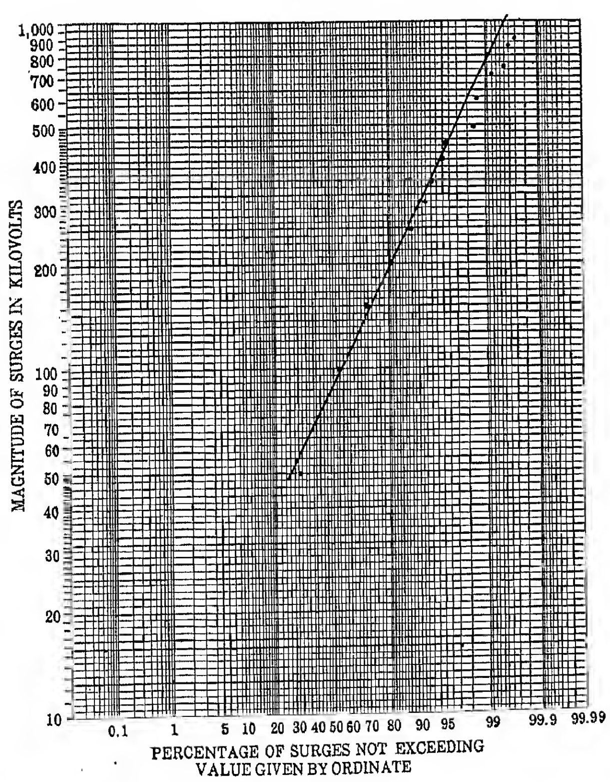
In Table I, a distinction is made between those surges which caused flashovers and those which did not. As would be expected, all the higher surges caused flashovers. A wide variation exists in the amount of insulation used on lines of the same voltage. However, a measure of the flashover value of the average insulation, for the wave-fronts produced by lightning, is indicated. Surges, which were over seven times normal

and did not cause flashovers, were recorded on only one system. This was No. 10, a 66-kv. system with a minimum insulation of seven suspension units.

The majority of the low-voltage surges are listed as "not causing flashovers." However, several surges of low magnitude are listed as "causing flashovers." Doubtless, the latter were of much higher magnitude at some point of the line remote from the klydonograph. It was found that high-voltage surges did not travel far. In traversing a few miles of line, they were always damped to a small fraction of their initial value. In several instances, a decrement from over 1000 kv. to about 150 kv. was observed over a distance of 35 miles (56 km.). In one case, a surge five times normal was recorded five miles (eight km.) from a direct stroke, which caused a flashover to ground in the middle of a long span. Thus, it appears that the higher-voltage surges are damped below the corona voltage in about 10 miles (16 km.). When this has occurred, the surge may travel a considerable distance without much attenuation. Frequently a surge of the order of 1.5 or 2.0 times normal, traveled 50 miles (80 km.), and occasionally, the entire length of a 250 mile (400 km.) line.



A



B

FIGS. 1A, B—RELATIVE PERCENTAGE OF LIGHTNING SURGES OF VARIOUS MAGNITUDES

The table shows that lightning voltages are unidirectional. When a flashover occurred, the klydonograph often indicated an oscillatory surge. Most of the oscillatory records are found in the column "causing flashovers." However, there are a few in the other column. These were probably due to surges producing lightning arrester discharges or flashovers on connecting lines, which were overlooked in collecting the information.

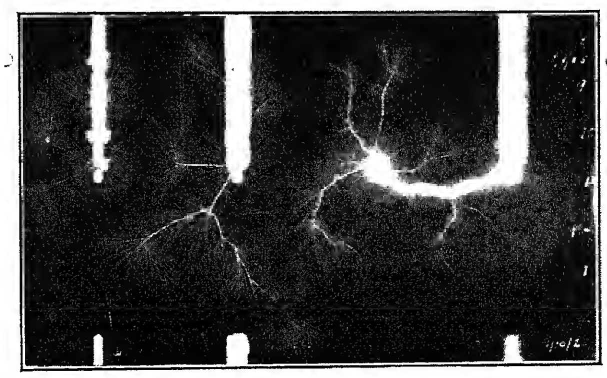


FIG. 2—KLYDONOGRAM OF A DIRECT STROKE OF LIGHTNING

The lightning data are plotted in Figs. 1A and 1B. The voltages produced by lightning are a function of the heights of lines, and not of the operating voltages, except as limited by the flashover of insulators. Therefore, in view of the variation in the operating voltages of the lines tested, the curves have been drawn with ordinates in kilovolts rather than "times normal" although the latter is a better criterion of the severity of a particular surge. The plotted results include all the data from the 27 tests. Fig. 1A is plotted in Cartesian coordinates and shows the relative percentages of lightning surges of different magnitudes. Fig. 1B represents the same quantities plotted on probability paper. The exceedingly small percentage of the total of the higher-valued surges, is illustrated in Fig. 1A. The reasonable conformity of the plotted results to a straight line in Fig. 1B indicates that sufficient data to represent true conditions were obtained, and that the magnitudes of lightning surges follow the law of probability. The plotted results deviate slightly from the straight line at the higher values. This is explained by the fact that, on the lower-voltage lines, insulator

flashovers limited the magnitudes of many surges, which otherwise would have reached higher values.

Various authors have discussed the value of the ground wire for reducing potentials induced on transmission lines by lightning. The theory of ground wire performance is relatively simple. It rests on the assumption that the charge on the ground wire can pass to ground as rapidly as the cloud discharges. The conclusions regarding the rate of lightning discharges indicate that this assumption is justified. Calculations

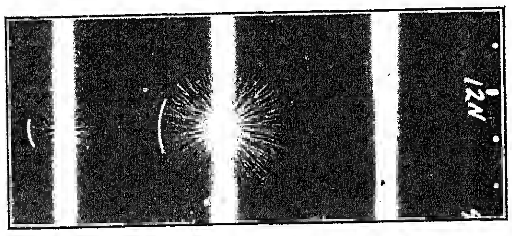

FIG. 3—KLYDONOGRAM OF SWITCHING SURGE

based on this theory show that, with typical spacings, the ground wire reduces by 25 to 45 per cent, the potentials induced on the conductors. Using small-scale models, F. W. Peek, Jr. obtained test results which indicate reductions as high as 50 per cent.[6] The percentage protection against flashovers is much greater than the percentage reduction of induced voltages. This is for the reason that, on high-voltage

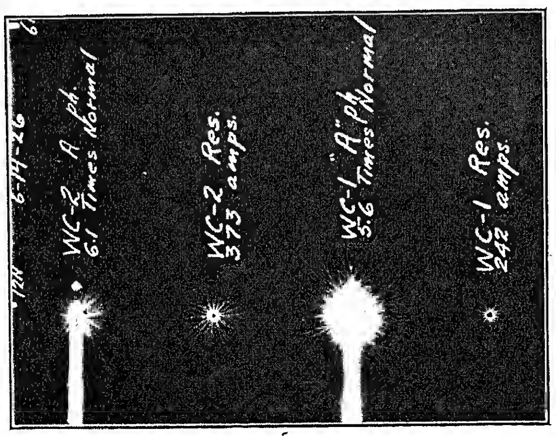

FIG. 4—KLYDONOGRAM OF A LIGHTNING ARRESTER DISCHARGE

lines, many of the induced surges which cause flashovers are not greatly in excess of the flashover voltages of the lines. It is readily conceivable that complete freedom from induced-voltage flashovers might result from a 50 per cent reduction of these voltages.[7]

Induced lightning voltages, simultaneously recorded on the three phases of vertically-spaced lines, were highest on the top phase and lowest on the bottom phase, particularly where no ground wire was installed. Operating records also indicated that most flashovers occurred on the top conductor. According to the theory of the ground wire, with the usual spacing arrangement, the greatest protection is afforded the top conductor, which needs it most. Hence, the relative voltages appearing on the conductors, where a ground wire is installed, are a compromise between the respective induced voltages, as affected by the heights of the conductors, and the respective reductions effected by the ground wire.

Because of the impossibility of obtaining lightning conditions at different times known to be similar, it is difficult to secure definite field data on the utility of the ground wire. However, Table I indicates a tendency in its favor. On those lines equipped with a ground wire, the proportion, of surges over five times normal to the total, is less than on lines without a ground wire. The most conclusive evidence was obtained on systems 4 and 5. These numbers represent the same system for the summers of 1925 and 1926 respectively. A ground wire was installed between

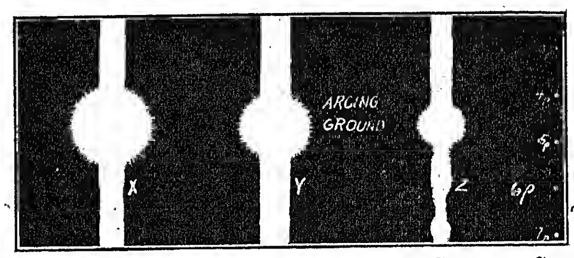

FIG. 5—KLYDONOGRAM OF AN ARCING GROUND SURGE

these dates. It is noticed that, after the ground wire was installed, there were no induced surges above five times normal. The number of direct strokes remained practically the same. However, it is not expected that a ground wire will render the line immune to direct strokes. It may be argued that these results are due to the vagaries of lightning, rather than to the efficiency of the ground wire. But, the fact that there were nearly as many direct strokes the second year, indicates that the lightning season was nearly as severe. Furthermore, the operators were of the opinion that the improvement in their operating record was more pronounced than can be accounted for by the difference in the lightning encountered.

It is hoped that these quantitative data and the accompanying discussion will contribute to the solution of lightning problems. As every engineer knows, these problems are a very important consideration in the operation of transmission lines.

Switching. As shown in Table II, switching surges are not a serious problem where the present accepted factors of safety for insulation are used. The maximum switching surge recorded was six times normal. Surges of this kind over 4.5 times normal were found on only five of the 27 systems investigated. On 15 of these

*U = Unidirectional. O = Oscillatory.

systems, no switching surge over three times normal appeared. The majority of all switching surges were below this value.

Not all switch operations produce surges. On system 1, the tests covered a period during which 3600 high-tension switching operations were performed. Approximately three-quarters of these caused no surges that were detected at the stations, although there were klydonographs at each of the high-tension switching points. Of those surges recorded, 93 per cent were less than two times normal. Thus, only 1.75 per cent of the switching operations caused surges over two times normal. The maximum surge recorded on this line was

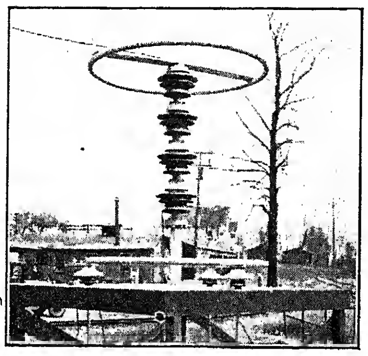

Fig. 6—One Potentiometer for a 120-Kv. Klydonograph Installation

3.2 times normal. It is estimated from the data for the 27 systems, that, on the average, less than one-half of all switching operations caused surges above normal voltage.

Although the results, obtained on systems of the same and different voltages, varied a good deal, the data have been reduced to an average for all systems, in Table IV. Again, to avoid fractions, the surges have been brought to the basis of 10 years at one point of each of 27 systems. As shown in this table, 80.8 per cent of all switching surges recorded, were less than two times normal, 93.0 per cent were less than three times normal, and 99.2 per cent were less than 4.5 times normal.

The higher-voltage surges were recorded on lines of 66 kv. to 140 kv. No surge as high as 4.5 times normal appeared on systems below 66 kv. With one exception there was none as high as three times normal. The absence of the higher surges on the lower-voltage lines is attributed to the fact that, in these cases, the klydonographs were usually connected to busses with many connected lines. As mentioned above, the highest surge recorded on the 220-kv. system was 3.2 times normal.

Little difference between the switching surges on systems with free and grounded neutrals, was detected. A grounded conductor on a free neutral system during switching operations accentuates the surges produced, by the factor 1.73. This is indicated by the surges listed for systems 2 and 3. The actual surges over 4.5 times normal, recorded on system 2, were caused by closing operations, when one conductor was grounded. They were all 5.2 times normal. On system 3, the actual surges over 4.5 times normal, listed under "closing switches at klydonograph stations," were caused by closing a 100-mile (160-km.) line and synchronizing with the power plants. All of these were 4.6 times normal.

Load switching does not cause surges as high as idle-line switching. This was found to be the case on all systems. In Table II, the switching surges have been grouped according to opening or closing operations at the klydonograph stations, or at other points. In general, de-energizing operations at the klydonograph station caused the higher surges. The high surges listed for closing operations on systems 2 and 3 are an exception to this. These were discussed above. Moreover, the large weighting factors necessary, particularly for system 3, give them more prominence than is warranted. With these exceptions, the surges caused by de-energizing idle lines are appreciably the highest of all switching surges. Of all the surges due to switching operations at the klydonograph station, 57.5 per cent were caused by opening operations and 42.5 per cent by closing operations.

It was found that switching surges occasionally traveled considerable distances. This is because they were low in magnitude, and thus not affected by corona. In other words, they were governed only by the resistance term of the attenuation constant.[5] Surges due to closing operations were recorded at distant stations

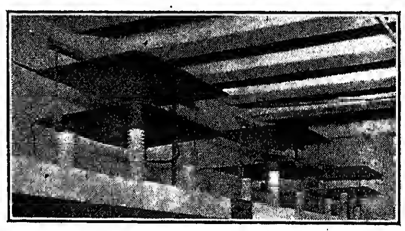

Fig. 7—Potentiometer for a Three-Phase Installation on a 12-Kv. Cable System

oftener than those due to opening operations. Of all the surges recorded at distant stations, 53 per cent were caused by closing and 47 per cent by opening operations.

It is interesting to note that changing taps on a transformer under load produced no surges. In general, charging electrolytic lightning arresters did not cause surges. However, on one system where the arresters were not equipped with charging resistors, oscillatory surges as high as 2.4 times normal sometimes resulted. On other systems an occasional surge about 1.3 times normal was produced.

Switching surges were quite abrupt when generated, the fronts being of the order of one microsecond. They were damped rapidly and the fronts became more

TABLE III

OPEN-WIRE SYSTEM SURGES OF WHICH THE CAUSES WERE INTERRUPTIONS, MECHANICAL SHORTCIRCUITS, AND UNKNOWN

System		Type of surge*	Number of Surges per station in 10 years, according to voltage magnitude

*U = Unidirectional. O = Oscillatory.

sloping. The greater the distances from the switch the longer were the fronts. The wave fronts of the switching surges recorded were from one microsecond to a few hundred microseconds.

Switching surges are of short duration. The table shows that 86.6 per cent were unidirectional and that 13.4 per cent were oscillatory. The only system contrary to the average was No. 12. Here, the majority of the surges were oscillatory. These were caused by interrupting the charging current of appreciable sections of line with disconnect switches. When reflections occurred and produced an oscillatory record, the surge lasted only one or two cycles. Further, the initial voltage was always appreciably higher than the succeeding half cycles. This indicates rapid damping, and consequently, the time of application of the high voltage was of short duration.

In view of (a) the moderate magnitude, (b) the low frequency of occurrence, and (c) the short time duration of the higher surges due to switching operations, they are not of serious importance either from the standpoint of continuity of service or of the effect on the life of apparatus insulation.

Flashovers and Interruptions. Surges, due to flashovers other than lightning, to overload interruptions, and to unknown causes, are listed in Table III.

Flashovers in general are objectionable from the standpoint of service interruptions. In some cases, they result in damage to the line in places where the repairs require considerable time and inconvenience. Also, the question of the effect of flashovers at one point, on the rest of the system, has often been raised.

Apparatus and line failures have been blamed on the suspected presence of high-frequency high-voltage oscillations. Klydonograph records show that, on grounded neutral systems, no serious high-voltages are produced by flashovers and no sustained high-frequency disturbances are produced by flashovers or by other causes. Sometimes small surges occur, due either to the fault or to the resulting switch operation—there is no way to distinguish between these causes. However, these surges are small and unimportant.

In the table, surges are classified as unidirectional or oscillatory. The latter classification really includes two types of surges. One is a highly damped oscillation of one or two cycles, the successive half cycles being much reduced in magnitude. These surges are really similar to unidirectional ones, in their effect. They sometimes occur in connection with switching, lightning, or flashovers on grounded neutral systems. Their oscillatory nature often is due to reflections in the circuits.

Oscillatory surges of the other type are sustained high-frequency oscillations. These occurred only on ungrounded neutral systems after flashovers, which result in arcing grounds. The frequency of these ranged from 2000 to 30,000 cycles per second; their maximum voltages were sometimes 4.5 times normal. The oscillations resulting from arcing grounds extended to all parts of the system.

It is known that the breakdown voltage of air is reduced, if the frequency of the applied voltage is high enough to maintain the ionization of the air from one cycle to the next. Thus, the ionization is cumulative, and the breakdown is progressive. Such a breakdown

TABLE IV

SUMMARY OF SURGES IN 10 YEARS AT ONE STATION ON EACH OF 27 OPEN-WIRE SYSTEMS

Cause	Type*	Below 2.0 times normal	2.0–2.9	3.0–4.4	4.5–6.0		
Opening a switch at a station where a klydonograph was located...	U	6000	960	700	40

will occur at a point below the 60-cycle breakdown voltage.

In recent years, certain devices, which were designed to prevent insulator flashovers from such disturbances, have been placed on the market. But sustained high-frequency oscillations occur only on isolated neutral systems, and there, only after a flashover. Obviously, it is futile, even on free neutral lines, to install devices designed to prevent flashovers due to this type of disturbance. Since, on long lines, the service is already impaired, protection against the second flashover is of minor importance. It is encouraging to know that no sustained high frequency high-voltage disturbances need be feared on grounded-neutral systems.

As shown in Table III, no high-magnitude surges resulting from interruptions other than those due to flashovers, were recorded. The surges found were low in value. In most cases they were less than twice normal. The highest recorded were less than 4.5 times normal and these occurred on only two systems. These results are consistent with the data on switching operations. Surges due to switching load currents always were low.

Those surges for which no cause was found are also listed in Table III. As mentioned before, they were probably caused by switching or lightning, but incomplete operating records prevented the detection of the causes. They were relatively low in magnitude and warrant no further consideration.

In five locations, klydonographs were installed on both sides of transformers. In two of these tests, no surges which were known to have passed through the transformers were detected. In the others, simultaneous surges sometimes were recorded on both sides, but they were not noticeably more severe on one side than on the other. The transmission of a surge through a transformer depends on the electrostatic relations of the parts. Thus, it should not be possible for a large surge to pass through from the low to the high side and still be important. This was found to be the case. Where the transmission was in the other direction, the surge was approximately the same "times normal" on both sides. This indicates that the reduction in the surge was of the same order as the ratio of the transformer. In several cases, lightning surges were recorded simultaneously on both sides of a transformer. However, each of these might have originated on its own side, but due to the same stroke. The actual data relating to the transmission of surges through transformers were rather meagre and, therefore, not conclusive.

The tests on open-wire systems show that, except for lightning and arcing grounds no high-voltage disturbances of particular importance to the operating engineer are present.

II. Cable Systems

The alleged presence of high voltage transients on transmission systems has been blamed for many cable failures in the past, both as a direct cause and a strong contributory factor. This naturally resulted in considerable controversy. It was a case of theoretical possibility versus meager and often conflicting negative evidence obtained in actual operation. Lack of a plausible alternative theory to explain failures and lack of suitable recording devices to investigate the surges made this situation possible and permitted it to survive for many years. That cable authorities have more or less discarded their former stand on this matter is indicated by the present general interest in the subject of dielectric breakdown and related problems in connection with cables. A number of theories which attempt to explain failures as due to the peculiar properties of dielectrics or the conditions under which they work in cables, have been advanced. Also, during the past two years, surges on cable systems have been investigated with the klydonograph. The information obtained in fourteen of these investigations is presented here.

In order to bring the data from various systems to a comparative basis, the records have been weighted to represent one year's operation of one three-terminal klydonograph on each system. The total number of voltage indications has been counted; for instance, if two or more abnormal voltages were recorded simultaneously on different phases or at different points of a system, each has been considered individually. While these methods of analysis have some undesirable features, it is believed they provide the most satisfactory comparison from the point of view of the effect of surges on insulation, which is the prime consideration.

Summarized data are shown in Tables V and VI. The former classifies the surges according to their causes; the latter demonstrates the variation between particular systems. In order to visualize these results as applied to the average system, they may be regarded as representative of the total number of surges to be expected at a given point of the average system in a period of fourteen years. Of course, this assumption has limitations—as will be seen later.

The klydonographs were usually connected to a system at generating stations or substations, and measured the surge voltages between the conductors and ground. All magnitudes were calculated with "times normal crest voltage to ground" as a unit. The highest voltage recorded was 4.6 times normal. Only 10 surges or 0.4 per cent of the total were over four times normal. Of these, six were on one cable-and-open-wire system, where certain contributory operating conditions prevailed. Only one of these high surges was on a pure-cable system.[8] Nearly 99 per cent of the total were under three times normal

8. It is realized that a "pure-cable" system possibly does not exist literally. However, the term is used here to classify those systems where cables strongly predominated, or where open-wire transmission lines were sufficiently remote to have no effect on surge conditions at the points investigated.

TABLE V

SUMMARY OF SURGES IN ONE YEAR AT ONE POINT ON EACH OF 14 CABLE SYSTEMS

Cause	Number of surges									
	Times normal voltage				Unidirectional		Oscillatory		Total	Per cent total
	1.1 to 1.9	2.0 to 2.9	3.0 to 3.9	4.0 to 4.9	1.1 to 2.5	2.6 & over	1.1 to 2.5	2.6 & over		
Closing a switch at a station where a klydonograph was located	1050	92		1	1120	23			1143	42.4
Opening a switch at a station where a klydonograph was located	340	25		1	360	6			366	13.6
Switching at other points of the system	117	13	5		120	15			135	5.0
Cables failures, automatic interruptions	300	49	13	5	150		185	32	367	13.6
Unknown	660	12	5	3	645	23	12		680	25.4
Total	2467	191	23	10	2395	67	197	32	2691

13 Kv	600	9	2.6	100				0
13 Kv	105	2	4.5	69	48		2.3	31
26 Kv	38		2.6	44	46	2	2.6	56
33 Kv	87		1.4	100				0
45 Kv	125		1.6	97	2	2	2.6	3
	2395	67		92	197	32		8

voltage. Also 92 per cent of the total were unidirectional and, therefore, of brief duration. Most of the abnormal voltages were caused by normal switching operations, and it is believed that many of those tabulated as unknown were also due to switching. Klydonograph clock errors and incomplete operating records undoubtedly prevented linking up a surge with its cause in many cases.

However, the surges produced when failures occurred were considerably more severe than those due to switching. Practically all the oscillatory surges, and particularly the higher-voltage ones, were caused by insulation breakdowns. That these surges were the effects, and not the causes, of insulation failures is strongly indicated by the fact that they did not occur unaccompanied by a short circuit. Surges of this nature invariably appeared on the two phases of the system other than the faulty one, with about the same magnitude on each. The theory of production of surges of this nature involves the characteristics of the arc. This theory calls for a maximum of 2.5 times normal voltage for surges due to arcing grounds on grounded neutral systems[9]. The results for all except one system check very closely with this value. A maximum of 2.6 times normal was recorded on these systems. Allowing for errors of measurement, the agreement is very satisfactory.

The relatively greater severity of surges due to short circuits is because of the following considerations. These surges affect a large part of a system. In many cases, appreciable voltages were recorded many miles from the location of the failure. As a rule switching surges failed to travel far. In addition, surges accompanying short-circuits usually were oscillatory, while switching surges were unidirectional. Thus it is seen that, for a given magnitude, surges resulting from short circuits are more severe on insulation. This is due to their longer time of application and to their greater energy which results in more of the system insulation being stressed. But the elimination of insulation failures would automatically eliminate surges of this class.

In addition to the surges included in the tables, there were many recorded when energizing and de-energizing short bus-sections or leads to the klydonograph equipment, or, in other words, where very small charging currents were involved. These reached a maximum of 4.5 times normal voltage, those for energizing operations averaging somewhat lower magnitudes. However these voltages appeared only on the sections being switched, involved very little energy, and usually were not the result of normal switching operations. For these reasons they are not included in the data. Certain physical conditions, which give the proper proportions between inductance and capacity, with high leakage resistance, are apparently necessary for the production of the higher voltages. Consequently, the great majority were of the order of two times normal or less. Surges, due to actual cable switching or operations involving appreciable currents, failed to reach three times normal voltage. In general, the production and magnitude of switching surges appear to be haphazard

9. *Voltages Induced by Arcing Grounds*, J. F. Peters and J. Slepian; TRANS. A. I. E. E., Vol. XLII, 1923, p. 478.

affairs and, for a given operation, no relation between the magnitudes on the various phases can be detected.

The large number of small surges shown for certain systems is somewhat due to the influence upon the tabulated data, of special switching tests or other-than-normal cable switching operations. The latter were necessary, in some cases, for changing the plates or films in the klydonographs.

It will be noted in Table VI that the surges on cable-and-open-wire systems were somewhat higher than those on pure-cable systems. This is partly due to the presence of lightning voltages on open-wire systems, although surges of this nature were eliminated from the data where known to be such. Incidentally, none of these known lightning surges were of a magnitude to make them important. Again, transmission line switching usually results in higher surge voltages than similar operations involving cables. One surge 4.5 times normal was recorded on a pure-cable system. However this was due to energizing a switch group, which is a low energy operation as discussed above, but, at the same time, routine switching. Otherwise, the highest voltage observed on a pure-cable system was 2.6 times normal. On one particular system the surges identified with short circuits were considerably higher than the average. For instance, this system accounted for 26 of the 32 oscillatory surges of 2.6 times normal voltage and over. Its only apparent difference from the other systems, all of which were grounded solidly or through a low resistance, is the presence of a 75 ohm resistor in the neutral ground. No doubt, additional data will reveal more definitely the conditions or phenomena underlying these exceptional results. The inclusion of the data from this system has exaggerated to a certain extent the seriousness of surges on the average system.

An interesting phenomenon has been observed in connection with cable failures on four or five occasions. During three to six hours before the breakdown a succession of surges of the order of 1.7 times normal voltage has been recorded on two phases of a system, with the final breakdown occurring on the third phase. In other words the fault made itself evident some time before the short circuit developed. The klydonograph records indicated that this was not a continuous process but occurred more or less irregularly at intervals of a few minutes. Apparently, impulsive discharges through temporary punctures of the insulation took place. These created sufficient unbalance to raise the other phases to approximately the delta voltage above ground for an instant, without developing into a short circuit severe enough to cause an interruption. This action has been noticed only on 26-kv. and 33-kv. systems, and in each case the system neutral was grounded.

Apparently, transient high-voltages are a very minor contributory factor to cable-insulation failures. Considering the test voltages which cables are required to withstand for an appreciable time, it also appears that surges cannot be held responsible for the failures encountered in practise. This conclusion is reached by virtue of the low magnitude, the short time duration and the low frequency of occurrence of surges. It might be argued that it is wrong to assume that very high voltages occur nowhere on a particular system because none appeared at certain points studied for a limited period of time. However, the data were obtained on several systems and under a wide variety of operating conditions. The rarity of surges of even four times normal voltage naturally leads one to doubt very strongly the existence of higher transient voltages on cable systems. Of course it is conceivable that surges, of the order of magnitude found in these investigations, might cause a failure, if the insulation at any point were to reach such a condition that a slight increase in potential would break it down. But it is doubted

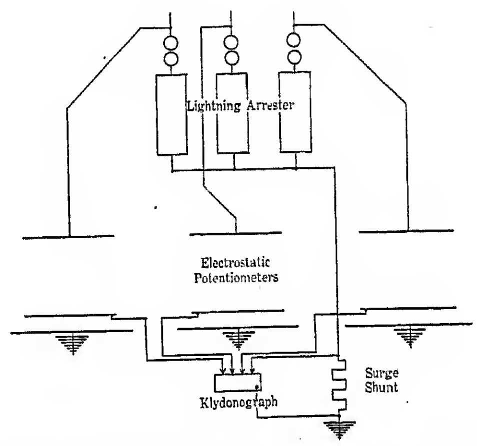

Fig. 8—Diagram of Connections for Lightning Arrester Tests

that these surges could create this abnormal condition and its elimination would be the primary problem.

III. Lightning Arresters

The klydonograph has proven valuable for recording the performance of lightning arresters under operating conditions.[10] The magnitude and nature of the arrester discharge current as well as the same quantitites for the impressed voltage surge can be determined. The current measurement is obtained by recording the voltage drop across a non-inductive resistor, which is inserted in the arrester ground lead. A 10 to 15 ohm resistor is suitable. Since the minimum recording voltage of the klydonograph is about 2000 volts, the detection of currents above 150 to 200 amperes is possible with this arrangement. On three-unit arresters the bases must be insulated from their supporting foundations to force current through the resistance shunt. The voltages measured at the terminals of the arrester are the maximum values reached by the surge at that

10. Arrester Tests with the Klydonograph, L. R. Golladay. *Electrical World*, Sept. 4, 1926.

point. These exist for the very brief interval required for the arrester to come into operation, after which they are reduced by the discharge. However, the extreme speed of the klydonograph permits the measurement of these short-duration peak values. A diagram of connections appears in Fig. 8. Fig. 9 shows a typical installation.

Unfortunately, in most of the tests it was not feasible to install equipment to measure the surge voltages on all three phases. Where this was the case, the highest conductor, or the highest and the lowest

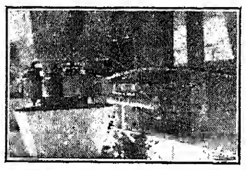

Fig. 9—Typical Installation for Measuring Arrester Discharge Current

conductors, were selected, for the reason that induced lightning voltages vary as the heights of the conductors above ground. However, the voltages impressed on the arrester terminals may not correspond to this law, if a flashover occurs at some distance from the arrester, or if transpositions are frequent.

In Table VII the data on the performance of lightning arresters are listed. All the arresters tested were of modern valve type. All were autovalve except No. 2, system 1, and No. 1, system 6. These two were different types. In order to bring the data from individual tests to a common basis, the records have been multiplied by a factor to make them represent the operation of each arrester for one lightning season of six months. Classification has been made according to the maximum recorded voltage of each surge. The divisions are: (a) above 3.5 times normal; (b) 3.5 to 2.6 times normal; (c) below 2.5 times normal; (d) discharges recorded on arresters on which no potentiometers for measuring voltage were installed.

The basis of most apparatus insulation tests is twice the operating phase-to-phase voltage. Consequently, lightning arresters are adjusted to relieve surges above this magnitude. However, all surge calculations have been based on the normal crest voltage to neutral. Therefore, a surge $2 \times 1.73 = 3.5$ times normal in the tables, corresponds to twice the phase-to-phase crest voltage. Discharges for surges below this value are unnecessary, and, in some respects, objectionable. This is particularly true for the lower-voltage surges in view of their greater frequency of occurrence.

As shown in Table VII, with few exceptions, the operation of the arresters was satisfactory for surges above 3.5 times normal. Some of these, for which no discharges were recorded, were caused by switching. As switching surges often are not of the same polarity on all three phases, the current discharge path may have been from phase to phase through the neutral interconnection of the arrester units. For such a discharge no indication results on the klydonograph. Again, some surges, over 3.5 times normal, only slightly exceeded this value. In these cases the magnitudes possibly were exaggerated by the limitations of accuracy of the klydonograph. During the tests, only three lightning surges, which undoubtedly were high enough to require

TABLE VII
SUMMARY OF LIGHTNING ARRESTER INVESTIGATIONS, ON A BASIS OF ONE LIGHTNING SEASON'S OPERATION OF ONE ARRESTER

System number	Arrester number	Voltage	Weeks of test	Number of potentiometers	Surges 2.5 times normal or less				Surges 2.6 to 3.5				Surges 3.5 or over				No voltage measurements

*This is a 140-kv. arrester connected to a 120-kv. system.

a discharge and for which none above the minimum recording point resulted, were recorded.

A considerable number of discharges occurred when the accompanying maximum surge voltages were below 3.5 times normal. This was particularly true on arrester No. 1, system 6 and, to a lesser extent, on arrester No. 2, system 1. In tests where voltage measurements were made on only one or two phases, higher voltages on the other phase or phases likely were responsible for many of the discharges of this type.

The function of lightning arresters, as ordinarily installed, is the protection of station apparatus. They do not necessarily prevent line flashovers. If a high-voltage lightning surge originates at some distance from an arrester, the line insulators may flash over before the surge reaches the arrester. This point is discussed in Part I. To protect against insulator flashovers it would be necessary to distribute arresters at short intervals along a line.

The results of these tests show that the operation of lightning arresters in the field confirms predictions based on laboratory tests. However, the data indicate that the occasions, upon which high-voltage lightning arresters are called upon to operate, are relatively infrequent.

Conclusions

1. Surge voltages due to lightning are unidirectional. The clouds which produce surges are of negative polarity, resulting in positive induced-voltages and negative direct-stroke voltages.

2. The maximum values, reached by lightning surges on transmission lines, are limited by the flashover of the insulators. It is believed that the flashover voltage of 220 kv. transmission line insulation, at the steepness of wave front of lightning surges, is comparable to the maximum potentials ordinarily induced by lightning.

3. The flashover voltage of the average insulation of lines up to 140 kv. is about seven times normal for lightning impulses.

4. Seldom more, and often less than two surges, comparable in magnitude to the insulator flashover voltage, appear at a given point of a line during a storm.

5. The frequency of occurrence of the higher surges does not seem to be greater for low-voltage than for high-voltage lines.

6. High-voltage surges are damped below the corona voltage in traversing a few miles of line. At low magnitudes they may travel long distances.

7. The quantitative measurements with the klydonograph agrees with the theories regarding induced voltages and the protection against these afforded by the ground wire.

8. Switching surges occasionally reach six times normal voltage, but 99.2 per cent of all produced are less than 4.5 times normal. Less than 50 per cent of all switching operations create a disturbance.

9. Switching idle lines produces higher surges than similar operations involving load currents. Opening operations result in higher voltages than closing operations.

10. Switching surges usually are unidirectional. When oscillatory, they are highly damped and therefore of short duration.

11. Switching surges are not of serious importance either from the viewpoint of continuity of service or of their effect on apparatus insulation, where the accepted factors of safety for insulation are used.

12. Flashovers and shortcircuits produce no serious voltage surges where the system neutral is grounded. The nearest approach to sustained high-frequency high-voltage oscillations is the arcing ground on isolated-neutral systems, where this form of disturbance reaches a maximum of about 4.5 times normal voltage.

13. Except for lightning surges and arcing grounds no high-voltage disturbances, of particular importance to the operating engineer, appear on transmission lines.

14. Nearly 99 per cent of the surges found on cable systems are less than 3.0 times normal voltage. The maximum voltages are of the order of 4.5 times normal; 92 per cent of the total are unidirectional.

15. Where open-wire lines are combined with cables, the surges are somewhat higher than on pure-cable systems.

16. The surges resulting from short circuits are *relatively* the most injurious to cables, owing to their longer time of application to insulation, and to their greater energy which results in more of the system insulation being stressed. However, except under certain rare conditions, their magnitude never exceeds 2.5 times normal, and their frequency of occurrence is low.

17. Apparently, transient high voltages are a minor contributory factor to cable-insulation failures.

18. In the investigations of the performance of lightning arresters in actual service, it was found that arresters in general give satisfactory operation, that is, they relieve all surge voltages above the standard test voltages for equipment insulation. Discharge currents up to 2500 amperes occur in practise. From these tests it is concluded that the field performances of arresters confirms predictions based on laboratory tests.

19. Lightning arresters do not protect a line against flashovers at distant points.

Acknowledgment

The authors wish to express their appreciation of the excellent co-operation accorded by the various operating companies, upon whose systems these tests were performed. Without this co-operative attitude, such extensive investigations would have been impossible.

Discussion

Transmission Line Voltage Surges

BY J. H. COX*

Associate, A. I. E. E.

Synopsis.—Records of the transients actually occurring on transmission lines of widely varying characteristics have been obtained recently with the klydonograph.

1. These records substantiate many of the theories of transients on lines.

2. They indicate the incorrectness or incompleteness of some of these theories.

3. They suggested modifications or extensions of these latter theories.

This paper is a coordination of those theories which agree with test data obtained up to the present time. Since the results of the klydonograph surge investigations are presented in a companion paper, only the data required to make this paper complete in itself are included.

Introduction

There has been a great deal of discussion regarding the high-voltage transients which appear on transmission systems. Switching operations and lightning are the most important causes of these transients. Due to their extremely short duration, there was, until recently, no instrument available for obtaining definite information regarding their characteristics. Their nature had been deduced from operating experiences such as flashovers and apparatus failures. Although electric circuit theory became quite well known, different assumptions in the premises led to different conclusions—hence the divergence of opinion.

Since the recent advent of the klydonograph and the cathode-ray oscillograph, field data, secured under a wide variety of conditions, have been obtained, with the former in America and with the latter in Europe. These data do much toward clarifying the situation. In this paper an attempt is made to coordinate the author's experiences and certain theories of surges, both switching and lightning, which are substantiated by field results.

I. Switching

Ideal Case. The well known theory of traveling waves will be briefly reviewed. For simplicity the ideal case will be considered first. This is the case where a single line is switched from a limitless source, and the potential is applied or removed instantly. At the instant of such an operation, a sheer-front voltage wave, equal to the applied voltage, proceeds out along the line. It is accompanied by a current wave, equal in magnitude to the voltage divided by the surge impedance. These waves, when they reach a terminal, reflect with full magnitude with the same or opposite sign, according to whether the line is open or short-circuited, and according to whether the voltage or current wave is considered. The reflected wave will then add to, or subtract from, the initial wave. The maximum voltage possible from this effect on a homogeneous line is twice the applied voltage. This is shown in Fig. 1. A transformer at the end of a line, due to its high open-circuit impedance, presents the same condition to a surge upon its first impression, as an open line.

In the case where the end of the line is neither open nor closed, but joins a line of different surge impedance, there is a reflected wave and a transmitted wave. Where E is the voltage of the initial wave, Z_1 the surge

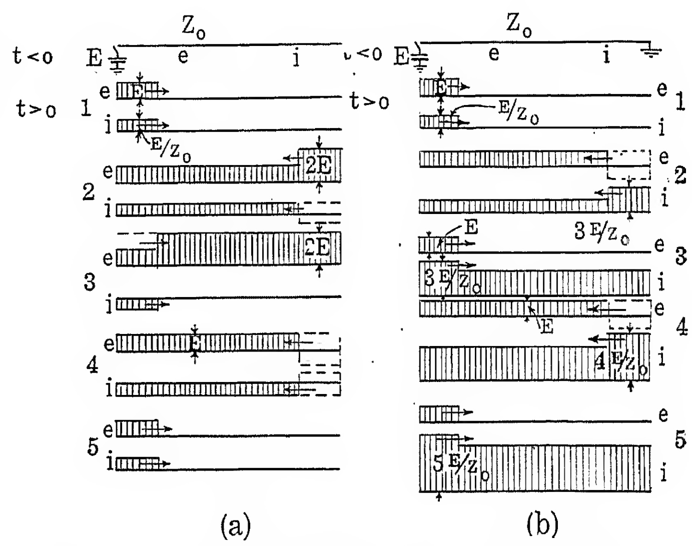

Fig. 1—Traveling Waves on Transmission Line
(a) End open (b) End short-circuited

impedance of the first line, and Z_2 that of the second line, the reflected wave is equal to $\dfrac{Z_2 - Z_1}{Z_1 + Z_2}\,E$,

and the transmitted wave is equal to $\dfrac{2\,Z_2}{Z_1 + Z_2}\,E$.

This effect is shown in Fig. 2. The usual open air line has a surge impedance of the order of 550 ohms, and a cable 50 ohms. Taking the case of a composite line, it is seen that, if a switch is closed on the cable section, there will be a reflection where the wave enters the open wire part, and the transmitted wave will have a magnitude of nearly $2\,E$. Then if the open wire line is open ended, or ends with a transformer, the wave will reflect giving a total potential of nearly $4\,E$. Obviously, if a line divides into two or more branches, the branches

*Westinghouse Electric & Manufacturing Co., East Pittsburgh, Pa.

Presented at the A. I. E. E. Winter Convention, New York, N. Y., February 7-11, 1927.

present to the line the same effect as a line of lower surge impedance.

Practical Case. In the practical case of alternating-current switching, the point of the applied wave at which contact is made, is a more or less haphazard affair. There is a tendency to arc over at the crest of the wave, especially at the higher voltages now used. However, with the usual closing speed of contacts, and

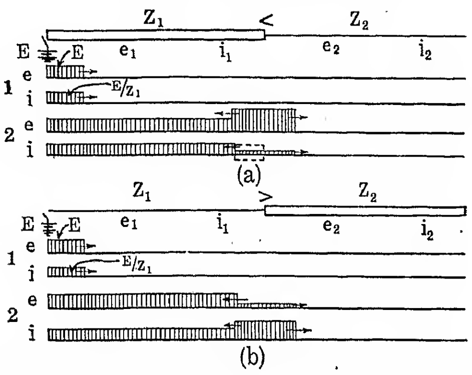

FIG. 2—REFLECTIONS AT THE JUNCTION POINT IN A COMPOSITE LINE

(a) Passing from cable to open wire
(b) Passing from open wire to cable

the breakdown strength of oil, this tendency is not the controlling factor. Thus the traveling wave, initiated by a switch closure, will not always have a magnitude as great as the normal crest voltage. Of course, the reflections are governed by the original wave.

It must be remembered that the above discussion applies to the ideal case. Although the application of voltage by a switch closure in practise is a rather abrupt phenomena, it is not instantaneous. The voltage on the part being energized rises from zero to the

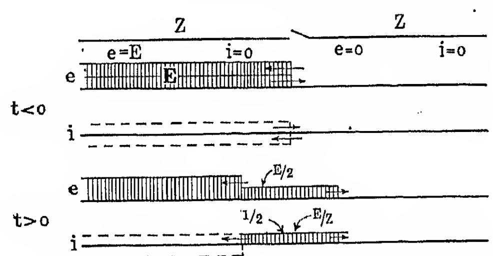

FIG. 3—A LINE ENERGIZED FROM A SIMILAR LINE

full value in a time of the order of 0.1 microsecond to a few microseconds; that is, the front of the wave sent out extends over from 100 ft. to a mile of line at the start. There are, however, two factors entering into the practical case, each of which tends to lengthen the wave fronts of surges and to lessen the voltages obtained.

Limitation of Source. In practise, when a line is switched, it is not done in connection with an infinite power source. The nearest approach to this condition is closing a single line on a high-capacity bus; that is, a bus which has many other connected lines. When a line is closed to a similar line, the wave sent out is equal to $\frac{1}{2} E$, as shown in Fig. 3. Here the maximum voltage with reflection will be E. When a line is closed on a bus having more than one other line energized, the wave sent out is greater than $\frac{1}{2} E$, and approaches E as a limit. Another common case is where a line is energized from a transformer. Whenever there is a voltage wave, there must be an accompanying current wave equal to E divided by the surge impedance Z_0. It is impossible, however, for current to build up instantly in a transformer. The rate of rise will be limited by the leakage inductance of the transformer, and the wave front will be sloping. If the front is more than twice as long as the length of the line, there can not be a complete reflection, since, after the foot of the wave has traveled to the distant end and back, it will disturb the conditions at the terminal point considered.

Fig. 4 shows the approximate circuit of a line being switched from the high-tension side of a transformer. The potential of the line is determined by the relation

$$e = i Z_0 \qquad (1)$$

The relationship between the currents and voltages in the circuit is

$$R i + L \frac{d i}{d t} + e = E$$

or upon substituting,

$$\frac{d i}{d t} + \frac{R + Z_0}{L} i = \frac{E}{L} \qquad (2)$$

where E is the voltage on the low-tension side of the

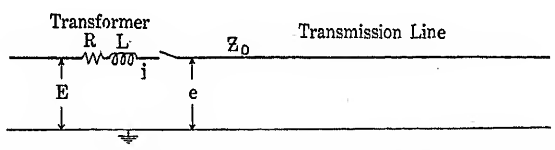

FIG. 4—APPROXIMATE DIAGRAM OF TRANSMISSION LINE AND TRANSFORMER

transformer referred to the high-tension, R and L are the equivalent resistance and leakage inductance of the transformer, and Z_0 is the surge impedance of the line with respect to ground. With E constant, the solution of (2) gives the equation of i:

$$i = \frac{E}{R + Z_0} \left[1 - \epsilon^{-\frac{R + Z_0}{L} t} \right] \qquad (3)$$

From equation (1) it is evident that the voltage wave has the same shape as the current wave and its front extends over the same length of line. The current, from equation (3), will rise to almost its maximum value in a time equal to twice the time constant $T = \frac{L}{R + Z_0}$. Thus, to accomplish a complete reflection, the line must have a minimum length of

$v\,T$, where v is the rate of wave propagation, 186,000 miles (300,000 km.) per second. Table I shows the lengths of open-wire lines, of various voltages, necessary for complete reflections, when energized from transformers of capacities commensurate with the line voltages given. Since the surge impedance of a cable is approximately one-tenth, and the speed of propagation one-half of that of an open wire line, the lengths of cable required are approximately five times those given in the table. For a double reflection, giving nearly $4\,E$ as discussed above, the cable must be connected to an open wire line twice as long. With the lengths of wave fronts generated on cables, it is evident that the lengths of cable and open-wire line necessary in a composite line for this double reflection are not common conditions. Further, with such lengths, the next factor discussed influences the situation.

Attenuation. The second factor tending to limit the surge potential is the attenuation of the wave. The attenuation factor of a line is:

$$\epsilon^{-\left(\frac{r}{2Z_0} + \frac{g\,Z_0}{2}\right)x}$$

where r is the series resistance and g the parallel conductance per unit length of line, Z_0 is the surge impedance, and x is the distance traveled in the same linear units used for r and g.

This reduces the wave as it travels down the line. In any case where there are abrupt wave fronts there are high-frequency components. The resistance of the conductor is higher to these high frequencies due to skin effect. Thus, the first term of the attenuation constant, $\frac{r\,x}{2\,Z_0}$ for the higher frequencies is many times its value using the d-c. resistance. This will tend to rapidly damp out the high-frequency components and slope the wave.

In the case of high voltages, corona enters and helps dissipate the energy of the surge[7]. This effect is higher for the more abrupt wave fronts. The effect of corona is to increase the second term of the attenuation constant $\frac{g\,Z_0\,x}{2}$. This term is negligible when only the leakage of the insulation is considered. For the higher voltages this second term is far greater than the first. Thus, when a surge above the corona voltage is generated, its energy is dissipated rapidly as the wave travels along the line. When the voltage has been reduced below the corona point, the wave proceeds, being governed by the first term of the attenuation constant, $\frac{r\,x}{2\,Z_0}$. This attenuates the wave more slowly.

It has been found in tests that extremely high voltage surges fall to a fraction of their original value in a distance of only a few miles. In several instances, a

7. For references see Bibliography.

surge was recorded at one station with a magnitude of 1000 kv. and at a station 35 miles away with a magnitude of 150 kv. It is believed that most of this attenuation took place in the first few miles. Lower valued surges which traveled 250 miles have been recorded.

Characteristics of an Arc. The considerations thus far discussed do not take into account any characteristic of the arc, which always takes place at the contacts of a switch. This may affect the results considerably.

Fig. 5a shows the static characteristic of an arc in air; that is, the variation between volts and amperes under slowly varying conditions. This gives the effect of a negative resistance and an approximate equation is $V = V_0 - I r_0$, where V is the voltage across the arc and r_0 is the value of negative resistance, or the slope of the straight line. This characteristic, however, is not maintained under rapidly varying conditions. Under such conditions there would have to be a rapid ionization and de-ionization of the air and the speed of these phenomena is limited. Fig. 5b shows the dynamic characteristic of the alternating current arc in air.

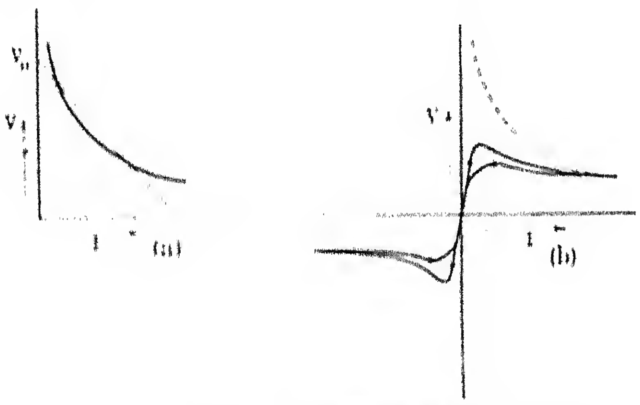

Fig. 5 — Characteristics of an Arc in Air
(a) Static (b) Dynamic

This characteristic is a function of both current and frequency. With small currents and low frequencies the characteristic approaches that of Fig. 5a. With heavy currents the intense ionization keeps the atmosphere of the arc conducting between alternations even at lower frequencies, while with light currents at higher frequencies there is not time for the de-ionization necessary to give the static characteristic. It is this characteristic, giving a low value of negative resistance at high frequencies, which minimizes the possibility of sustained high frequency oscillations on transmission lines. It is acknowledged that, if the negative resistance of the arc, in a sustained short circuit, were greater than the positive resistance of the connected circuit, oscillations with indefinitely increasing amplitude would be possible. Tests have proved that these do not exist. Where the arc is in rapid air currents or a magnetic field the tendency is toward the static characteristic. An arc in oil also has a negative resistance characteristic, so the following discussion applies to oil-circuit-breaker, as well as air-break, switching.

Effect of the Arc in Switching. Where power currents are switched, the arc persists over any high-frequency oscillation and conditions are controlled by the 60-cycle wave. This is also true in the usual case of charging currents since appreciable currents usually are involved. In the case of closing either, the arc does not ordinarily extinguish after once striking. Where power current is interrupted the arc will extinguish at the zero

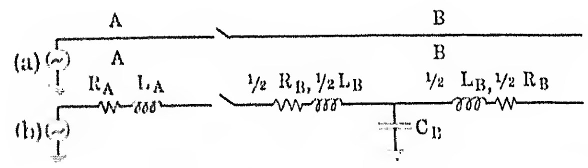

Fig. 6 — Transmission Line Supplied from Alternating Current Source

point of the current wave which is also at a low point of voltage. Also, when charging currents are interrupted, the arc will first extinguish at the zero point of the current wave, but this will be at the maximum of the voltage wave. In this case, surges three times normal are possible. For short lengths of line or station busses, where exceedingly small currents are involved, the arc maintains more of its static characteristic and higher potentials are possible.

Switching Charging Currents—Larger Values. The above considerations may be better explained in connection with the following diagrams; Fig. 6a represents one phase of an open end line. Fig. 6b represents the

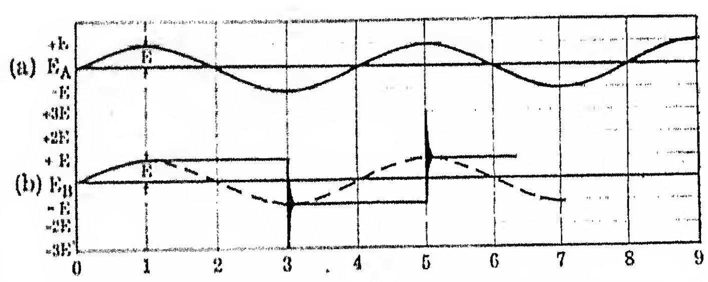

Fig. 7 Switching Controlled by 60 Cycle Conditions
(a) Voltage on supply side of switch
(b) Voltage on line side of switch

approximate equivalent circuit. Fig. 7a shows the wave of voltage at the supply side of the switch. Fig. 7b shows the voltage on the line, or condenser. The arc between the switch contacts will first extinguish at 1, the zero point of the current wave and the crest of the voltage wave. This will leave the line charged to a maximum of E_m in one direction. The switch contacts are assumed to be separating continuously. From 1 to 3 the voltage across the switch contacts varies with the impressed voltage to a maximum of 2 E_m at 3. There will be no restriking if at this time the contacts are too far apart to break down at 2 E_m. If not, reignition will occur, and there will be a resulting oscillation about the point of the applied

voltage E_A, or $-E_m$, and with an amplitude of $2E_m$, the amount of the transition to the new condition. It is obvious that the potential will thus reach a maximum of $-3E_m$ across the condenser. Since there is appreciable current the negative resistance of the arc is low and it will not extinguish during the high-frequency oscillation. This oscillation will then damp down to the applied voltage. Again, it will extinguish at that point, as shown between 3 and 5, leaving the condenser charged to a potential of $-E_m$. At 5 it may again re-ignite with a potential of $2E_m$ across the contacts. Here again the oscillation will have an amplitude of $2E_m$, giving a maximum of $3E_m$ across the condenser, and the oscillation will damp down to the applied voltage, where it will extinguish. It is evident that, no matter how often the arc reignites, the potential can never be higher than $3E_m$.

Switching Charging Currents—Small Values. When small currents are involved, it is possible under certain circumstances for the arc to extinguish at the zero point of the high-frequency current wave, and ignite at the

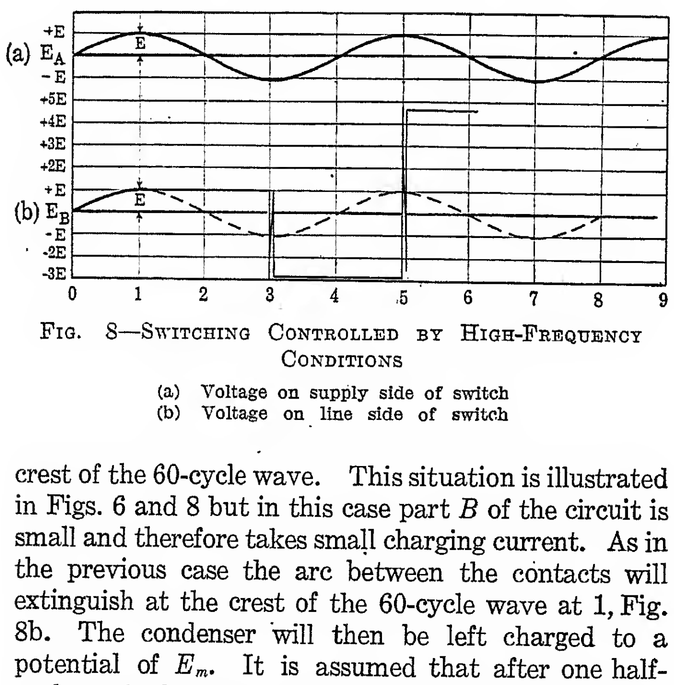

FIG. 8—SWITCHING CONTROLLED BY HIGH-FREQUENCY CONDITIONS

(a) Voltage on supply side of switch
(b) Voltage on line side of switch

crest of the 60-cycle wave. This situation is illustrated in Figs. 6 and 8 but in this case part B of the circuit is small and therefore takes small charging current. As in the previous case the arc between the contacts will extinguish at the crest of the 60-cycle wave at 1, Fig. 8b. The condenser will then be left charged to a potential of E_m. It is assumed that after one half-cycle, at 3, the switch separation is such that $2E_m$ will just reignite the arc. There will then be an oscillation with an amplitude of $2E_m$ about the applied voltage E_A, or $-E_m$. The potential across the condenser will thus reach a maximum of $-3E_m$. When this oscillation has damped to a value slightly less than $2E_m$ the arc may extinguish at the zero point of the high-frequency current wave and leave the condenser charged to slightly less than $-3E_m$. Again the voltage across the contacts will vary between points 3 and 5 to a maximum of $4E_m$ at 5 when it is assumed that the switch contacts have separated to a position where $4E_m$ will just reignite the arc. This time the oscillation will have a magnitude of something less than $4E_m$ about E_m which will bring the voltage across the condenser to a maximum of slightly less than $5E_m$. This process may be carried on with an increase of nearly $2E_m$ with each restriking of the arc.

While it is conceivable for the process discussed in the last paragraph to continue beyond two restrikings, it is extremely unlikely; and even two should be rare. There are many factors which tend to prevent the high frequency condition from controlling the situation. The theory assumes that the charging current to the section being disconnected is broken at the zero point of the high-frequency current wave after the first interruption. In the usual case of line switching the inductance and capacitance are both linear functions of the length of circuit. Thus, when the capacity is small, giving small currents, the inductance is also small and the frequencies are high. Usually these frequencies are high enough to maintain the arc over the high-frequency oscillation even though the currents are extremely small. The worst condition as discussed assumes that the rate of opening of the contacts is such that the breakdown is increased nearly $2E_m$ each half cycle of the applied voltage. Further, it is just as likely that in position 3 Fig. 8, the arc will extinguish leaving the bus charged $+E_m$ rather than $-3E_m$. In this case there would be no second restriking.

From the foregoing, it appears that high-speed switches would tend to prevent the higher voltage surges. If, after the first extinction, the separation of the contacts is so rapid that in one half-cycle its breakdown is more than $2E_m$, there can be no restriking. With the same speed of opening the breakdown between contacts in oil increases more rapidly than in air. Thus there should be greater freedom from surges from oil switch operations than air-break switch operations.

Closing operations should not cause potentials as high as opening operations. This is for the reason that the switch contacts are drawing continuously closer and therefore there should be at most only one restriking. This would limit the potentials obtainable to $2E_m$ on homogeneous lines. However, since switch contacts, especially disconnect switch contacts, are not perfect arcing contacts, it is possible for the second striking to be at a higher voltage than the first. This makes possible surges slightly higher than $2E_m$ from closing. It is fortunate that the higher surges come upon de-energizing since in this case the element of highest potential is being disconnected from the system and a flashover is not as serious. Further, there is usually the least apparatus connected to the part being disconnected.

In all the above it is assumed that the neutral of the system is held at ground potential. In the case of an isolated neutral system the potentials discussed above are aggravated by the amount of the shift of the neutral; that is by a maximum of 1.73.

Experimental Data. During the past three years, field tests using the klydonograph as a surge recorder

have been conducted on a large variety of open-wire and cable systems. These have given definite information as to the surges actually present on lines. The complete results of these tests are being given in a companion paper by Messrs. McAuley and Huggins and the writer. Certain of these data, however, will be discussed here in connection with the above theories.

Switching in general caused no serious surges. The majority of switch operations produced no overpotentials and the majority of the surges which were produced were less than two times normal. Occasionally higher voltage surges occurred, but these were rare. This would be expected due to the small chance of the simultaneous presence, during a switching operation, of all the conditions and events necessary for their production as discussed above. Surges due to switching load currents or energizing lines were of the lower values. The higher surges always resulted from low energy operations, such as switching short lengths of line or busses. Many of these higher ones were caused by de-energizing busses or open oil switches with disconnect switches. As examples: In a test on a 220-kv. grounded-neutral system, with instruments at four points, about 3600 high-tension, oil-switch operations were performed. Approximately one-fourth of these caused surges. The largest surge recorded was 3.2 times normal due to de-energizing a 40-mi. section of the line. The next highest were two 2.7 times normal due to opening a bus. On a 140-kv. isolated-neutral system in ten months tests at four points there were five surges between 3.0 and 4.6 times normal. On a 120-kv. grounded-neutral system during ten months normal operation with recorders at four points there was one surge six times normal, one 4.0, one 3.7, and five between 3.7 and 3.0 times normal. All of the above were caused by idle-line switching, and the higher ones by de-energizing operations.

On cable systems, due to the higher charging currents per unit length, the higher attenuation constant, the longer initial wave fronts, and the denser networks usually encountered, milder surge conditions would be expected. This is what was actually found: The maximum surges recorded due to cable switching were of the order of 2.5 times normal. In one test, after a year's operation, a surge 4.5 times normal was recorded. However, this was due to energizing a switch group and not strictly a cable operation. On another test, high surges resulting from opening a bus section prompted a series of tests. The highest values were as follows:

Opening bus with disconnect switches—4.5 times normal.

Closing bus with disconnect switches—2.9 times normal.

Opening bus and transformer with oil switches—4.3 times normal.

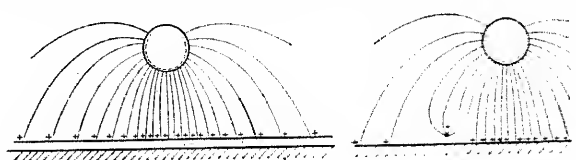
Closing bus and transformer with oil switches—2.9 times normal.

Both of these conditions are low-current operations. Although the current would be larger with the transformer connected, the natural period of the circuit would also be longer, thus permitting the action discussed under "Charging Currents—Small Values."

II. Lightning

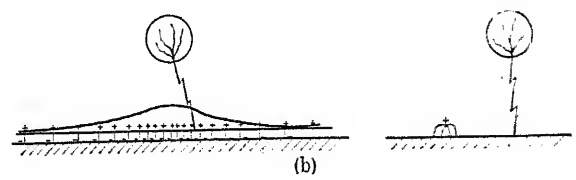
The principal characteristics of lightning of interest in connection with its effect on transmission lines are: the gradient of the field produced by the cloud charge; the nature of the discharge, that is, its rate, and whether it is unidirectional or oscillatory; and the polarity of the cloud. Ryan, De Blois, Norinder, Creighton, Peek, Simpson, and others have all contributed towards our present knowledge.

From any isolated charged body in the atmosphere there is an electrostatic field ending in an equal charge of opposite polarity gathered on the earth. As a



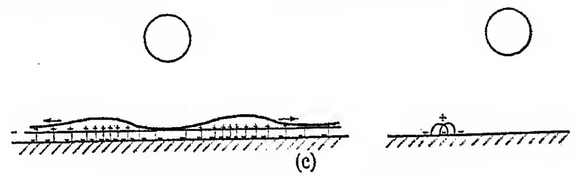
(a)

Cloud, and Bound Charge on a Line, Before a Stroke



(b)

Bound Charge and Voltage on a Line After a Stroke



(c)

Traveling Waves After a Stroke

Fig. 9

charged cloud approaches a transmission line, a charge, opposite in sign to that on the cloud, gathers on the line. Since the cloud approaches slowly, the charge passes up from the ground through the neutral or leaks over the insulators. This charge in the presence of the field keeps the line at zero potential with respect to the earth. Fig. 9a illustrates this condition. Upon the stroke of lightning the field disappears and, if the collapse be rapid, leaves the charge bound on the line. If the collapse is instantaneous this raises the line potential to a voltage corresponding to the field before the stroke, but opposite in sign. The magnitude of this voltage is the product of the change in field gradient and the height of the line. Upon the disappearance of the field, the charge divides in the center and propagates a traveling wave in each direction as shown in Fig. 9c. Each of these waves has a magnitude equal to one half of that of the initial voltage directly under the cloud. It is readily seen that the rate of rise of voltage, and the maximum magnitude, on that part of the line occupied by the charge before the stroke, is

determined by the rate of discharge of the cloud, as well as the value of the field destroyed. The reason for this is that while the cloud is discharging, part of the charge is traveling out and increases the length of the surge, but reduces its magnitude. On the remainder of the line to which the traveling wave goes, the rate of rise of voltage is determined by the wave front, that is, the space configuration of the charge liberated, as well as by the rate of discharge of the cloud. It is obvious that for this phenomenon to take place the cloud must discharge rapidly, that is, in a few microseconds. Otherwise the charge will have time to spread out over the line gradually, without causing an appreciable rise in voltage. The amount of this rise is determined by the ratio of the length of the line occupied by the bound charge to the total length of the line, and the change of field gradient caused by the stroke. Also, if the neutral of the transformers is grounded and the discharge is slow, the charge may pass to earth through the short-circuit impedance of the transformers.

Norinder. In 1924, Dr. H. Norinder published the results of his tests in Sweden.[11] These tests, which contributed a valuable addition to our knowledge of lightning, consisted of extensive measurements of the actual intensities, and variations of the cloud field. Most of the data were measurements with a static voltmeter of the potential induced on highly insulated wires by the cloud field. Other measurements were made with a cathode-ray oscillograph of the potential induced on an antenna, grounded through a high damping resistance, by the lightning discharge. Still others were made with the ordinary oscillograph of the discharge-induced potential.

Although the inherent variation of the physical conditions under which lightning occurs is reflected in the data, the salient points in Norinder's results were as follows: the gradient of the cloud field at the height of the average transmission line was often of the order of 30 to 45 kv. per ft. (100 to 150 kv. per m.) and occasionally 60 kv. per ft. (200 kv. per m.). Dr. Norinder estimated the gradient near the lightning path to have been 90 to 120 kv. per ft. (300 to 400 kv. per m.); the cloud was just as often positive as negative. One of his charts showed the potential reversing during the passage of the cloud. The range of influence of the usual stroke was over 1.3 mi. (2.3 km.) and under 6.2 mi. (10 km.); the discharge was non-oscillatory; and the discharge was relatively slow, the induced potential on the antenna rising to a maximum in the order of 0.01 to 0.02 sec. From the results Dr. Norinder drew various conclusions some of which pertained to the operation of transmission lines.

Since both the data and the conclusions were somewhat at variance with current opinion on the matter, both were criticized rather severely.[12] The most disturbing feature of these data was the long wave fronts indicated. If lightning strokes were as slow as 0.01 sec., it would be impossible for surges as actually experienced to be induced on transmission lines. In a time of this order the bound charge could travel the length of the line many times and distribute itself over the line or leak off through the terminal apparatus. It is evident that the strokes which produce the surges experienced must take only a few microseconds to discharge the cloud. While some of the conclusions seem rather loosely drawn, there does not seem to be anything wrong with the methods used in obtaining the data. The ordinary oscillograph is not fast enough to record wave fronts of only a few microseconds. However, the fact that some of the oscillograms showed a wave front considerably longer than the minimum which the ordinary oscillograph would have recorded satisfactorily, indicated that these long wave fronts actually occurred. While the above facts seem to be inconsistent, recent information shows that they are not. This will be discussed later.

Simpson. In March, 1926, Dr. G. C. Simpson presented to the Royal Society an excellent paper on lightning. It is not feasible to repeat the complete theory here and the reader is referred to the original paper.[13] Briefly, the author stated that when a point on a positive cloud reaches a state of electrical intensity at which ionization begins, the point proceeds towards earth, forming a conducting channel of ionized air. The point of this channel attracts negative electrons from the surrounding atmosphere. These electrons being very mobile pass up the channel and spread out into the cloud. This leaves the channel positive and it thus burrows its way to the earth. The channel may branch but each fork remains pointed and the stress high. The rate at which the channel can grow is determined by the rate at which the cloud can absorb the negative electrons. As the electrons pass into the cloud they soon become negative ions, after which their speed is reduced; thus they tend to block up the mouth of the channel and prevent further flow. This accumulation of ions disperses in the cloud, the field is again established, and the flow continues if the ions in the channel have not had time to recombine entirely. Thus the flow will be slow or even intermittent. The intermittent flow is most marked in a discharge from one cloud to another.

With a negative cloud the process is different. If the formation of a channel toward earth at the point of highest stress is assumed, the point of the channel attracts positive ions from the surrounding atmosphere. These ions, being relatively immobile, are unable to pass up the channel rapidly. They thus neutralize the point which reduces the stress and the point spreads out. In this way the charge in the cloud is held until the stress at the earth's surface is high enough to start a channel. This channel operates as discussed above, for the positive cloud, with the following exceptions: The negative electrons are able to spread out readily in the ground, and the channel instead of passing into a region of lower stress continues always into a region of greater stress. The average stress is much higher. There is not the tendency to branch, as the field concentrates towards a smaller area, until the cloud is

reached where it branches out and discharges a large volume of the cloud in a single flash. Thus the negative cloud discharges rapidly and violently.

Dr. Simpson substantiated the above theory with laboratory studies of discharges in conjunction with a large number of photographs of actual lightning strokes. Out of 418 photographs studied, 242 showed branches downward indicating positive cloud discharges, three were negative strokes with branches upward, and 173 were unbranched. Since the negative branches are within the cloud, in general they would be obscured. It was further pointed out that in all cases branches were less intense than trunks and that many of the 173 apparently unbranched strokes likely had branches downward which were obscured by the rain. Dr. Simpson divided the unbranched discharges into equal parts which made in all 328 positive strokes and 89 negative strokes, or nearly 4 to 1. He expressed the opinion that even this is too small a ratio.

Quoting Dr. Simpson, "If this reasoning is correct lightning flashes between earth and a negatively charged cloud will be much more intense than flashes to a positively charged cloud, although the two clouds may be charged to the same intensity. In fact one would expect on this reasoning that discharges from positively charged clouds would be frequent but weak, while discharges from negatively charged clouds would be infrequent but very strong."

Experimental Data. In transmission line surge investigations with the klydonograph it has been found that there are surprisingly few surges induced in a given locality during a thunder storm. Instead of surges of varying magnitude to correspond to the numerous lightning flashes usually observed during a storm, there result only from one to perhaps 10 surges; usually not more than two. Further, it has been found that practically all of these lightning surges are positive. The few negative surges recorded are always high and abrupt. Of these negative surges some are definitely known to have been caused by direct strokes. Bearing in mind that an induced surge is of opposite polarity to the cloud and that a direct stroke is of the same polarity, the above results indicate, at first sight, that all clouds are negative. The number of surges recorded, however, is not consistent with the numerous flashes visible during a storm.

These data, when analyzed in the light of Dr. Simpson's theories and Dr. Norinder's results, seem to substantiate both. Most of the lightning strokes are from a positive cloud. Perhaps as many clouds are negative, but the positive clouds discharge more frequently. These positive strokes are relatively slow, having a wave front of the order of 0.01 seconds, as shown by Norinder. They are slow enough to permit the bound charge to distribute itself over the line or to escape through the transformer neutral, as discussed above. Even on an isolated neutral line, where the charge does not escape, its distribution over the usual power line prevents a greater rise than a few thousand volts, which is negligible. It may be serious on communication lines, which are isolated from ground and insulated for low voltages. Tests on communication lines have shown more negative surges than tests on power lines. The effect of positive strokes may also be important on isolated neutral lines which are so short that the entire line is in the field destroyed by a single stroke. According to Norinder, this length would be of the order of two miles. Further, the effect of a positive stroke is less severe, due to the fact that less of the cloud is discharged and therefore less of the field is destroyed by a positive stroke. The negative clouds discharge violently but less frequently. They discharge a greater volume of cloud and hence destroy a larger field. The time of discharge is of the order of three microseconds, which is too brief to permit a bound charge on the line to dissipate, and hence high voltages are induced. Likely, Dr. Norinder's apparatus was not sufficiently rapid to detect these negative strokes in their true shape. Klydonograph records also indicate that direct strokes have abrupt wave fronts. These records show that induced strokes have wave fronts from a few microseconds to over 100 microseconds. As mentioned above, the measured rate of rise of voltage due to induced strokes depends upon whether the measurement is made at the position of the initial bound charge or at some other point of the line. The records agree with both Simpson and Norinder in that they indicate that the stroke is unidirectional. An oscillatory surge on the line may result, however, if the stroke causes a flashover.

It was found that the maximum surge potentials appearing on lines of various operating voltages are approximately a constant times the normal voltage. That is, the maximum surges are from 10 to 15 times the normal crest voltage above ground. This indicates that the lightning stroke is not faster than the insulator flashover at these high over-voltages. When the insulator flashes over the charge is released and the voltage can go no higher. It should be remembered that the higher the over-voltage, the less the time lag of breakdown of any dielectric.

III. Conclusions

The following conclusions may be stated:

Switching. 1. If there were no attenuation, a switch closure on a cable connected to an open-ended, open-wire line would reflect with nearly four times the applied voltage.

2. In practise, increase in the attenuation constant, due to steep wave fronts and to corona at high voltages, prevents high-potential steep-front waves from traveling long distances.

3. The limitations of the source from which a line is switched limit the steepness of wave front possible.

4. The characteristics of the arc at the switch contacts influence the surges caused by switch operations.

It has been shown that over-potentials caused by low-energy charging current operations are more severe than those caused by power or heavy charging current operations. Thus de-energizing short lines or busses causes the highest surges.

5. No switching operations cause surges high enough, or with a duration long enough, to affect the operation of properly insulated lines. Only rarely is a surge above 2.0 times normal produced.

Lightning. 1. Positive lightning strokes are frequent but weak. They are slow, of the order of 0.01 seconds, and hence do not induce surges on transmission lines.

2. Positive strokes, even though slow, may produce surges of importance on isolated low-voltage lines, such as communication lines.

3. Negative lightning strokes are less frequent but more violent. They discharge in about three micro-seconds and hence produce high voltage surges on transmission lines.

4. The field gradient is often as high as 60 kv. per ft. and may reach 100 kv. per ft. Thus a surge of over 2000 kv. might be induced upon a line of ordinary height with sufficiently high insulation. Eighteen hundred kv. has been recorded by the klydonograph.

5. The time lag of an insulator flashover is less than the time of discharge of a negative stroke and thus the impulse flashover voltage of the insulators limits the possible potential.

6. The stroke of lightning itself is unidirectional. If an oscillatory surge due to lightning is recorded, it is a line oscillation resulting from a flashover.

The Measurement of Surge Voltages on Transmission Lines Due to Lightning

BY EVERETT S. LEE* and C. M. FOUST*

Associate, A. I. E. E. Associate, A. I. E. E.

Synopsis.—This paper, after referring to the work of previous investigators in the application of the photographic Lichtenberg figures to the measurement of surge voltages, describes results of additional work in this field by the authors.

Laboratory calibrations of photographic Lichtenberg figures, using the cathode ray oscillograph and the lightning generator, are shown. Data are presented relative to the accuracy obtainable with these figures as a means of measuring surge voltages.

An extension of instrument design is described in which two recording elements are used to give greater certainty of result.

Means for connecting a surge voltage recorder instrument to a transmission line by an insulator-string potentiometer are described, and calibration of the instrument with potentiometer is given up to 1400 kv.

Specimen field records of surge voltages up to 2000 kv. are shown.

* * * * *

Introduction

THE results of continued recent study and use of the photographic Lichtenberg figures as a means of measuring voltages of short time duration in the order of microseconds, particularly surge voltages on transmission lines due to lightning, are creating a confidence in these figures which is gratifying both to the engineer who is called upon to make such measurements and to the engineer who uses the results in design and application. It was in 1777 that Dr. G. C. Lichtenberg[1]

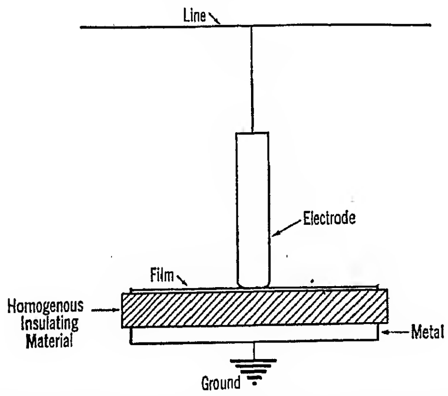

Fig. 1—Arrangement of Elements for Producing Photographic Lichtenberg Figures

Directly connected recorder

first described the figures in sulphur dust caused by the presence of a charged electrode. In 1888, Trouvelet[2] and Brown[3] showed that the same figures would be produced on a photographic plate. Several investigators[4, 5, 6] have since devoted much time to studying the nature of these figures, although at the present time their exact mechanism is still an uncertainty.

But it remained for Mr. J. F. Peters[7] in 1924 to suggest the application of these figures to the measurement of surge voltages and to develop a suitable instrument based on this application which he called the klydonograph. In June, 1925, Messrs. Cox and Legg[8] presented before the A. I. E. E. the results of field tests with this instrument and described extended developments in the instrument design. In September, 1926, Mr. K. B. McEachron[9] presented before the A. I. E. E.

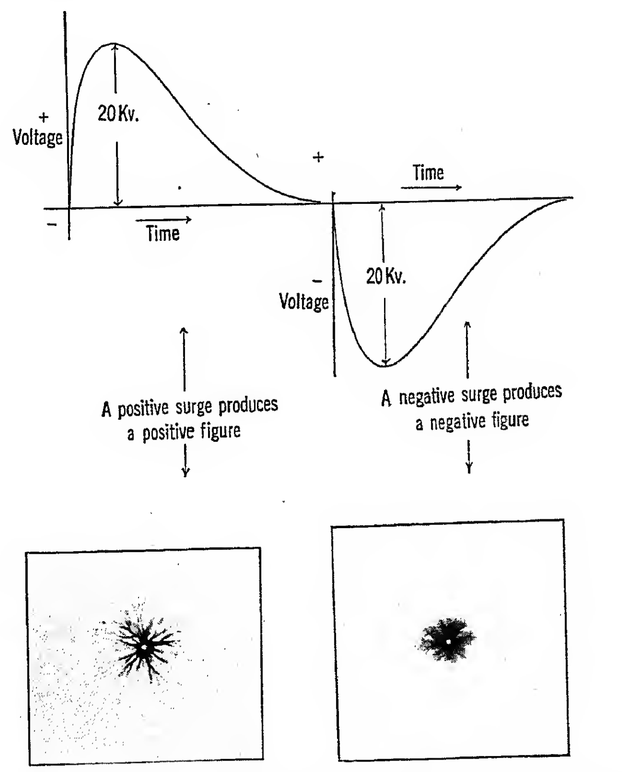

Fig. 2—Showing Appearance of Positive and Negative Photographic Lichtenberg Figures Produced by Positive and Negative Surge Voltages of Same Magnitude and Wave Shape

Directly connected recorder

the results of a most detailed study of the calibration of the photographic Lichtenberg figures using the Dufour cathode ray oscillograph as the means for determining with certainty the wave shape of the impressed voltage. Thus the discovery made 150 years ago has recently been applied to advantage.

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., Feb. 7-11, 1927.

To the work previously described, this paper contributes additional correlative data, describes an extension of instrument design, and shows that the art has advanced to a stage where surge voltages on transmission lines in the order of 2,000,000 volts may be recorded with a reasonable degree of accuracy.

GENERAL

As now used, the klydonograph or surge voltage recorder consists of an electrode bearing upon the emulsion side of a photographic film or plate which rests on the smooth surface of a piece of homogeneous insulating material, as shown in Fig. 1. If the electrode is connected to the line side of a circuit, and the insulation connected to the ground side through a metal plate, and a positive surge voltage of, say, 20 kv. maximum is impressed from line to ground, a positive figure as shown in Fig. 2 will be found on the photographic film after development. If, with the same connections, a negative surge voltage of, say, 20 kv. maximum is impressed from line to ground, a negative figure, as shown in Fig. 2, will be found on the photographic film after development

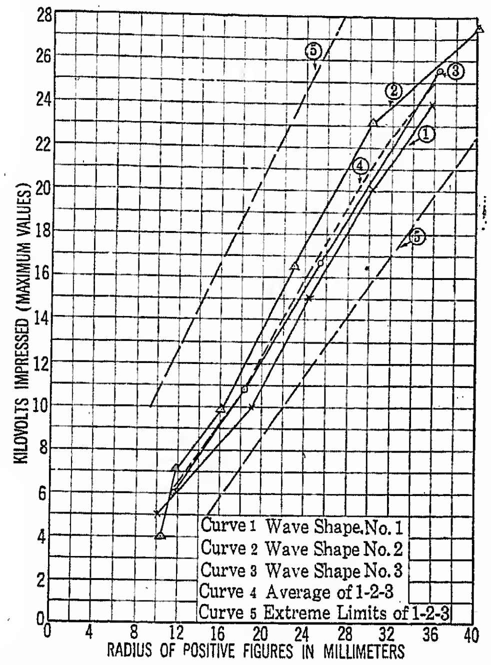

FIG. 3—CALIBRATION CURVES FOR SURGE VOLTAGE RECORDER
Insulation, varnished paper 1/8 in. thick
Electrode, brass, 1/8 in. diameter, rounded spherically
Film, Eastman No. 152

It has been found that figures will be produced even though the time duration of the impressed voltage is only a fraction of a microsecond, also that the size (radius) of the figure is a function of the magnitude of the maximum value of the impressed voltage, while the shape and configuration of the figure is a function of the wave shape of the impressed voltage. The problem of the instrument engineer therefore becomes one of deciphering the figures into terms of voltage and wave shape.

MAGNITUDE OF VOLTAGE

The calibration of Lichtenberg figures for a given instrument to determine magnitude of voltage is obtained by impressing voltages of different values and observing the size of the resulting figure. This can be done for as wide a range of wave shapes as are available.

Table I and Fig. 3 of this paper give results of the authors' calibrations obtained on a film-type instrument with varnished paper insulation and a brass electrode ⅛ in. in diameter rounded spherically. The wave shapes varied from one-half cycle of a sine wave at 60 cycles (wave shape No. 1) to surge voltages rising to their maximum value in two microseconds (wave shape No. 2) and in four microseconds (wave shape No. 3). The surge voltages were impressed from sections of a 500-kv. rectifying type lightning generator (Fig. 4), the circuit for wave shape No. 2 being as shown in Fig. 5 and for wave shape No. 3, as shown in Fig. 6. The wave shapes were determined by Dufour cathode ray oscillograph Figs. 7 and 8. Wave shape No. 2 is shown in Fig. 9. Wave shape No. 3 is shown in Fig. 10.

When calibrating the surge voltage recorder or when photographing the wave shapes with the cathode ray oscillograph, these instruments were connected between ground and the various voltage taps as shown in Figs. 5 and 6. The magnitude of the voltage was measured by sphere spark gap similarly connected.

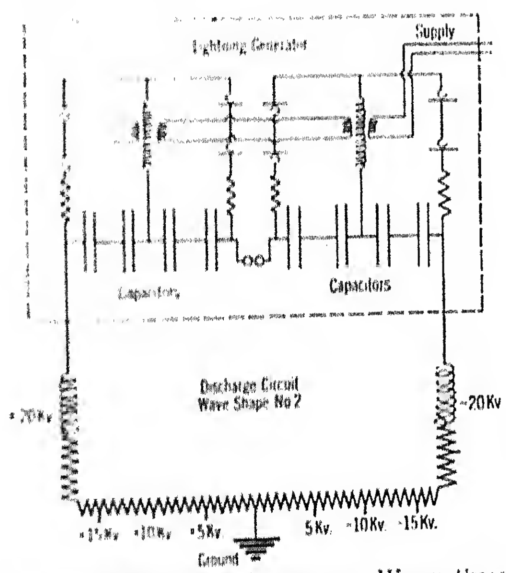

FIG. 5—ARRANGEMENT FOR PRODUCING WAVE SHAPE NO. 2

The capacitors of the lightning generator discharge through the inductance and resistance shown in the external discharge circuit, in which the balanced arrangement of circuit constants with respect to the grounded point eliminates local oscillations

Referring to Table I, it is seen that the average deviation from the mean for 100 figures on the three wave shapes investigated at the different voltages is within $\pm$ 15 per cent, while the maximum deviation from the mean is in the order of $\pm$ 30 per cent.

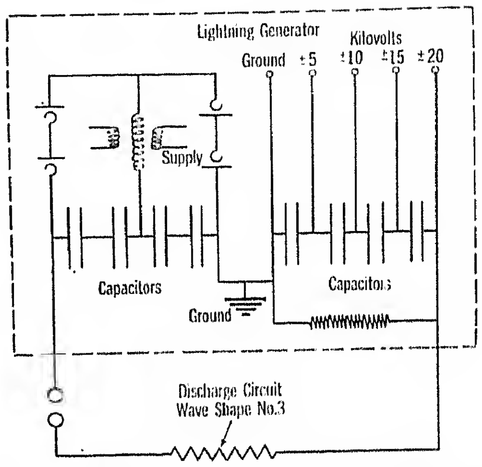

FIG. 6—ARRANGEMENT FOR PRODUCING WAVE SHAPE NO. 3

The capacitors of the lightning generator on the left, discharge into the capacitors on the right through the resistor shown in the external discharge circuit

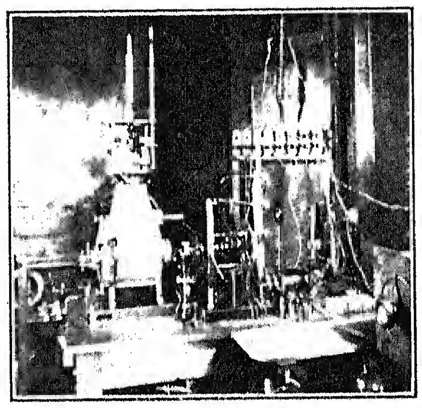

FIG. 7—THE DUFOUR CATHODE RAY OSCILLOGRAPH, SIDE VIEW

The timing switch shown at the right of the oscillograph is for low-speed work. The timing switch used to discharge the lightning generator when calibrating the surge voltage recorder is of high-speed type of special design, not shown

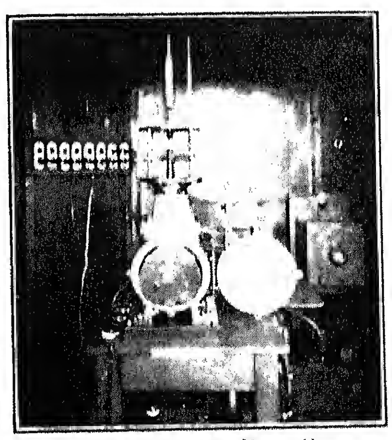

FIG. 8—THE DUFOUR CATHODE RAY OSCILLOGRAPH, FRONT VIEW

These results are shown graphically in Fig. 3. For any voltage all figures obtained on 100 measurements were within the extreme limits as shown. These limits are determined by one figure out of one hundred, and are quite outside of the values which may be

reasonably expected from the average values shown. It appears that an accuracy of 25 per cent can be reasonably expected from any single measurement made with these figures. Where several figures of somewhat the same size are obtained under similar conditions, the agreement of these among themselves permits a more exact interpretation.

Messrs. Cox and Legg, in Fig. 39 of their paper[8], show a calibration curve for an experimental model of a film-type klydonograph. The wave shapes impressed varied from 25- and 60-cycle a-c. sine wave, to a surge voltage which attained its maximum value in five microseconds, the latter surges being obtained from a given network and their shape determined by calculation. The magnitude of the voltage was determined by sphere spark gap.

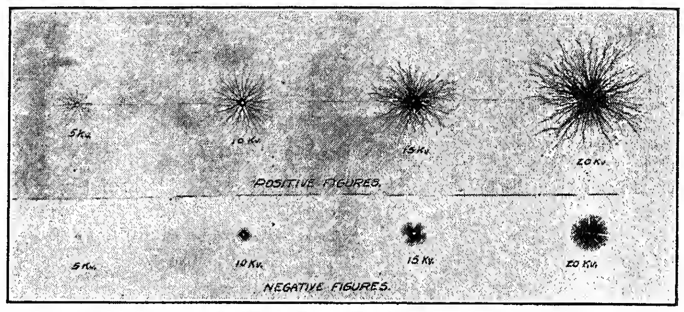

Fig. 11—Positive and Negative Lichtenberg Figures for Different Voltages. (Wave Shape No. 2)

McEachron, in Fig. 7 of this paper[9], shows calibration curves for Lichtenberg figures obtained with Eastman's super-speed portrait films, placed on a glass plate, and using a cylindrical brass electrode one cm. in diameter with square edges. The shape of the impressed voltage was determined by Dufour cathode ray oscillograph and the magnitude by sphere spark-gap. The range of wave shape was from a long wave wherein 22 min. were required to reach a maximum value of 25 kv., to a short wave where the time to reach maximum value was 0.1 microsecond.

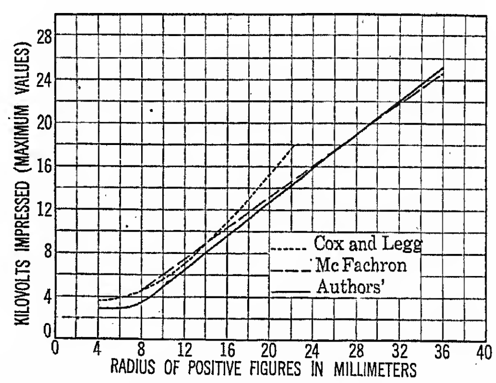

Fig. 12—Calibration Curves of Surge Voltage Recorders for Positive Lichtenberg Figures

Cox and Legg, Bibliography Item 8, Fig. 39
McEachron, Bibliography Item 9, Fig. 7
Authors' Fig. 3 (average curve)

The results of the calibrations reported by Messrs. Cox and Legg, and McEachron, are shown combined with the authors' in Fig. 12. These results show remarkable agreement for the work of different observ-

ers in different laboratories with different instruments and circuits, and give added weight and certainty to the calibration of the Lichtenberg figures as regards magnitude of voltage.

Wave Shape of Impressed Voltage

In studying surge voltages, the wave shape as well as the magnitude is of importance, for on this depends the

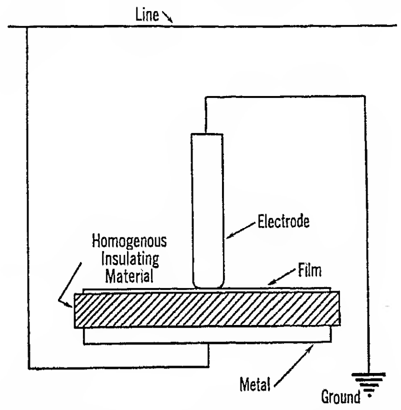

Fig. 13—Arrangement of Elements for Producing Photographic Lichtenberg Figures
(Oppositely connected recorder)

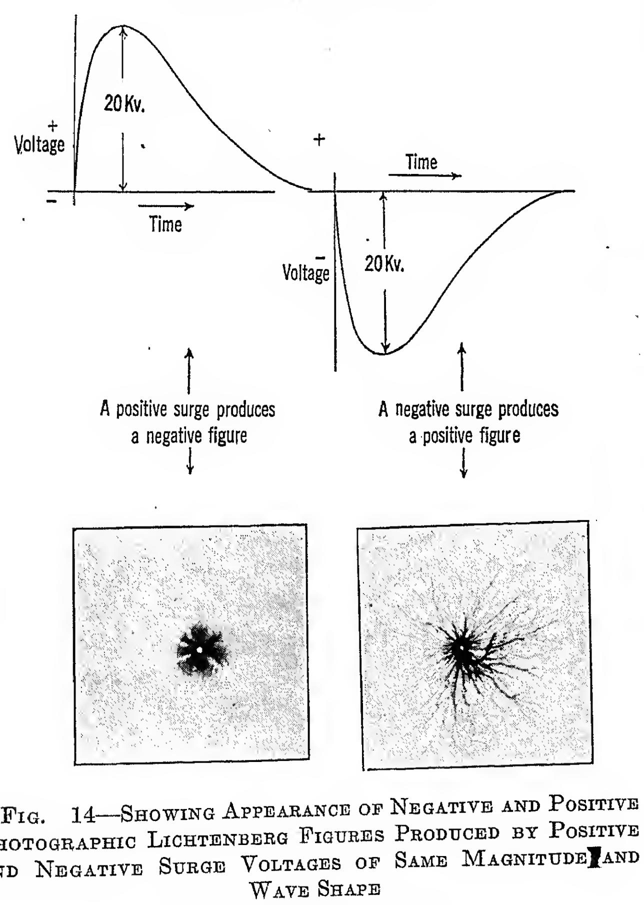

Fig. 14—Showing Appearance of Negative and Positive Photographic Lichtenberg Figures Produced by Positive and Negative Surge Voltages of Same Magnitude and Wave Shape
(Oppositely connected recorder)

duration of the voltage. At the present time, the determination of the wave shape from the Lichtenberg figure characteristics is not as definite or as certain as the determination of the magnitude from the figure size and herein there is room for added study. At the present time the figures recorded with unknown wave shapes can be compared with figures recorded with known wave shapes as determined by cathode

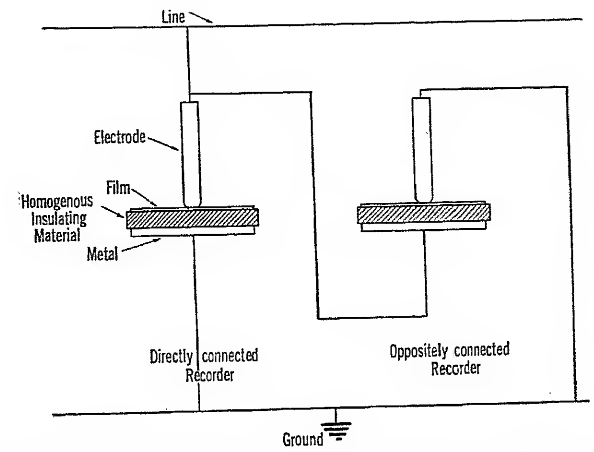

Fig. 15—Arrangement of Elements for Producing Both Positive and Negative Figures for any Surge Voltage

ray oscillograph. This allows prediction of the time duration to within a general order, but not with the exactness required. The work by McEachron in this regard, as shown in Fig. 5 of his paper[9], wherein he

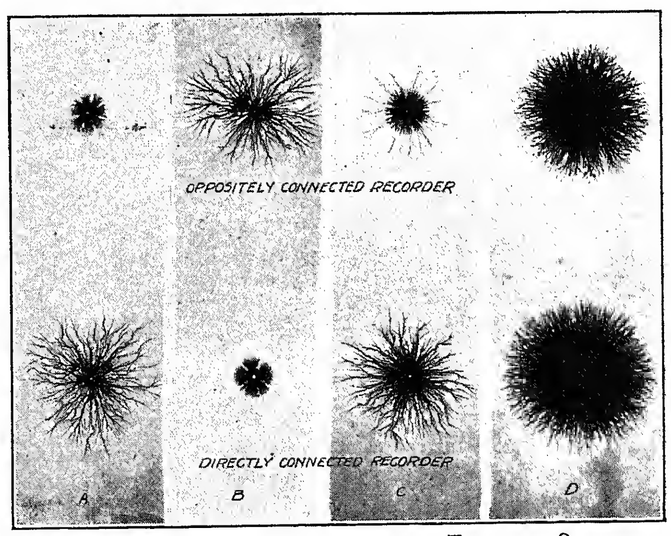

Fig. 16—Photographic Lichtenberg Figures Obtained with Two-Recorder Type Instrument

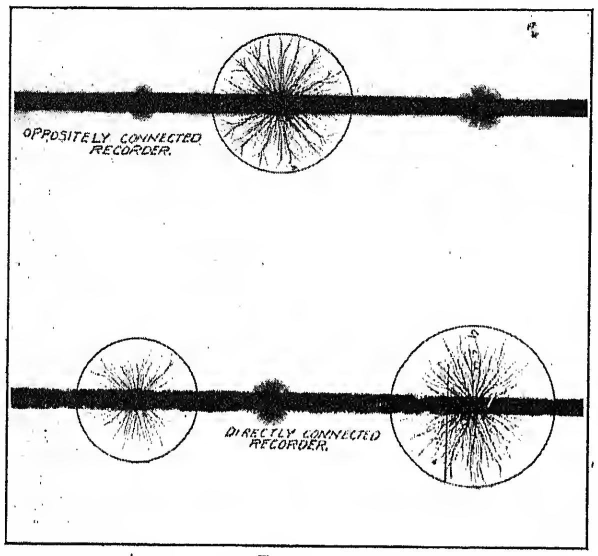
B—Negative surge voltage 20 kv. maximum
C—Oscillatory surge voltage 20 kv. highly damped
D—Oscillatory surge voltage 20 kv. slightly damped

designates the figures as Type I, Type II, and Type III, is to be commended. Further study along these lines tending towards greater exactness in the interpretation of figure characteristics is desirable.

Directly and Oppositely Connected Recorders

From Fig. 11 it is clearly evident that the negative figures are quite inferior to the positive figures for purposes of voltage measurement since for a given voltage

they are less than half the size of the positive figure; also McEachron has shown[9] that the negative figures present a greater deviation for differing wave shapes. There is also another serious objection which is that when the instrument with a moving film is connected to a transmission line with normal voltage continuously impressed, the width of the band produced by the line voltage (see Figs. 17 and 18) is enough to hide negative surges up to values as high as 2.3 times normal line voltage and to give uncertainty to values somewhat above this. This would result in erroneous conclusions as regards the number of negative surges recorded.



A B C

Fig. 17—Figures Obtained with Two-Recorder Type Instrument Showing Line Voltage Band

A—Positive surge voltage 13 kv. maximum (20 mm.)
B—Negative surge voltage 14 kv. maximum (22 mm.)
C—Positive surge voltage 17 kv. maximum (25 mm.)
The circles shown are drawn with the figure center as a center, and with the circumference touching the most distant streamer tip. The radius of this circle is the measure of the magnitude of the voltage
The line voltage band is from 60-cycle source of 2.84-kv. maximum value

A B

Fig. 18—Photographic Lichtenberg Figures Obtained with Two-Recorder Type Instrument Showing Hidden Negative Figure

A—Directly connected recorder B—Oppositely connected recorder
Negative surge voltage 9.0 kv. maximum. The negative figure is hidden under the line voltage band. Its presence is indicated by the full-size positive figure on the oppositely connected recorder
The line voltage band is from 60-cycle source of 3.0-kv. maximum value

To overcome these objections, Mr. Foust conceived the idea of connecting two recorders in parallel with the connections of one opposite from that of the other, thus insuring a large positive figure for every surge. Referring again to Figs. 1 and 2, the results of directly connecting the recorder to the line are shown. If, however, the recorder is connected oppositely, that is, the electrode to ground and the metal plate to the line, as in Fig. 13, the positive surge will record a negative figure and the negative surge will record a positive figure as in Fig. 14.

If an instrument is made up with two recorders, one connected directly and one connected oppositely, as shown in Fig. 15, then all surges, positive or negative, can be measured from the positive figure. In addition, oscillatory surges will be more clearly recorded, and negative surges completely hidden by the line-voltage band will be shown distinctly as positive figures. These features are shown in Figs. 16, 17, and 18.

Fig. 19 shows an instrument of the two-recorder type. It uses an Eastman film eight feet long and eight inches wide as standard with "Cirkut Outfits." It is driven by a clock at a rate of ½ in. per hour, so as to give a continuous record for eight days. Timing is obtained by photographing the hour numbers on the film.

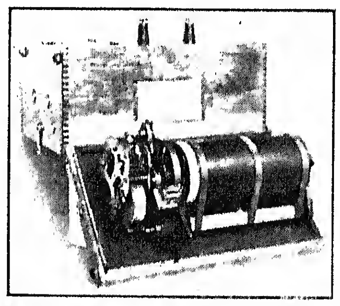


Fig. 19—Surge Voltage Recorder. Two-Recorder Type Instrument

This construction largely excludes polyphase instruments, because of constructional difficulties, but the obvious advantages of having all figures available as positive figures is so great as to accept this condition. It is felt that the application of this idea represents a real extension of the use of the Lichtenberg figures and results already obtained in the field show its merits. For example, out of 103 surges measured on three different transmission systems, 31 were of positive polarity, 26 were of negative polarity, and 46 were oscillatory.

Connection to Transmission Line

The voltage range of the instrument shown in Fig. 19 is from 2.8 to 25 kv. maximum. Above 25 kv. maximum, so-called "slips" occur in the figures as shown in Fig. 20, for which condition calibration curves do not apply. The arcover of this instrument on a two-microsecond wave, wave shape No. 2, Fig. 9, is 35 kv. maximum. Thus, some provision must be made for connecting the instrument to transmission lines up to values where the normal maximum voltage to ground is 180 kv. maximum for a 220-kv., 3-phase line, and where

the maximum values of surges may be ten times this value.

Messrs. Cox and Legg[9] describe an electrostatic potentiometer and antenna coupling. The authors

FIG. 20—PHOTOGRAPHIC LICHTENBERG FIGURES ABOVE THE INSTRUMENT RANGE

*Positive surge voltage 31 kv. maximum wave shape No. 2

(The black lines clearly evident in the positive figure (below) are commonly called "slips" and their presence indicates the figure to be of uncertain calibration. However, such figures can be stated with certainty to be above a given voltage value depending upon the instrument design.

The negative figure (above), though symmetrical and appearing to be suitable for voltage measurement, nevertheless is not so in this range because of the great variation in figure size with wave shape. (See bibliography item 9. Figs. 6 and 7.)

have investigated and used insulator coupling. Of the various schemes proposed for such connection, that shown in Fig. 21 has been recently used in 27 installations and has been found to be simple, reliable, and easy

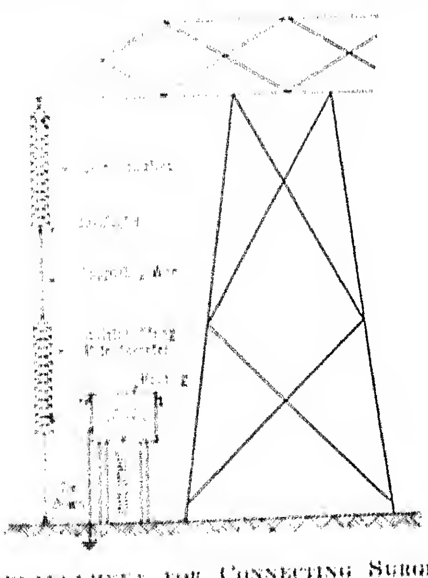

FIG. 21—ARRANGEMENT FOR CONNECTING SURGE VOLTAGE RECORDER INSTRUMENT TO TRANSMISSION LINE

to calibrate. The instrument is connected in parallel across several insulators of an insulator string with added protection over the line insulation as desired. The instrument is placed in a sheet metal housing, Fig. 22, equipped with suitable entrance bushing and automatic grounding device when the door is opened. The door is equipped with a padlock. This housing protects the instrument from the weather and insures safety against tampering. The metal housing also acts as an electrostatic shield to eliminate stray field effects.

Fig. 23 shows the arrangement of housing, insulator string, and connecting leads for a field installation.

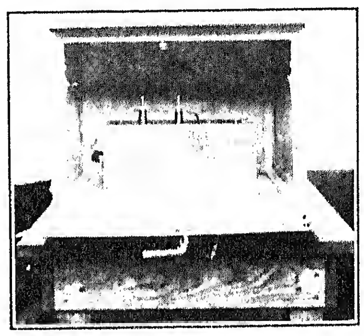

FIG. 22—SHEET METAL HOUSING FOR SURGE VOLTAGE RECORDER

It is important to have the instrument connecting leads short, preferably not longer than five feet. From Fig. 24 it is seen that the figure size decreases considerably with a longer lead, and if the instrument is used with leads of different length than that with which it is calibrated, the resulting error is large.

ADJUSTMENT OF INSULATOR STRING POTENTIOMETER

The adjustment of the insulator string potentiometer is made by adding a sufficient number of insulator units in series with the normal line insulators to give adequate

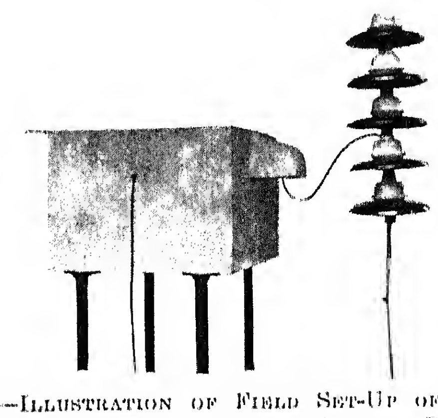

FIG. 23—ILLUSTRATION OF FIELD SET-UP OF INSULATOR STRING POTENTIOMETER AND SURGE VOLTAGE RECORDER IN SHEET METAL HOUSING

protection, and to provide enough insulator units across which the surge voltage recorder instrument may be paralleled to obtain a satisfactory line voltage band. This procedure may be carried on in the laboratory by impressing normal voltage at normal frequency across the entire insulator string with the surge voltage recorder in position.

Table II gives the number of insulators which have

been used successfully in the insulator string for different line voltages.

TABLE II

Line voltage between conductors three-phase kv.	No. of insulators line insulation	No. of insulators instrument string potentiometer	No. of insulators in parallel with instrument (included in col. 3)

220	14	20	4

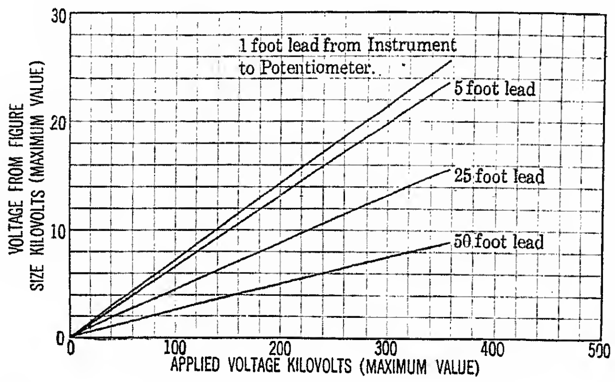

FIG. 24—CALIBRATION OF SURGE VOLTAGE RECORDER AND POTENTIOMETER TO SHOW EFFECT OF LENGTH OF INSTRUMENT LEAD

CALIBRATION OF INSULATOR STRING POTENTIOMETER

The multiplying factor of the potentiometer can be calculated for normal voltage and frequency from the data obtained in adjusting the potentiometer string.

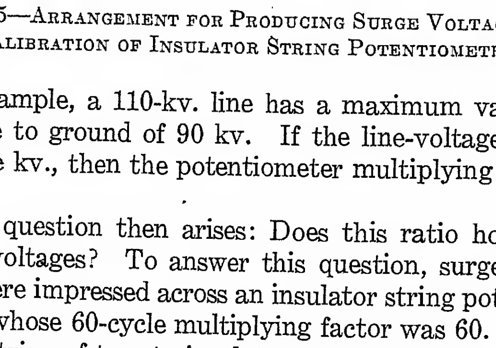

FIG. 25—ARRANGEMENT FOR PRODUCING SURGE VOLTAGES FOR CALIBRATION OF INSULATOR STRING POTENTIOMETER

For example, a 110-kv. line has a maximum value of voltage to ground of 90 kv. If the line-voltage band is three kv., then the potentiometer multiplying factor is 30.

The question then arises: Does this ratio hold for surge voltages? To answer this question, surge voltages were impressed across an insulator string potentiometer whose 60-cycle multiplying factor was 60. This was a string of twenty insulators, four of which were in parallel with the surge voltage recorder. The source of the surge voltages was a lightning generator of the non-rectifying type discharging into an external circuit as shown in Fig. 25. This circuit had to be used rather than the circuits as shown in Figs 5 and 6 in order to attain the requisite voltage. The magnitude of the voltage was determined by sphere spark gap. The time of rise of the surge voltage to its maximum value calculates to be in the order of a fraction of a microsecond.

The results of the calibration of the potentiometer up to 1,400,000 volts are shown in Fig. 26. These results show a generally decreasing multiplying factor from the higher to the lower voltages. At the higher voltages the multiplying factor is practically the same as that obtained with 60-cycle voltage.

Results of tests with circuit arrangement with the rectifying type of lightning generator (Fig. 5) to give a wave similar to that shown in Fig. 9 are also shown in Fig. 26. Tests were made with the insulator string potentiometer both dry and wet with spray. These were at the highest voltage which could be obtained

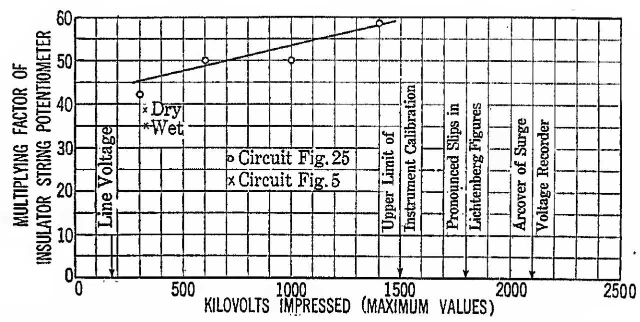

FIG. 26—SURGE VOLTAGE CALIBRATION OF INSULATOR STRING POTENTIOMETER

Potentiometer for 220-kv., three-phase line

Set-up as shown in Fig. 23

with this generator for this type of work. The results seem to agree quite well with the non-rectifying type of lightning generator at the same voltage. The results of tests made with the insulator string when dry and also when wet show that for surge voltages the voltage distribution is practically unchanged under these two conditions. This is different from the condition at 60 cycles where at least at lower voltages the differences between the distributions wet and dry are greater.

From the calibration of Fig. 26, for figures showing an instrument voltage of 25 kv., the surge voltage on the line is 1500 kv. Figures with slips would indicate surge voltages from 1500 kv. to 2100 kv. Film arcover at 35 kv. on the instrument would indicate surge voltages on the line of 2100 kv. or over.

The results of these calibrations indicate that surge voltages up to ten times normal maximum value, line to ground, on a 220-kv. line can be measured with considerable certainty as regards magnitude.

Specimen Field Records

On Fig. 27 are shown some Lichtenberg figures obtained on a transmission line installation. The surge record is from 3 p. m. until 10 a. m. of the next day. During this time there were lightning storms in the vicinity of the line. It is clearly seen that these figures have the same characteristics as those produced with laboratory equipment. (The circles are drawn for voltage measurement, see Fig. 17.) The figures on the left and right are interpreted to be from oscillatory surges of highly damped nature, such as shown in Fig 16c which is known to be from an oscillatory surge voltage. The oscillatory nature of these surges is derived from the presence of both positive and negative Lichtenberg figures on both recorders. The middle figure indicates a unidirectional surge voltage of negative polarity such as shown in Fig. 16b.

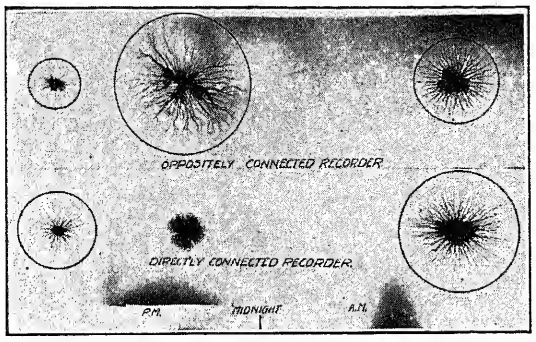

Fig. 27—Lichtenberg Figures Obtained on a Transmission Line Installation during a Lightning Storm

It is noted that there is no line-voltage band upon the film. This sometimes occurs and it is thought that this is due to the variation in voltage distribution across the insulator string potentiometer at normal line voltage and frequency.

Fig. 28 shows a photographic record of surge voltages obtained on a 220-kv., three-phase power transmission line, using a surge voltage recorder of the two-recorder type (Fig. 19) with an insulator string potentiometer as described above. The normal maximum value of the voltage to ground is 180 kv. and the multiplying factor of the potentiometer was 60. The record shown is from 11 a. m. on one day to 2 p. m. the day following. The line-voltage bands show when the line voltage was on and off during this period.

The record shows distinctly a high surge voltage at 4:20 p. m. on Friday and the weather reports indicate severe lightning in the vicinity of the installation at this time. The loss of the line-voltage band some thirty minutes before this surge shows that the line was de-energized at 3:50 p. m. A close examination of the original film reveals a surge at 4:03 p. m. but this is not distinguishable from the print. The figure obtained at 4:20 p. m. on the oppositely connected recorder is a positive "slip" (see Fig. 20) and therefore represents a voltage of negative polarity on the instrument of between 25 kv. and 35 kv. Using a potentiometer multiplying factor of 60, this figure represents a surge voltage on the line of from 1500 to 2100 kv. The corresponding figure on the directly connected recorder is predominently negative. Since some positive figure characteristics are discernible on the directly connected recorder, however, the surge must have been oscillatory and of a highly damped nature (see Fig. 16) with a first half-cycle of negative polarity and the second of positive polarity and very much lower voltage.

At 10:30 p. m. on the same day another surge was recorded. A lightning storm was in progress at this time and the line excitation had been removed about fifteen minutes before this surge. Positive figures were obtained on both recorders. The figure on the oppositely connected recorder indicates an initial half-cycle of negative polarity of 780 kv. The figure on the directly connected recorder indicates the second half-cycle to be of positive polarity of 270 kv.

The weather records for Saturday morning show another lightning storm in progress. The surge record reveals two surges, one at 8:11 a. m. and one at 8:18 a. m., the line having been de-energized at 8:11 a. m. From the print, these two surges are not so clearly distinguished, though from the original film the record is clear. The figure obtained at 8:11 a. m. on the directly connected recorder is of positive characteristics and on the oppositely connected recorder of negative characteristics. The line surge was therefore unidirectional and positive in polarity. The figure on the directly connected recorder is a positive "slip" and therefore indicates a line voltage of between 1500 and 2100 kv.

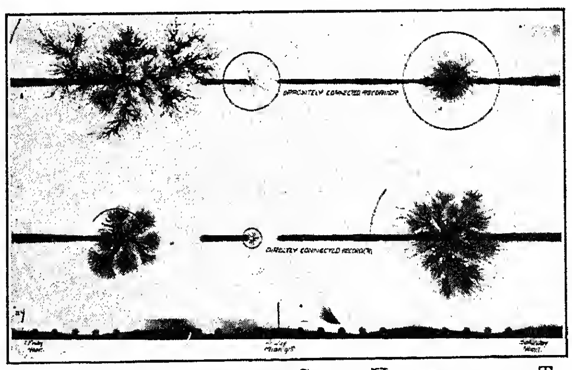

Fig. 28—Specimen Record of Surge Voltages on a Transmission Line during Lightning Storms

The figure obtained at 8:18 a. m. is positive on the oppositely connected recorder. The instrument voltage corresponding to this figure is 21.5 kv. and this gives a line voltage of 1290 kv. of negative polarity.

This specimen record shows how the figures may overlap on the slowly moving film when the surges occur in quick succession. Even under these conditions, however, it is generally possible to analyze the figures with considerable accuracy when the original film is

used and when the figures from the two recorders are available.

Practically all figures obtained on transmission lines have been of the type II class[9], and may be placed, therefore, within the wide range of wave fronts which vary roughly from that of a slow 60-cycle wave to a surge which comes to its maximum value in a fraction of a microsecond's time.

In connection with the surge voltage values obtained from the figures shown on the specimen record (Fig. 28), it is interesting to note that they compare favorably with the laboratory results of insulator flashover tests. The value 1800 kv. for the lightning sparkover of a 14-unit insulator string given by Mr. Peek[10] seems to be close to the upper limit of voltages actually measured on the line by means of the recorders.

Summary

It has been shown that surge voltage recorders using the positive photographic Lichtenberg figures have given essentially the same calibration data under a variety of conditions; also that the accuracy of such an instrument is in the order of 25 per cent, with a somewhat better value possible for those measurements wherein several similar observations may be obtained.

An extension of instrument design has been described wherein two recorders are used together, which allows the use of the positive figure as a voltage measure of all surge voltages, thus insuring greater certainty of result. A more comprehensive analysis of the figure characteristics is also possible, since both positive and negative figures are available.

A means of connecting the surge voltage recorder to a transmission line of higher than instrument voltage has been described which has been proved in service to be simple, reliable, and easy to calibrate. Calibration data are presented to show that with such connection, reasonable accuracy may be obtained in recording voltages up to values in the order of 2000 kv. A specimen record of such voltages obtained in the field is shown.

The records which can be obtained from surge voltage recorder instruments connected as desired along a transmission line will allow the facts regarding surge voltages on transmission lines to be determined with reasonable exactness.

Discussion

KLYDONOGRAPH SURGE INVESTIGATIONS

(Cox, McAuley, and Huggins)

TRANSMISSION-LINE VOLTAGE SURGES

(Cox)

THE MEASUREMENT OF SURGE VOLTAGES ON TRANSMISSION LINES DUE TO LIGHTNING

(Lee and Foust)

New York, N. Y., February 10, 1927

K. B. McEachron: In discussing the paper by Messrs. Cox, McAuley, and Huggins, and also the paper by Mr. Cox, I wish to raise a question concerning the conclusions. It does not seem to me that the data given support the definite conclusions drawn. For instance, the first conclusion in the Cox, McAuley, and Huggins paper states that the voltages due to lightning are unidirectional, and that the cloud which produces surges is of negative polarity resulting in positive induced voltages and negative direct-stroke voltages. The evidence which we have at the present time supports this conclusion but sufficient evidence to make such a positive statement appears to be lacking.

For instance, consider the direct stroke on a transmission line. Negative records have been obtained due to direct strokes but it does not necessarily follow that whenever a steep-wave negative surge appears on a transmission circuit, it was the result of a direct stroke, nor does it necessarily mean that all direct strokes must be negative. Simpson's theory, which has been mentioned in the paper by Mr. Cox, appears to bear out the conclusions given by the author, but it is necessary to remember that it is a theory, and in the case of lightning phenomena a very large amount of experimental data is necessary to prove that such a theory is correct.

I would like to draw attention particularly to a statement made on the second page of the paper by Messrs. Cox, McAuley, and Huggins. "It has been estimated that gradients as high as 100 kv. per ft. (330 kv. per meter) are reached near the earth's surface." On the same page the statement is made "It is believed that the flashover voltage of 220-kv. transmission-line insulation at the steepness of wave front of lightning surges is comparable to the maximum potential ordinarily induced by lightning." This same statement is also made in the conclusions.

Such a statement seems rather premature. Conditions have been experienced during the summer of 1926 on a 220,000-volt transmission circuit with fourteen disks of line insulation which were sufficient to flash over the line insulation several times. This indicates that 220,000-volt systems are not immune from lightning troubles provided those systems are where the lightning occurs.

Although the line flashovers may have been due to direct strokes yet the evidence is not clear and both positive and negative surges have been found whose potentials were between 1500 and 2100 kv.

Concerning the matter of attenuation which is given in the paper by Mr. Cox there is a factor in connection with the theory of bound charges which I believe has not been fully recognized.

Assume for instance a long transmission line with a charged cloud one mile in extent over the middle of the transmission line. When this cloud discharges, a voltage appears on the trans-

mission circuit which is equal to the potential gradient multiplied by the height of the line assuming, of course, that the entire cloud discharges in zero time. Underneath the edge of the cloud, the voltage distribution along the conductor will conform to the distribution of potential gradient before the cloud discharges. As a matter of fact, however, the cloud requires time to discharge and therefore the charge will begin to move out along the line having moved a distance equal to the time required for the cloud to discharge. If this time is less than 2½ microsec. the voltage on the transmission line underneath the middle of the cloud will reach an actual potential equal to the potential gradient, times the height of the conductor. A klydonograph located at this point would indicate a voltage of E volts, while another klydonograph located on the transmission line a few miles away would not indicate a maximum voltage of more than $\frac{E}{2}$ volts. This reduction in voltage[1] is due to the fact that all of the energy in the bound charge is electrostatic, while the energy of the traveling wave is half electrostatic and half electromagnetic.

The attenuation to be considered is that which takes place with reference to the traveling wave, rather than between the initial wave and the traveling wave. Measurements which have been made indicating that the voltage drops to a fractional part of its original value when passing over a distance of 15 or 20 mi., are probably due largely to this reduction in voltage which occurs when the bound charge becomes a traveling wave.

In connection with the paper by Messrs. Lee and Foust, considerable work has been done with the calibration of these figures

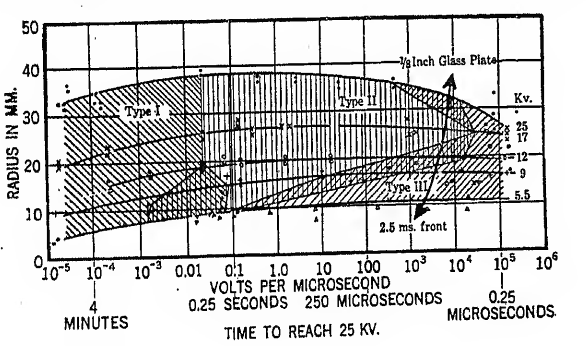

FIG. 1

with respect to their appearance, which the authors referred to in their paper. In Fig. 11, the first two positive figures are of the appearance which we have called type 3 figures, and the last two positive figures are of the type 2 class. From the information available it would be possible to predict roughly that these figures were made with a wave of the order of 2 or 4 microsec. Fig. 1 herewith gives the calibration curve[2] which shows roughly how such an estimation of the wave front can be obtained. Locating on this curve a line representing type 2 figures for 15 or 20 kv., and type 3 figures for 5 and 10 kv., the curved line with the arrows shown on the figure is obtained. This line indicates a wave front of between two and three microsec. to reach crest value.

The statement is made that practically all figures obtained on transmission lines have been of the type 2 class and therefore come within the wide range of wave fronts which vary roughly from that of a slow 60-cycle wave to a surge which comes to its maximum in a fraction of a misrosec. time. Referring again to the calibration curve given, the most abrupt wave front giving a type 2 figure was of the order of 1 microsec. to reach its crest value and this only for one particular voltage, namely 17 kv. as measured on the instrument. Thus the evidence indicates that for the waves measured, at least surges of more abrupt front than 1 microsec. did not occur and most of them were considerably slower than this.

A. H. Schirmer: Mr. Cox's paper, as well as the paper by Messrs. Cox, McAuley, and Huggins, presents a number of interesting conclusions, which in general are substantiated by the results obtained from a number of tests made on telephone lines during the past summer. These tests were made on a 5-mi. open-wire line carrying eight wires. Approximately twenty recorders were in use during the major portion of the lightning season.

In no case did we obtain record of more than two surges during a single storm, and usually only one surge per storm was recorded. It should be noted that in our case the klydonographs were connected directly to the line, there being no line voltages to contend with, so that when only one surge was recorded, it means that during that storm no voltage in excess of 2000 volts was obtained on the line. The results also show that the surges produced by lightning are either unidirectional or highly damped oscillatory surges. Our data also agree with the conclusion given in the papers that lightning arresters do not protect the line against flashovers, even at relatively short distances from the arrester. For example, in one case six recorders were placed on a line wire within 1000 ft. of the protector. The first recorder, located at the arrester, showed no evidence of potential. The second recorder, located only 66 ft. from the protector, indicated a voltage of approximately 8000. The third recorder, located 224 ft. from the protector, showed voltage above the range of the instrument, and the fifth recorder, located 700 ft. from the protector, flashed over between the electrode and the ground plate.

Our data, however, do not support the conclusion that the clouds which produced surges are always of negative polarity, resulting in positive induced voltages or negative direct-stroke voltages. None of the telephone wires under test was directly hit by lightning during the period of observation. Nevertheless, extremely high surges of both positive and negative polarity were recorded. Both the positive and negative surges were of relatively steep wave fronts, which also does not support the conclusion that the surges from positive lightning strokes are slow, of the order of 0.01 sec. A summary of our results shows that five storms produced positive surges and three storms produced negative surges, while three other storms showed positive and negative surges. These last surges we have attributed to discharges between clouds, rather than between cloud and earth. Even in these cases, voltages induced were well above the range of the instrument.

As pointed out before, many high-voltage surges were obtained on the telephone line. However, these surges were of extremely short duration, and in no case, even where the recorders flashed over only a short distance from the protectors, did these surges cause any damage to telephone cables, or permanently ground telephone arresters, as usually occurs from lower voltages imposed on telephone lines either by induction from, or momentary accidental contact with, electric light and power circuits. While in the latter cases the voltage may be applied for only 0.1 sec., still, this time is so much longer than the period of application of the lightning potentials that the effects are more severe even though the maximum voltages reached are substantially smaller than the lightning voltages.

Fig. 8, in the paper by Messrs. Cox, McAuley, and Huggins, gives a diagram of connections for lightning-arrester tests. This diagram shows the klydonograph connected to the same ground as the lightning arresters. With this connection, the klydonograph merely records the drop in potential across the lightning arrester, and not the potential of the line to ground. During heavy discharges the potential of the protector ground connection may be many volts above true earth. In order to

1. Time Voltage and Current Characteristics of Lightning Arresters, K. B. McEachron, *G. E. Review*, Vol. 29, p. 678, 1926.

2. This curve is taken from "Measurement of Transients by Lichtenberg Figures" A. I. E. E. TRANS., 1926, V. 45, p. 712.

obtain a record of the effectiveness of protection at a given location, it is necessary to connect the ground plate of the klydonograph to an independent ground.

R. W. Atkinson: Messrs. Cox, McAuley, and Huggins in their paper state that transient voltages are a rare and unimportant cause of cable failure. These may of course be comparatively rare without being comparatively unimportant. Even a few failures per hundred miles per year for a given cause are evidently a matter of great concern to operating companies.

The writer shares what he believes is a general agreement in the industry with the opinion expressed by these authors, that transient voltages are not a major cause of cable failure. However, both of these papers throw a great deal of light on the fact, which has been known that a certain number of cable failures have resulted from transient voltages, particularly from unusual transient voltages. For instance, it is shown in these papers, that certain types of transients are of relatively low frequency so that they travel with substantially sustained peaks throughout the system. It is also pointed out that some of these are of the same character and thus materially more harmful than a single impulse. Probably the most direct application of this is in connection with the testing after installation with alternating current which fortunately is now becoming a thing of the past.

Thus, while a transient voltage of a given number of times the operating voltage may be only slightly or not at all destructive, a transient of the same number of times a test voltage may be very destructive.

There is an effect of even comparatively small over-voltage transients which is usually overlooked, but which, as has been pointed out previously, may well be of importance. The shape of the curve of power factor versus voltage of a cable is different depending upon the direction of the cycle, that is depending upon whether the voltage is being raised or lowered. To whatever extent this change of power factor with voltage is a measure of ionization of air spaces within the cable, this simply means that the amount of ionization at a given voltage depends on the previous history, and is greater if the cable has been subjected previously to a higher voltage. The action of a transient voltage has been likened to a trigger, which releases the energy from the normal operating voltage in such a way that its effect may be as severe as would be a steadily maintained operating voltage of considerably higher magnitude.

Published records show not only that there are individual instances where cable failures have been directly traceable to transient voltages but information is published in at least one instance concerning a system where a change with respect to the amount of transient voltages existing, produced an important effect on the number of cable failures experienced.

I wish to emphasize that transient voltages are important in connection with cable operation, and that it will be very valuable to continue to obtain information as to the transient conditions in various systems so that these may be evaluated in terms of what might be termed an equivalent steady operating voltage. Where a system is exposed to such transient voltages, it is obviously just as important to make the apparatus on it capable of meeting any transients which cannot be prevented, as it is important to have the apparatus and cable meet the steady operating condition.

Yet one more word as to a specific instance where the data shown by these authors explain that cable may be subjected to damaging transient voltages. If a cable insulated for relatively low voltage is connected to an overhead line insulated for considerably higher voltage, it is obvious that lightning potentials sustained by the cable may in this case be especially destructive.

F. W. Peek: The klydonograph is of special interest to me because it affords further means of checking conclusions regarding lightning which I arrived at several years ago. I am going to tell you a little about my work to show how well it is in agreement in the most important respects with the results of Messrs. Cox, McAuley, Huggins, and Lee and Foust.

Several years ago I undertook to determine, if possible, the order of the voltage and other characteristics of lightning, the gradients produced, etc.; the magnitude and character of lightning on transmission lines; the strength of apparatus and line insulators when subjected to lightning voltages; and the value of the ground wire and other protective apparatus. With such information it is possible to make lines that are immune from lightning. Whether or not immunity is secured is, to a great extent, an economic problem. The results of my investigation have already been given to the Institute.[3,4] As far as I know it was the first time that estimates of the actual values of lightning voltages on transmission lines were ever made. The rules for pre-determining lightning voltages and the lightning strength of insulators, etc. are quite simple. I will give a brief summary of my conclusions.

The voltage of a lightning flash is of the order of 100,000,000, the current 80,000 amperes, and the energy 4 kw-hr. The maximum gradient is 100 kv./ft. (330 kv./m.). The discharges are usually non-oscillatory and some times take place in a few microseconds.

Lightning disturbances on transmission lines are generally steep waves of a few microsec. duration though the lower voltage disturbances may be of larger duration. The induced voltage increases directly with the height of the conductors. It is found by multiplying the apparent gradient by the height of the line, but is limited by the lightning flash-over voltage of the insulator. Thus $V = g \alpha h = Gh$. When h is the height in feet, g is the gradient in volts, and α is a factor depending upon how rapidly the cloud discharges. G is the apparent gradient. The maximum possible gradient is 100,000 volts/ft. (330,000 volts/meter). This value can usually apply only in case of a direct stroke. In practise, because of the time required to discharge the cloud, G is usually less than 50,000. A voltage wave is reduced in a few miles by corona losses. After the wave is well under way the voltage is also reduced to one-half because part of the energy becomes magnetic. The lightning flash-over voltage of insulators and the strength of insulation is always higher than the 60-cycle values. An insulator flash-over curve made by artificial lightning has been checked to 1,800,000 volts by natural lightning with good agreement.

The ground wire, by cutting lightning voltages in half, has the effect of increasing the line insulation and at the same time reducing the stress on apparatus. It must be properly installed.

If a line is over-insulated, apparatus failures may result if protective gaps or arresters are not used.

Reasons that more trouble is not experienced are that most high voltages originate at some distance from the station, and a large number of induced voltages are from slowly discharging clouds.

By comparing the lightning strength of apparatus and insulators with possible lightning voltages the probability of failures and outages can be estimated. Whether a line is made immune or not is a question of economics.

It can be seen that my conclusions agree, in most respects, very well with the conclusions arrived at in these papers.

I was particularly interested in the value of 1800 kv. given by Lee and Foust for the lightning flashover voltage of a 14-unit insulator string as measured by klydonographs on an actual line. Estimates were made of the maximum possible and usual highest lightning voltages for such a line, and are given in Table I in my paper[6]. The insulators arc-over values are given as 1800. For conductors 40 ft. high the maximum possible voltage is given

3. F. W. Peek, Jr., *Lightning and Other Transients on Transmission Lines*, TRANSACTIONS, A. I. E. E., 1924, Vol. 43, p. 1205. Lightning, *Journal Franklin Institute*, Feb. 1925.

4. F. W. Peek, Jr., *Lightning (A Study of Lightning Rods and Cages with Special Reference to the Protection of Oil Tanks)*, A. I. E. E. TRANS., 1926, p. 1131.

Either of these values is high enough to cause insulation flashover. The maximum voltage would be limited to 1800 kv. by the insulator. This is the value actually measured by Lee and Foust. The values in Table I were made long before such a line had been built. Table I also shows the effectiveness of a ground wire on such a line.

H. B. Vincent: I want to ask a few questions of Messrs. Cox, McAuley, and Huggins on their paper. In the data submitted were the lines in all cases energized, or were there any as 4000 kv. and the usual highest 2000 kv. without ground wires cases where the records were taken of the lightning voltage while the line was not energized?

There is no mention made of any so-called control devices in connection with the insulators, which might or might not affect the flashovers? Referring to their Table I, in case No. 2, which is a 140-kv. line, they recorded 2 flashovers with a voltage over 10 times normal, and on another line of the same kv. they had 15. Now, did the first line only have 2 and not 15 because there were fewer lightning storms, or were the insulators installed with some control device which presumably decreased the possibility of flashovers? If such records were kept, I am wondering whether it would throw any further light on the question of flashovers. I am not questioning the value of the klydonograph, which is beautifully shown and recorded. But, inasmuch as the cause is tied in with the effect (the effect being the flashover of the insulators), I simply question whether anything has been lost sight of in not mentioning the matter of control devices.

The operating man is also interested in the amount of damage that is done, as much as he is in whether the voltage is ten times or twenty times normal. I am wondering whether the data could not be amplified to show the effect a little more clearly, in addition to the cause.

R. G. Hooke: The Public Service Electric and Gas Company of New Jersey, with which I happen to be associated, have been using the klydonograph for nearly three years, and I want to amplify a little the data that have been given; particularly that in the paper by Messrs. Cox, McAuley, and Huggins. In their Table V, they give the relation between causes of surges and magnitudes.

I compared this roughly with our own records, because it is given as the average that might be expected on any one system, and I wanted to see how nearly our system lined up with that average. I found that the percentages due to different causes were rather interesting in that we had only about half as many surges resulting from switching at the klydonograph station, whereas we had twice as many as they give caused by switching at other points in the system. From that table also it appeared that we had an unusually high percentage of surges of the larger magnitudes. This is brought out particularly, perhaps, in their Table VI.

I would call attention to their remarks that, "On one particular system the surges identified with short circuits were considerably higher than the average. For instance, this system accounted for 26 of the 32 oscillatory surges of 2.6 times normal voltage and over. Its only apparent difference from the other systems, all of which were grounded solidly or through a low resistance, is the presence of a 75-ohm resistor in the neutral ground." They also say that "The highest voltage recorded was 4.6 times normal. Only ten surges or 0.4 per cent of the total were over four times normal. Of these, six were on one cable-and-open-wire system, where certain contributory operating conditions prevailed."

The system referred to, happens to be that operated by Public Service Electric and Gas Company in what we call our Southern Division. We have in Trenton approximately 10 mi. of 26-kv. cable, connected through about 32 mi. of open wire, to a cable network in Camden. In the latter city there are about 20 more mi. of 26-kv. cable, including ties with the Philadelphia Electric Company. I am going to give the details of two or three of the higher surges in this area because I think they are of particular interest.

We have recorded about 500 surges there in two years; 4.6 per cent of these have been between three and four times normal and 1.4 per cent have been above four times normal. The highest was 4.7 times normal. That highest surge was caused by a cable failure in Trenton. A report was received at our office that a cable was smoking. We sent a man out to investigate, but before he could get there the cable failed. Simultaneously, we lost a cable in Camden not far from the klydonograph location. The disturbance, therefore, originated in Trenton and traveled some 40 mi. to cause trouble at the other end of the system. This, however, is the only case in our records of a failure which may have resulted from a high surge. On the contrary, with one exception, all of the higher over-potentials appear to have been the result of cable breakdowns rather than their cause. The basis for this statement is the fact that insulation failures frequently are not accompanied by surges, but the surges, when they do occur, are always coincident with faults. This means that if we eliminate the cable faults, we shall practically eliminate the high voltages, as is brought out in the paper.

The one exception that I mentioned is interesting. It was a surge of 4.6 times normal and was the result of an accidental relay operation. A line was tripped out which happened to be carrying a fairly heavy load, together with the synchronizing power between our system and Philadelphia. We have no satisfactory explanation for the resulting surge. Similar switching operations are quite frequently performed. We often separate from Philadelphia intentionally and we never have had any such occurrence on any other occasion.

We have also had a klydonograph located in another transmission system containing something like 135 mi. of open wire and 51 mi. of cable. This system was operated for a good many months with a solidly grounded neutral, but it has now been in service for about six or eight months with a 75-ohm resistance in the neutral. At the time we changed the operating condition, we made some fairly extensive ground tests with different neutral resistances; we tried 75 ohms, 150 ohms, and 300 ohms, throwing grounds directly on the system. The object of these tests was not to see what surges we would get, but to try out the functioning of our relays. The surges which occurred, however, are very interesting.

While operating with a solidly grounded neutral, three transients of above four times normal were recorded due to the deenergizing of low-capacity equipment in the substation where the klydonograph was located. Surges of this nature are mentioned by the authors and since they are of very short duration, they are not considered to be important. They are, therefore, excluded from the following table which gives the results obtained with the different neutral resistances. Southern Division data are included for comparison.

	Central Div.				Southern Div.
Neutral resistance, ohms....	0	75	150	300	75
Number of surges recorded..	240	115	9	15	498
Per cent from 1 to 1.9 times normal voltage...........	84.6	75.6	55.5	46.7	84.5
Per cent from 2 to 2.9 times normal..................	15.4	21.8	44.5	46.7	9.5
Per cent from 3 to 3.9 times normal..................	0	2.6	0	6.7	4.6
Per cent from 4 to 4.9 times normal..................	0	0	0	0	1.4

These figures indicate very clearly that the higher the resistance in the neutral, the greater will be the percentage of surges of the higher magnitudes. Under no conditions, however, have transients in excess of four times normal occurred in the Central Division.

Comparing this with the data obtained in the Southern Division, as indicated in the table, it appears that nearly twice as high a percentage of surges between three and four times normal have been recorded in Camden on the 75-ohm resistor, and that seven, or 1.4 per cent of the total, have been above four times normal, whereas there was none of this magnitude in the Central Division. Obviously, there is some difference between these two transmission systems and the high surges on one cannot be explained on the basis of the neutral resistor. It happens that at numerous points in the southern part of New Jersey, the soil is dry and sandy and we find it difficult to obtain low-resistance grounds at our stations and substations. Since the high surges which have occurred seem, in general, to be due to faults in certain areas, while faults in other parts of the system cause much less voltage disturbance, we are of the opinion that the ground resistance at the point of fault is of particular importance. In fact, it is of more importance than the resistance which we find it necessary to use in the neutral in order to keep on friendly terms with the Telephone company whose lines parallel certain of our transmission circuits.

To summarize, then, with different neutral resistances, we have found that the higher the resistance the more surges might be expected of magnitudes of between two and three times normal, but there is very little likelihood of any transients of above four times normal occurring even with 300 ohms in the ground connection unless there are other causes either in the constants of the system or in the ground resistance at the point of fault. In connection with this general discussion, it is of interest that in one case an arcing ground in a cable joint caused surges of less than 2 times normal for a period of about 30 hr., the figures being obtained intermittently until complete failure finally developed.

In studying our particular problem, namely the high surges which occur in our Southern Division, we are now planning to install three or four more klydonographs in the area, attempting to find out whence the surges come and whither they travel. We have had only one instrument in that whole system thus far. We have, however, carried on some cooperative work with the Philadelphia Electric Company. They installed a klydonograph on their side of the Delaware River about 4½ mi. from our klydonograph station. We found that for a surge to be recorded simultaneously at both places it must be over two times normal on one side or the other. Attenuation amounted to about 45 per cent in the 4½-mi. cable tie. We think that is very interesting because with the klydonograph at one point if we get such an attenuation we don't know very much about what the surges may be elsewhere. However, in spite of the surges which we have—and I think they have been as serious as any company has experienced—we tend to disagree with those who charge cable breakdowns to high-voltage transients. We feel that the cable which we are now able to buy, in view of the voltages which it stands on test, should be almost entirely unaffected by surges up to four or even five times normal. I don't see any way to draw definite conclusions on this point, but it would be very interesting if some manufacturing company could conduct tests to determine the effect of transient voltages on cable insulation.

J. H. Cox: In the development of the klydonograph, we found the probable error of a record to be about $\pm$ 15 per cent, with a possible error of about 30 per cent. It is encouraging to note that the Messrs. Lee and Foust check this value.

There are two principal points in which the authors' procedure has differed from ours. They have used two oppositely connected electrodes for each connection, and they have used a different form of potentiometer for connection to lines. The use of two oppositely connected electrodes has certain advantages as pointed out by the authors and it is to be commended under certain conditions. Its principal advantage is that it gives a positive measure of the maximum voltage when the potential is a damped oscillation and the initial impulse is negative. There is also some advantage in having a positive figure for a negative surge, but it must not be inferred that the negative figures are entirely useless. The hiding of the small negative figures by the normal voltage band in the single-element instrument, can be prevented, if desired, by setting the potentiometers to eliminate the normal voltage band. In any case, negative records above 2½ times normal will be detected and it is questionable if surges on transmission lines below this value are very important. The advantages of the double connected arrangement are gained at the sacrifice of certain others. The instrument has a higher electrostatic capacity and hence imposes a greater burden on the necessary electrostatic potentiometer, which at best has a low capacity itself. It makes a more expensive arrangement both in installation and in operation as it eliminates the possibility of the multi-electrode instrument. With the inherent inaccuracy of spring clocks, having the records of three terminals on one film makes the time record much more complete. A double-electrode arrangement was considered when the first film-type klydonograph was designed, but it was discarded at that time in favor of our present arrangement. However, the method to be preferred for a particular test is determined by individual opinion and the nature of the test.

While the authors have gone to greater refinement in the instrument they have chosen the opposite trend in the potentiometers used. The use of a string of suspension insulators as a potentiometer was suggested for approximate work by Cox and Legg in their paper on page 869 in the 1925 Transactions, A. I. E. E. When the klydonograph was first developed this form of potentiometer was investigated by Mr. Peters and discarded as unsatisfactory. The scheme works well as long as the surroundings remain constant, and as long as the insulators are dry, or wet and clean, but when the insulators become slightly dirty and get wet, as is inevitable in service, the leakage conductance disturbs the ratio. This can be readily seen by a comparison of the electrostatic capacities involved. The capacity of the singly connected film-type klydonograph is about 8 micro-microfarads per terminal. I have been told that the capacity of the doubly connected klydonograph is 23 micro-microfarads. Its greater capacity is due to the fact that it has two terminals and a ground sheet connected to one of them. The capacity of a single 10-in. insulator disk is about 25 micro-microfarads, which value is divided by the number of insulators in series. It is easy to see that a variable leakage path in parallel with a capacity which is smaller than the connected instrument will seriously disturb the ratio. As mentioned by the authors, this disturbance should be less for impulsive applications than for the normal frequency.

The authors mention the effect of a change in the lengths of the leads used. This is inevitable where such small capacities are involved. In an actual test it is often difficult to keep the lengths of the leads down to 5 ft. Altogether, the most desirable form of potentiometer is that having the highest capacity. At best this is none too high. The capacity of a 6 ft. ring of 2-in. iron pipe mounted 12 in. above a ground plate is from 100 to 200 micro-microfarads.

We have recently made use of condenser bushings as potentiometers. The klydonograph is connected from one of the condenser steps to ground. This scheme gives excellent results. The arrangement is not subject to as many variable leakage paths as the others. Furthermore these paths are not as important since the capacity across which the klydonograph is connected is from 250 to 800 micro-microfarads. No calibration in the field is necessary as the bushing can be designed for a definite ratio and this ratio remains fixed.

H. L. Wallau: (communicated after adjournment) The following data as to the magnitude of voltage surges experienced when switching high-voltage (66-kv.) cable circuits may be of interest.

The circuit was as follows:

No. 1 Breaker—Connecting 11-kv. generating plant bus to 30,000-kv-a. transformer bank stepping up to 66 kv.

No. 2 Breaker—Connecting high-tension side of transformer bank to 66-kv. cable circuit.

No. 3 Breaker—Connecting 66-kv. cable to low-tension side of 66-kv./132-kv. transformer bank. Length of cable circuit 8¼ mi. 3 single-conductor 500,000 cir. mil. cables 30/32-in. paper insulation 9/64 lead, spaced vertically 6½-in. centers.

No. 4 Breaker—Connecting high-tension side of bank to 132-kv. 4/0 three-phase circuit 47 mi. long..

Tests were made at no load.

The magnitudes of the over-voltage surges were obtained from oscillograph records.

*66-kv. neutral ground open at far end.

The maximum over-voltages obtained were for both closing and opening operations when the first 66-kv. breaker (No. 2) was actuated. For the closing operation the highest surge obtained when the 132-kv. bank had been previously closed on the cable circuit through the No. 3 breaker, thus simultaneously energizing both the cable circuit and the transformer bank. For the opening operation the next highest surge resulted when deenergizing the cable circuit only.

A. L. Atherton: (communicated after adjournment) We who deal with lightning arresters have what is perhaps the most indefinite problem in the electrical industry today. Although it is recognized that the results secured thus far do not cover all conditions and are not extensive enough to justify the drawing of final conclusions, there are several points of vital importance to the lightning-arrester question which warrant notice.

(a) First of these is the amazingly small number of times a lightning arrester is called upon to operate in a season. In the old days, when electrolytic lightning arresters were generally used, the manufacturers' recommendations for setting of the series gaps were rather indefinite, it being left to the user to adjust the gaps so that the arrester operated frequently but not too frequently. It was general practise to set the gaps so that the arresters operated quite often. The customer had invested some money and wished to have some visible evidence that he had bought something. It was not infrequently the case that these arresters would operate many times in a single storm and possibly several hundred times in a year. Observe now the date of Table IV, keeping in mind that voltages less than double normal line-to-line voltage, which corresponds to 3½ times normal voltage to ground, are not in the dangerous class and do not require an arrester operation. It is to be presumed that the only times when the arrester would be required to operate, would be for those voltage values greater than 3.5 times normal for which a flashover did not occur along the line. The total number of these is less than two per year per location. If we include those cases when the line insulators flash over, the total number of voltages in excess of 3.5 times normal is less than 6 per year per location. Even including all cases of flashover, to consider the condition of line insulation so greatly increased beyond present practise as to eliminate flashover, the total is less than 18 per year per location. This is a very startling reduction below the previous conception of how many times an arrester should operate in a season.

These figures are averages for all voltages and the weight of data lies at the higher voltages. The variation with voltage will be touched on later.

(b) Along this same line is another point almost equally startling. For years we have considered that it is desirable to provide as short a path as possible between lines to take care of switching transients. It appears clear from the information available here that switching transients are practically negligible. Wherever the length of line involved is appreciable, the voltage is low, and in general the voltages in excess of the value 3½ times normal voltage to ground for which an arrester operation might appear to be required, occur on very short lines and therefore are practically negligible because of short duration. The function of a lightning arrester is definitely the protection against lightning voltages.

(c) All of this arouses renewed interest in the time-honored question as to whether arresters are required on the higher voltage systems, and if not, where the dividing line can be placed. From the data given, it is clearly evident that voltages dangerous to the insulation of any apparatus at present made or contemplated for commercial use may readily be induced in the line conductors, providing the circuit is located in a territory where lightning conditions are at all severe. It appears that the magnitude of voltage which reaches a station is determined in general by the flashover value of line insulation. Insulators flash over even on lines for the very highest voltages. One way to look at this question then is that the need for lightning arresters is dependent on the ratio between insulation strength of the apparatus and flashover of the line insulators both presumably under the same conditions of transient voltage. Considered on this basis, the line insulators probably offer the same order of protection to terminal apparatus throughout the voltage range and, if this line of thought is correct and complete, lightning arresters are as necessary at the higher voltages as at the lower.

To get a further idea as to the relative need for protection in the various voltage classes, and to try to take into account the number of overvoltages per year which was neglected in the line of thought we just followed, we may total the data of Table I by voltage classes as follows:

System		Surges per station per year		
No.	Voltage	Without flashover 3.5 times normal and above	With and without flashover, 3.5 times normal and over	Without flashover, 3.5 times normal and above plus all with flashover
26 and 27	6.6–13.2	0	6	29
20 to 25	22–23	5	8	23
9 to 19	44–66	2	8	18
1 to 8	100–220	1	3	13

In this summary, fractional values are given as the next higher whole number.

There may be indications of a slight trend toward higher

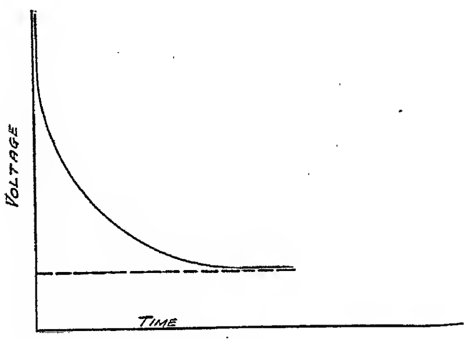

FIG. 2

figures for the lower voltages, but there is no indication that the figures are of a different order of magnitude. On this basis, the need for arresters seems to be about the same for all voltages, neglecting any differences there may be in factors of safety of apparatus insulation and relative importance of serial continuity.

Assuming, for the moment, that the need is equal, we must not take this to mean that the justification for the use of present-day arresters is equal for all voltages. Justification for use still depends on economics and the cost per kv. of present-day arresters increases very rapidly with voltage in the higher ranges.

To get the correct idea from these thoughts, we must keep in mind that experience with and without lightning arresters at the middle voltage classes, 33 or 25 kv. and down, has clearly

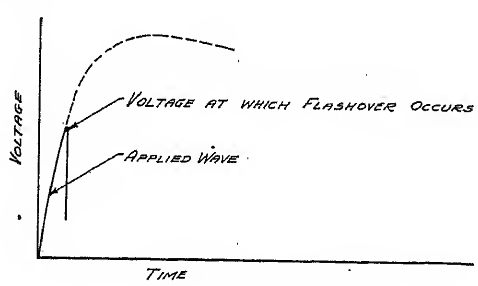

FIG. 3

demonstrated that good service cannot be rendered without lightning arresters if the circuit is in a location where lightning is prevalent.

We must also keep in mind that we cannot draw definite and final conclusions at this time. The data are not nearly complete enough to eliminate the possibility of large errors. It is interesting however to note the trend of opinion as the information accumulates.

(d) One further point in this connection bearing particularly on the question of line insulator flashover and the measurement of transient voltages which I should like to stress is the rather general present practise of referring to "Impulse Flashover Value" for insulators or insulation. It seems to me that this is a very dangerous practise. When we say impulse flashover voltage, we give the definite impression that there is one such voltage value for any particular piece of insulation. This is not the case. The impulse flashover voltage may be anything between the 60-cycle flashover voltage value and some value very close to infinite dependent on the duration of the application. If we apply a million volts to a path, and flashover occurs after one microsecond, it is evident that we can prevent flashover not only by reducing the voltage value but also by reducing the time. A curve something like that shown in the accompanying Fig. 2, doubtless exists. It is difficult to see how we can justify speaking of such a curve by one voltage value and it is very easy to see how such a locse practise may get us into misconception and future trouble.

For example, if we determine the "impulse flashover voltage" for a string of insulators by applying a rapidly increasing voltage and measuring the voltage at the flashover by means of a sphere gap or klydonograph, we measure the voltage value as indicated in Fig. 3, herewith. We get the same kind of value as a maximum by klydonograph tests in service at the time of flashover. When the klydonograph says 10 times normal voltage for a flashover, the induced voltage may have been on the way to 100 times normal when the flashover stopped it. If we refer to this kind of value as the "impulse flashover voltage," we give the impression that lower voltage values will not cause flashover. Suppose, however, that a transient voltage appears which never reaches this crest value but persists for some microseconds. It is entirely possible that such a transient will cause flashover, and if transient voltages on transmission circuits may be of appreciable duration, such as 10 to 20 microseconds, as is likely, this voltage value may be very much below "the impulse flashover voltage" above referred to. It is not unlikely that some of the flashovers with relatively low recorded voltages may be explained in this way.

There is a growing interest in the proper proportioning of line insulation, apparatus insulation, and protective equipment to make the design of systems consistent as a whole. If we base such system design on a single voltage value, as the tendency now is, we are liable to be in error. Even if we could assume that a test, as in Fig. 3, gives one point of the curve of Fig. 2, we would still have no assurance that this curve would have the same shape for various kinds of insulation, and when we are dealing with such widely different things as air flashover around insulators and dielectric puncture under oil in transformers, the difference is not likely to be negligible.

The manufacturers have been asked to give impulse flashover voltages for various kinds of apparatus and line insulation, particularly when applications are to be made on the very high-voltage systems in lightning territories. Such statements are meaningless and can only lead to misunderstandings and disagreements. Let us learn from past engineering experience that inaccuracies of speech are dangerous and adopt precise terms in this matter as we have had to in others. If we must specify a value for impulse flashover voltages, let us specify also the duration of this voltage or better yet, a curve of time against voltage.

V. E. Goodwin: (communicated after adjournment) I fully agree with the comments of Mr. Atherton and wish to emphasize the importance of a proper understanding of the term "impulse flashover" or "impulse failure" of apparatus. It is, for instance, common practise to speak of insulators as having a definite flashover or of the impulse strength of an insulated structure such as a transformer. The flashover of an insulator may be taken as illustrative, although this discussion applies equally well to the puncture of insulation or to other apparatus subjected to the action of transient phenomena.

Whether or not a given insulator will flash over depends on both the voltage and the time of application. The lower the voltage applied, the longer the time of application to cause failure. This means that the back of the wave is important since the flash-over may occur after the wave front has passed. On the other hand, if the voltage rises to a high enough value the insulator will flash over on the wave front, thus preventing further rise in voltage.

When stating that a piece of apparatus has a certain impulse flashover, it is necessary to specify the wave used in determining this value and state whether the arcover occurs on the front, or if after the front has passed how long a time elapsed before the arcover took place.

The terms "time lag" and "impulse ratio" are open to the same criticism as the term "impulse strength." Time lag as ordinarily understood is an indefinite term since the wave is not specified and the lapsed time may involve a simultaneous voltage increase, as in the front of the wave, or it may be a constant or decrease in voltage as in the back or tail of the wave.

One method of measuring time lags is to apply various over-voltages above that which the specimen will withstand continuously, and determine the times required in each case to cause breakdown. For this method to be satisfactory, the potential must rise to its maximum value in a time short compared to that required to cause breakdown. Until the cathode-ray oscillograph became available, this method could not be used for it was not possible to determine the time relations satisfactorily.

The other and more common method for measuring time lag is to determine the time required for the breakdown to occur on a steep wave front after the potential has reached a value which it could withstand if continuously applied. With this method, the exact wave front must be known and several points taken. Comparison of curves of these two methods for determining time lag will show quite different results.

The term "impulse ratio" does not have a definite value unless the impulse applied to the test specimen is prescribed and it is known that the breakdown occurred on the wave front and not after the voltage has reached its maximum value.

The terms "impulse strength, time lag, and impulse ratio" have come to have a variety of meanings and are terms which the Institute might well define to prevent confusion.

H. H. Plumb (communicated after adjournment): Mr. Cox has brought out some interesting data in his first paragraph under *Experimental Data*, applying to lightning discharges. His deductions appear to be somewhat in conflict with other conclusions in the paper, and I wish to submit a different deduction which will harmonize the conclusions.

That there are surprisingly few discharges indicated by the klydonograph during a thunder storm, and the figures showing positive, supports the deduction that only negatively charged clouds discharge with sufficient severity and swiftness to make a record on the klydonograph. The few negative Lichtenberg figures recorded may have been direct strokes in every case. The evidence thus analyzed shows that in a thunder storm, many discharges take place, from both positively and negatively charged clouds, the discharges from positive clouds are relatively slow and fail to register on the klydonograph; the negatively charged clouds are discharged swiftly and with severity, and these usually register, with a positive Lichtenberg figure if by induced or bound charge, but negative if by a direct hit on the line. This view is in complete accord with Dr. Simpson's theory and Dr. Norinder's results.

J. H. Cox and P. H. McAuley: Mr. McEachron has objected to certain of our conclusions as somewhat premature with present available data. It should be obvious that the inherent variations in the physical conditions under which lightning occurs are reflected in any data obtained, and that the reliability of the conclusions is relative to the amount of data from which they are drawn. Moreover, deductions from data of this nature are invariably influenced, to a certain extent, by individual experience. Several of the discussions illustrate this point. To make a paper complete, however, results must be summarized and conclusions indicated. As Mr. Peek has pointed out, the magnitude of an induced surge is influenced by the rate of discharge of the cloud and is less than the product $G\,h$. Thus, although gradients as high as 100 kv. per ft. (330 kv. per meter) are reached near the earth's surface, it is entirely possible that surges high enough to flash over 220-kv. insulation seldom are *induced*. Furthermore, these higher gradients are present only in the vicinity of the lightning stroke. The division of an instantaneously released charge into two traveling waves, each with a surge voltage of one-half that of the initial voltage, is one of the most elementary laws of wave propagation and was not neglected by the authors. The reduction referred to was from more than 1000 kv. to about 150 kv. This indicates a rapid attenuation in spite of a maximum initial reduction factor of one-half.

Mr. Schirmer has reported some results which appear to conflict with Simpson's theory of lightning. These, however, are not so inconsistent when it is remembered that the voltages measured on telephone lines are low compared to those on power lines. Mr. Schirmer has some interesting data which show that the drop across the protector ground on telephone circuits is relatively high. The drop across power-line lightning-arrester grounds has not been investigated, but tests on this are now being started.

Mr. Vincent has asked some questions regarding test conditions which may have affected the results. In some cases the lines were not energized during lightning storms. This did not appear to influence the results very greatly. The only influences of having the line energized are that terminal conditions are different, and that the net surge voltage to ground becomes the sum of the instantaneous applied voltage and the surge potential. Lines 2 and 3 in Table I were of similar construction, neither being equipped with control devices. The difference in the number of surges over ten times normal was due to difference in the lightning encountered. The only claims made for flashover control devices are that they increase the flashover voltage of the line, and therefore higher surge voltages should be recorded on lines so equipped. In our experience with the klydonograph, however, we were unable to detect this difference.

Mr. Plumb has made certain comments regarding the first paragraph under *Experimental Data* in the paper *Transmission Line Voltage Surges*. This paragraph merely includes a number of statements regarding the data recorded and what these indicate at first sight. The conclusions stated by Mr. Plumb are discussed in the remainder of Part II of the paper. For instance, it is explained that positively charged clouds discharge too slowly to cause surges on transmission lines and that the surges experienced, both induced and direct, are caused by negatively charged clouds.

E. S. Lee and C. M. Foust: Several phases of the work on Lichtenberg figure measurements of surge voltages have been touched upon during the discussion, particularly by Mr. Cox, and we wish to add a few remarks relating to the points raised.

Regarding the use of the positive Lichtenberg figures to record all surges whether of positive or negative polarity, it is felt that this practise is advantageous for three reasons:

1. Because negative surge voltages up to approximately 2.5 times normal give negative Lichtenberg figures upon a directly connected recorder which are entirely obscured by the normal line-voltage band, and the interpretation of negative figures somewhat above this value may be uncertain.

2. Because negative Lichtenberg figure sizes are dependent upon the rate of voltage rise to a much greater degree than the positive figures.

3. Because the availability of both figures for all high-voltage

surges permits a more accurate determination of the nature of the surge producing the figures.

We do not consider the limitation of the two-recorder type of instrument to a single-phase instrument to be a disadvantage, since the certainty of the result obtained is greater. The use of the three-electrode type of instrument as a three-phase instrument requires that the conditions be arranged so that there is no interference between electrodes.

We have investigated both insulator and electrostatic-potentiometer methods of connecting the instrument to the transmission line and have used the insulator-potentiometer method for several reasons, among which are the following:

1. Availability of normal line insulator units, ease of installation, and small space occupied.

2. Requisite safety is assured by the use of an insulator-potentiometer string having a greater number of units than normal line insulation.

3. All measurements are made across a portion of the normal line insulation.

4. Laboratory tests have not demonstrated that the electrostatic-potentiometer method may be relied upon for any greater degree of accuracy than the insulator-string method.

While there is considerable evidence to support the contention that for 60-cycle voltages the distribution over a string of insulators may vary with conditions, such as indicated by the decrease in flashover under wet conditions, there also appears to be considerable evidence which indicates that this change in distribution does not take place where the applied voltages are of very steep wave front. This seems reasonable because of the much larger charging current present with very steep waves and the consequent unimportance of the low surface-leakage current. Data have been published which indicate that for steep waves the flashovers wet and dry do not differ greatly. Our laboratory test on insulator strings of various lengths seems to bear this out. Using a wave front of about two microseconds the distribution of voltage across the individual units of a string of six insulators was found to be independent of the magnitude of the voltage and similar to the 60-cycle distribution. These investigations check our ratio results on various insulator strings at 60 cycles and impulse voltage, and indicate that our ratio of line voltage to instrument voltage will be constant and identical both wet and dry on impulse voltages, and dry on 60 cycles.

The 60-cycle ratio with the string wet will vary somewhat due to the increase in surface-leakage currents. The use of the electrostatic potentiometer, however, does not seem to rectify this condition because the rings are still necessarily supported by porcelain insulators, again supplying surface-leakage paths which tend to disturb the normal frequency distribution. As regards the high capacitance of the electrostatic potentiometer, this may be a disadvantage since the higher the capacitance, the greater the distortion of the surge voltage from normal.

Mention has been made of the lead effect shown in Fig. 24 of the paper in connection with the insulator-string potentiometer. The results shown on this graph however, were, not obtained upon an insulator string but on an electrostatic potentiometer. While this potentiometer did not have the capacitance of some of those which have been used in practise, the results obtained do demonstrate a characteristic which will be obtained in any type of capacitance voltage-dividing arrangement used. In such devices, connecting leads should always be as short as possible. Therefore, Mr. Cox's statement "Altogether the most desirable form of potentiometer is that having the highest capacity" must necessarily be modified, since recognition must be given to the fact that high-capacitance potentiometers distort the line transient.

A New Electronic Rectifier

BY L. O. GRONDAHL[1] and P. H. GEIGER[1]

Associate, A. I. E. E. Non-Member

Synopsis. *A new rectifier utilizing a partially oxidized disk of copper as a rectifier unit is described. The disks may be arranged into groups suitable for all fields of rectifier applications.*

The rectification appears to take place at the junction between the copper and the oxide without observable physical or chemical changes, and is similar in character to rectification by the hot-cathode type of rectifiers.

The physical characteristics of assembled rectifiers and a method of designing the same for special purposes are outlined and some of the design problems discussed.

It is pointed out that the new rectification phenomenon is of a radically different nature from those observed in structurally somewhat similar contact rectifiers. The usual theories of contact rectification, which are based on electrolysis or thermoelectricity, are not applicable to the present case. The new phenomenon is discussed in the light of more recent theories based on electron affinities of copper and copper-oxide, which are in better accord with the observations.

Some applications are given for which the rectifier seems to be especially suited.

THE present paper is a discussion of the results of a development which has been based on a phenomenon discovered by one of the writers and reported at the meeting of the American Physical Society held at Washington, April 23-24, 1926.[2]

In the course of an investigation of copper oxide formed on a piece of copper, during which current was passed through the oxide in a direction at right angles to the surface of separation, it was observed that the resistance of the combination was less when the current flowed from the oxide to the copper than when it flowed in the reverse direction. In the first unit, the ratio of the resistances in the two directions was about 3 to 1. The phenomenon was so different in nature from anything that had been observed in other known types of rectifiers that an intensive study and experimental investigation was undertaken during which it became more and more evident that the new device has characteristics which make it very probable that it will find general application as a rectifier.

Description

A rectifier element consists of a disk of copper on which has been formed a layer of copper oxide, as shown in Fig. 1. A good electrical connection is made with the exposed surface of the oxide layer by means of a terminal member of soft metal, such as lead or metal foil. The copper disk and the terminal member of soft metal are conveniently made in the form of washers and assembled on a bolt to provide a good connection between the outer surface of the oxide and the soft metal washer.

Fig. 1 shows such an assembly of a half wave rectifier.

In the new rectifier, the rectification appears to be restricted to a microscopically thin layer at the junction between the copper and the oxide, and takes place under entire absence of electrolytic action or other observable physical or chemical changes.

Any number of individual elements may be assembled in series and in parallel into rectifier groups for any desired value of current and voltage. The two standard methods of connecting rectifiers for full wave rectification are shown in Fig. 2. Fig. 3 shows an assembly of four copper oxide rectifier elements into a group for full wave rectification, the connections being the same as in *b* of Fig. 2. Such an assembly may be used without a central tap in the transformer.

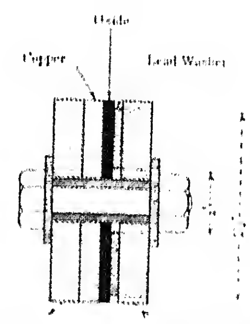

FIG. 1—ASSEMBLY OF SINGLE HALF WAVE RECTIFIER

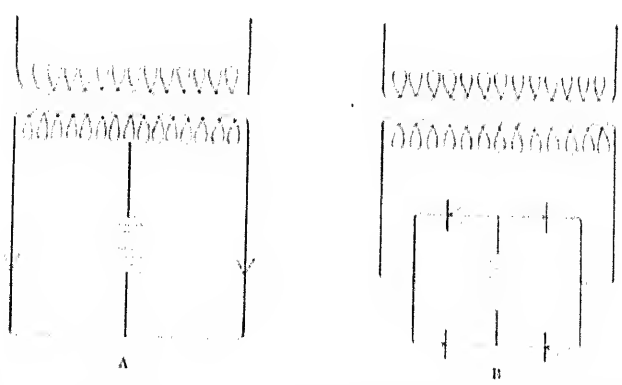

FIG. 2—ARRANGEMENTS OF RECTIFIERS FOR FULL WAVE RECTIFICATION

With good ventilation, such a unit will supply a unidirectional e. m. f. of 6 volts and a current which depends on the area used. The current density that may be used depends on the effectiveness of the ventilation that is provided. In order to dispose of the power lost in the rectifier, it may be provided with ventilating fins as illustrated in Fig. 4. With current densities greater than two amperes per square inch, a forced air

draft or immersion in oil is necessary. A rectifier provided with ventilating fins and immersed in oil has been operated continuously at 3.5 amperes per sq. in. The necessity of making special provision to dissipate the heat developed is due to the fact that for a given capacity, the volume and therefore the radiating surface of the rectifier itself are comparatively small.

Characteristics of Single Rectifiers

Although at first thought the fact that contact is made with the exposed surface of the oxide layer would suggest a certain similarity to contact rectifiers such as those of the "cat-whisker" type used in radio, a careful investigation seems to point definitely to the junction between the copper and copper oxide as the seat of rectification. The ordinary "cat-whisker" type contact rectifier has a comparatively high resistance and is entirely unsuitable for the supply of any considerable amount of power. Those who have worked with such rectifiers will realize that the apparatus, even discounting its power limits, is unsatisfactory for most uses on account of the instability of the contact and the erratic behavior of the unit as a conductor. The present rectifier is consistent in its behavior, does not depend on a point contact, and the resistance is so low that the rectifier is capable of carrying large currents. The whole area at the junction between the copper and the oxide participates in the rectification and there is nothing that would suggest the idea of a sensitive spot such as is characteristic of the contact rectifier.

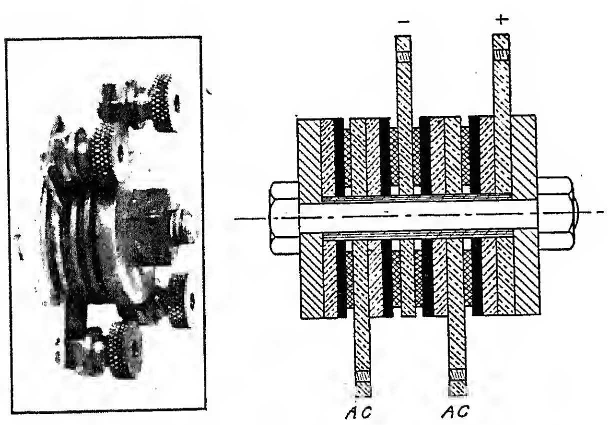

Fig. 3—Assembly of Full Wave Rectifier

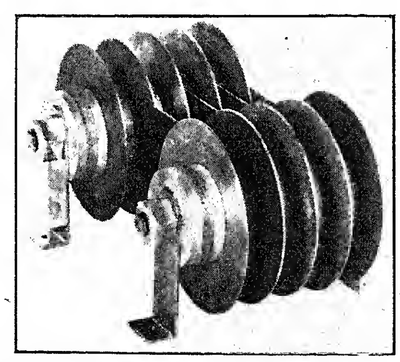

Fig. 4—Assembly Showing Series Parallel Connections used for High Capacities

The following curves illustrate the points that are emphasized in the preceding paragraph. Fig. 5 shows the relation between current and electromotive force in the two directions through the copper oxide. In this figure, the part of the curve that represents the current in the high-resistance direction has been drawn to a scale 1000 times as great as the remainder of the curve. The scale for currents above the horizontal axis is in amperes; the scale below the horizontal axis is in milliamperes.

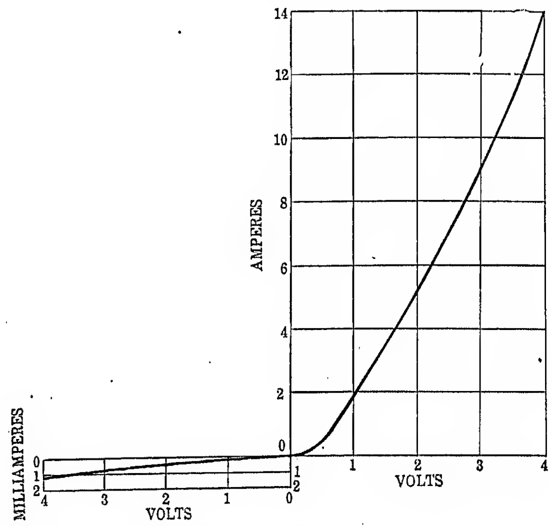

Fig. 5—Current Voltage Characteristics of Copper-Copper Oxide Element

Fig. 6 gives the relation between resistance and electromotive force. The negative values of electromotive force correspond to the high-resistance direction. The resistances approach a common value as the voltage approaches zero. As the voltage is increased from zero, the high resistance increases and the low resistance decreases, at first very rapidly, and then at a decreasing rate as the voltage increases. The low resistance con-

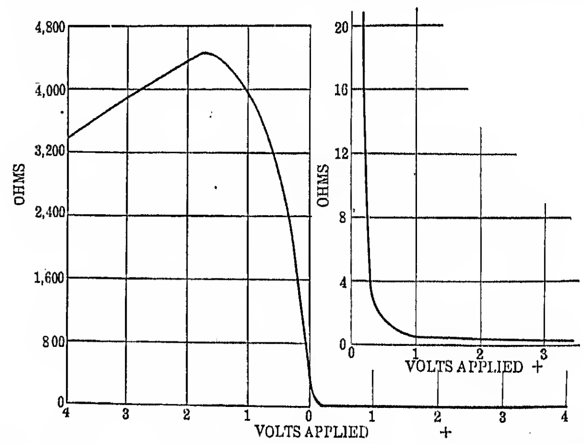

Fig. 6—Resistance Voltage Characteristics of Copper-Copper Oxide Element

tinues to go down practically along an exponential curve while the high resistance increases to a maximum beyond which it decreases slowly with further increase in voltage. The low resistance is shown in the curve in the upper right hand corner with the scale magnified 200 times. The ratio between the two resistances

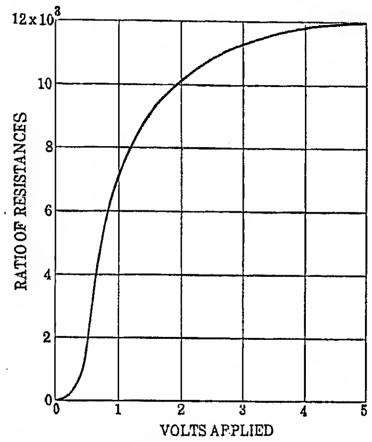

FIG. 7—RELATION BETWEEN RATIO OF RESISTANCE AND VOLTAGE APPLIED TO RECTIFIER

increases up to values well beyond those at which the rectifier may be allowed to operate.

The rectification ratio, which is obtained by dividing the low resistance at any particular value of e. m. f. into the high resistance at the same e. m. f., is shown in the curve of Fig. 7. This ratio bears a definite though

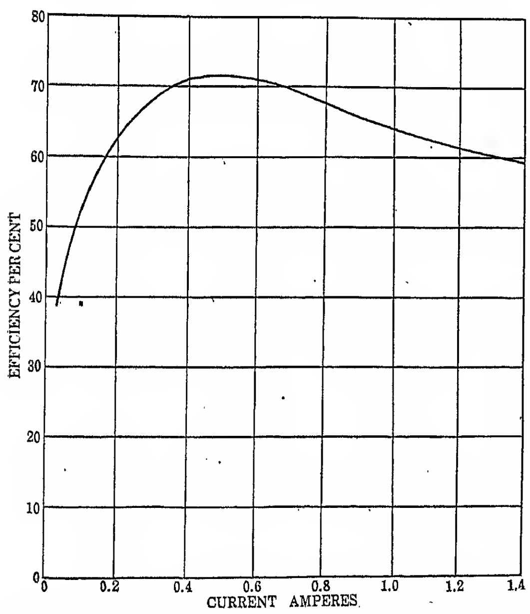

FIG. 8—EFFICIENCY OF FULL WAVE RECTIFIER CONSISTING OF FOUR DISKS

not a simple relation to efficiency. The relation between the two is complicated by the fact that in practise the voltage across the elements of the rectifier varies from zero to a maximum which is different in the two directions. The efficiency of a full wave rectifier built with four washers is shown in Fig. 8. This is an average unit. The efficiency here shown is the ratio of d-c. watts output to a-c. watts input. True power efficiencies of over 80 per cent have been observed. Since the rectification ratio at very low voltages approaches unity, it follows that the efficiency of the unit as a rectifier at very low voltages approaches zero. At the voltages that are common in the usual applications of a rectifier, the ratio is so high that variations are not often important. A few principles that have to be kept in mind in the design of rectifiers are given below.

DESIGN

For most applications, the losses due to reverse current should be taken into account although they are small. This may be seen from the following considerations.

In a full wave rectifier connected as shown in *b* of Fig. 2, the voltage across each element during the part of

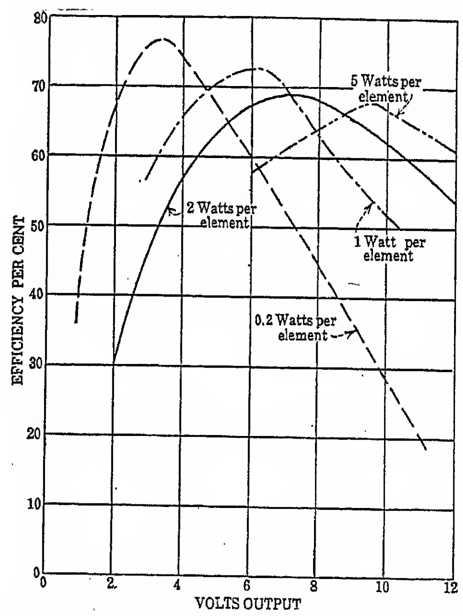

FIG. 9—EFFICIENCY WITH VARIOUS VALUES OF CONSTANT POWER

each cycle when the voltage is applied in the high-resistance direction is considerably greater than the voltage applied in the low-resistance direction. Usually the voltage applied in the high-resistance direction is such that the rectifier is working well beyond the maximum of the high-resistance-voltage curve (Fig. 6). For these reasons the ratio of the current in the low-resistance direction to the current in the high-resistance direction is considerably less under actual working conditions, than the ratio as shown in Fig. 7 of the high to the low resistance measured at the same voltage.

Fig. 9 shows the true power efficiency of a rectifier made up of four 1½-in. elements as shown in Fig. 3. The power output was kept constant for each curve, the designating number of each curve being one-fourth the total power output. Points to the left of the maximum efficiency represent an excess of losses in the low

resistance direction; points to the right, an excess of losses in the high-resistance direction. If a given rectifier is used to supply a practically constant output voltage, as is required for battery charging service, the losses in the high-resistance direction remain nearly constant, while the losses in the low-resistance direction decrease with a decrease in charging rate. For this reason, it is sometimes advisable to use a larger number

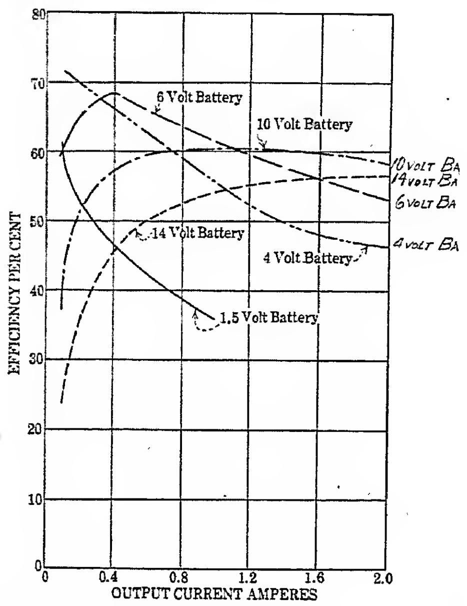

FIG. 10—EFFICIENCY OF FULL WAVE RECTIFIER USED AS BATTERY CHARGER

of elements for a rectifier with a small output than is required for one with a larger output.

The number of elements required for a given power output depends also upon the method of cooling. The manner in which the elements are to be connected, *i. e.,* the number in series and the number in parallel, may be determined from curves such as those shown in Fig. 9. To obtain maximum efficiency in a complete unit, the number of elements in series between any two terminals of the rectifier is found by dividing the desired voltage output by the voltage giving the maximum efficiency on the corresponding curve. Enough elements are to be connected in parallel to give the desired current output, keeping the output per washer at the value previously decided upon. If the method of connecting that is shown in *a,* Fig. 2 is used, the number of washers in series should be doubled, thereby operating each element on the same portion of the characteristic curve as in the four-cell type rectifier.

For applications requiring a current of a few tenths of an ampere or less, such as supplying the plate current of vacuum tubes, it is sometimes necessary in order to obtain the maximum efficiency to use an element of less than 1½-in. diameter, or else to use a smaller output per washer than would be used in other applications. This can be seen from the curves, for the maximum efficiency (1½-in. washers) occurs at low current values only for the curves of small values of output per element.

CHARACTERISTICS OF RECTIFIER GROUPS

Fig. 10 gives the efficiency of a rectifier group used as a battery charger. Since in the charging of a battery we are interested in the average value of the direct current, efficiency is taken as the ratio of d-c. volt-amperes to the a-c. watts, and is less than the power efficiency.

The oscillograms of Fig. 11 show how the relation between the battery voltage and the a-c. voltage impressed on the rectifier affects the wave form of the charging current. These currents result from a combination of the steady battery voltage and the fluctuating voltage supplied by the rectifier. The portion of the cycle during which charging current flows into the battery increases with the increase of the applied voltage.

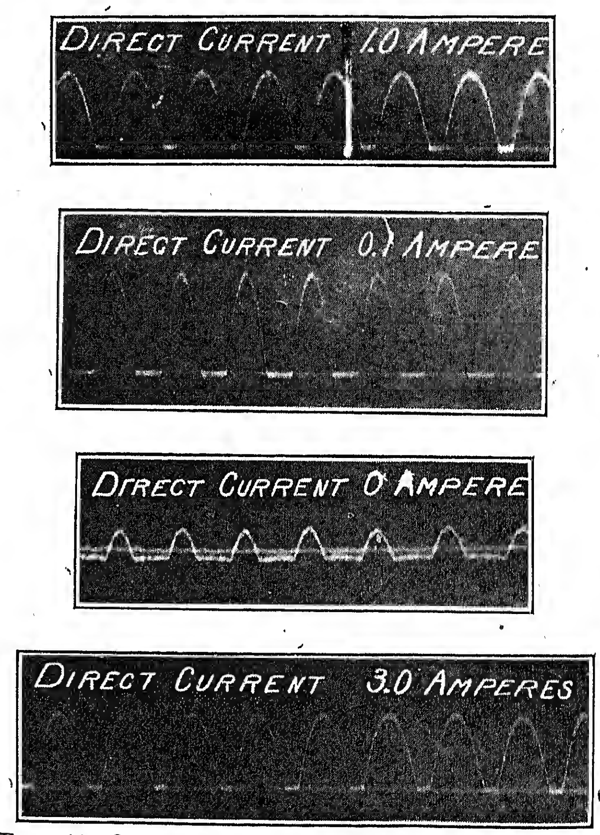

FIG. 11—OSCILLOGRAMS OF CHARGING CURRENT IN SIX-VOLT BATTERY WITH DIFFERENT VALUES OF A-C. VOLTAGE APPLIED TO THE RECTIFIER

The form factor of the rectified wave has been found to vary in different units between 1.13 and 1.25. The form factor of a pure sine wave is 1.11. The oscillograms of Fig. 12 represent the wave forms of the rectified current from a full wave and a half wave rectifier in a non-inductive load. On account of the fact that the resistance varies with the voltage applied, the low values of current are a little lower than they are in a sine wave. The distortion is barely noticeable.

The rectifier may be used at any ordinary frequency without any effect on its operation. It has been tried with measuring instruments and found to give good rectification up to a frequency of over 3,000,000 cycles per second[3]. Above 100,000 cycles per second, there is a gradual decrease in rectification ratio which may be due to capacity.

The effect of temperature on efficiency may be compensated in various ways and the following is an illustration of what may be done by the proper choice of

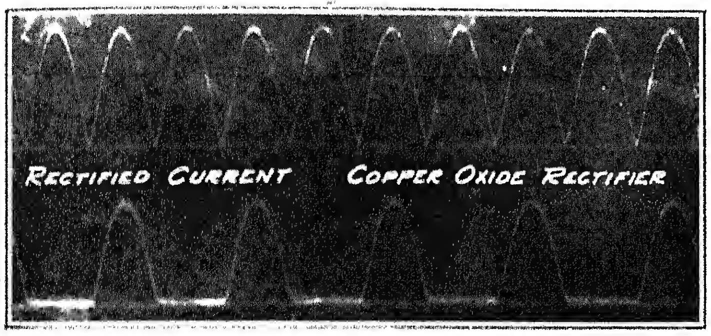

FIG. 12 OSCILLOGRAMS OF RECTIFIER CURRENTS IN NON-INDUCTIVE CIRCUIT

the size of the unit and by the use of a reactive ballast. The problem under consideration was to supply a certain constant amount of rectified power at all temperatures from 0 deg. cent. to + 80 deg. cent. with a constant voltage supply. The results are shown in the curve of Fig. 13.

The voltage regulation of a rectifier depends primarily on the effective resistance of the unit. It may be pointed out that just as in a battery of storage cells or of primary cells, the regulation may be controlled by varying the number of cells that are put in parallel, so in the case of this rectifier it is possible to control the regulation. Within reasonable limits, practically any excellence of regulation can be obtained by building into the rectifier the necessary amount of copper. In a test of a rectifier of small capacity, the regulation between no load and full load was changed from 16.5 per cent to 8.5 per cent by doubling the amount of copper in the rectifier.

THEORY

While the investigation of the new phenomenon has not yet been carried on to a point where it is fully understood, it is safe to say that it cannot be explained by application to it of the theories which are usually advanced in connection with contact rectifiers.

One of these theories is based on thermoelectricity. Since the oxide in our rectifier is very often not over 0.0015 in. in thickness, it is difficult to imagine any considerable temperature difference between the two surfaces. In addition, experiment shows that the asymmetric resistance is concentrated at or very near the surface of the junction between the oxide and the copper and that the heating of this junction produces an e. m. f. which is in the wrong direction for the rectification that actually takes place. The thermoelectric explanation is, therefore, not tenable.

Another explanation that has been adopted by some physicists is based on electrolysis. This explanation is probably applicable to some contact rectifiers. Where it is applicable, the rectifiers have characteristics that are easily recognized. They require some time after the e. m. f. is applied to reach their steady state. The current is very irregular and shows frequent and very sudden variations. After operation for a comparatively short time, products of electrolysis appear and the rectifier deteriorates. The rectifier under consideration has none of these characteristics. After the application of the e. m. f. it is immediately operative in its steady state. The current is smooth as would be expected with a conductor that has a definite value of resistance for each value of e. m. f. There are no indications of products of electrolysis even after operation for a year or two with current densities of 0.5 ampere to 1 ampere per sq. in. It seems safe to say that the explanation based on electrolysis must be rejected.

Schottky's[4] theory, involving the work required to carry an electron across the boundary between the two substances, also fails to give a satisfactory explanation

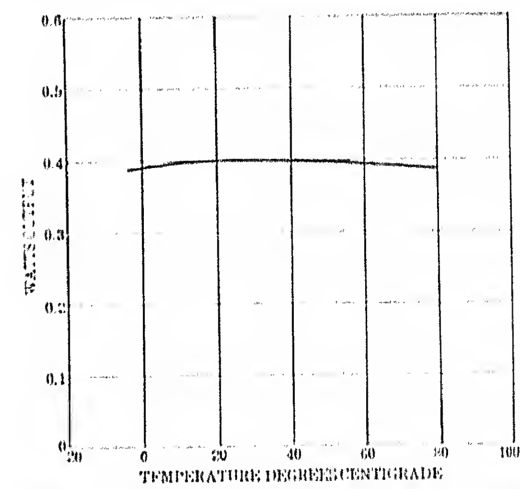

FIG. 13 OUTPUT POWER AT TEMPERATURES BETWEEN 0 DEG. CENT. AND 80 DEG. CENT.

as it is probable that the electron affinity of copper is greater than that of copper oxide.

Jolley in his book on Alternating Current Rectification mentions a theory which assumes a double layer, each half of which is made up of one constituent of the crystal. This condition may exist in the present instance at the surface where the two substances are joined to each other. It may be that beyond the last layer that contains oxygen atoms, there is a layer of

3. Data obtained through the courtesy of the Research Laboratory, Westinghouse Electric and Manufacturing Company.

4. Schottky, *Zeits. fur Physik*, 14, p. 63, March 1923.

copper atoms all, or most, of which are in chemical combination with the oxygen. It is not easy to get a mental picture of the action of such a double layer. It may have value when taken together with the work function considerations.

One of the present writers[5] has proposed a theory based on the fact that the copper and the oxide are in very intimate relationship. The transfer of an electron from copper to oxide, or vice versa, may then take place without passing through the whole potential drop represented by the electron affinity of either substance, but only through a potential drop corresponding to their difference. Under this condition it is conceivable that even at room temperature and without any application of e. m. f. a great number of electrons are able to escape from the copper and into the copper oxide. The copper then serves the same purpose as the hot wire filament in a vacuum tube, and maintains an atmosphere of electrons in the oxide in excess of the normal amount. On account of the short distance between the electrodes, the comparatively large area, and also probably assisted by the dielectric constant of the oxide, the resistance to the flow of electron current in the direction from the copper to the oxide is small.

When the e. m. f. is applied in the opposite direction, there is a tendency to drive the electrons back into the copper. This is opposed by the ready diffusion of electrons from the copper into the oxide so that the electrons become concentrated near the surface of the copper. The resultant gradient in electron concentration in the oxide produces a potential gradient which opposes the flow of electrons in the direction from oxide to copper. This theory seems to fit the voltage resistance curves very well. Experiments are under way which will test it more completely.

Practical Applications

The simple structure, excellent performance, and promise of long life of this rectifier make its use in practical applications seem particularly desirable. Engineers are already recognizing and beginning to exploit these characteristics.

In discussing the possibilities of the new rectifier, a prominent engineer suggested the idea of an entire automatic substation in the form of a tank mounted on a pole with the transformer, rectifier, and suitable switches housed in the tank. The complete absence of the requirement of servicing the rectifier, the length of its useful life, which gives promise of being very great, possibly even equal to that of the transformer, make this idea seem very likely to become practical.

The rectifier gives a smooth rectified current which looks very much as though it had been commutated by means of a perfect commutator. It is very constant in its characteristics, requires no electrolyte, and does not involve any moving parts or contacts to be made or broken; in fact, it consists only of parts that are solidly bolted together. It requires no attention or servicing, and can be built into units to meet any reasonable requirement of current and voltage. Each element represents a relatively small increment of current and voltage and they may be assembled into groups just as storage cells are assembled into batteries. The following are meant to be suggestive illustrations, rather than a comprehensive list, of its immediate uses.

5. L. O. Grondahl, *Science*, September 24, 1926, Vol. 64, No. 1656, pp. 306-308.

1. Instruments. A practical use to which the rectifier has been put is in connection with d-c. instruments used on a-c. circuits. Here it is found exceedingly convenient. With a wavemeter, for instance where it has been common practise to use a thermocouple meter, the rectifier is advantageous. A thermocouple takes some time to reach a condition of equilibrium so that after every setting of the wavemeter, the operator has to wait for the instrument to reach a steady state. The rectifier responds instantly and in wavemeter work, therefore, it is possible to proceed very much more rapidly with a rectifier meter than with a thermocouple meter. It is also very sturdy, so that a temporary overload causes no injury to the rectifier. In general, the rectifier with a d-c. instrument is very convenient for reading small alternating currents. As is seen from the curves, the rectifier is not sensitive at low values of power so that there is a limit below which the rectifier is very inefficient. This limit is very low and the instrument can be used satisfactorily down to a few micro-amperes. Here it is important to match the impedances of the rectifier with the instrument and of the rectifier-instrument combination with the source. The impedance of the rectifier changes with the power so that an instrument that is well matched for one range is not necessarily satisfactorily matched for another range. The desired results may be obtained by matching impedances for the lowest range and the scales can be adjusted to take care of the higher ranges.

The direct-current output of the rectifier at low values of power is approximately proportional to the square of the a-c. input.

For reasonable precision in measuring instruments, it is necessary either to provide temperature compensation for the resistance variations in the rectifier or to choose the constants of the instrument so that the resistance variations of the rectifier are unimportant. This has been done very satisfactorily in special applications. Both the high and low resistance of the rectifier have a high temperature coefficient. The temperature change in the efficiency of a rectifier is due in part to the changes in resistance and in part to the changes in pressure due to the unequal expansion of the bolt and the other parts from which the rectifier is made. Pressure changes may be used to compensate partly for the resistance changes. Compensation may also be accomplished by introducing in the circuit

resistances which have an effect that is opposite to that of the rectifier itself.

For use with very sensitive instruments, the rectifier should be protected against illumination. Illumination not only changes the resistance, but produces a small e. m. f. in the rectifier.

2. General Battery Charging. The application of chargers are as numerous as the applications of storage batteries. The automobile starting battery may be used as an illustration since it is very often found

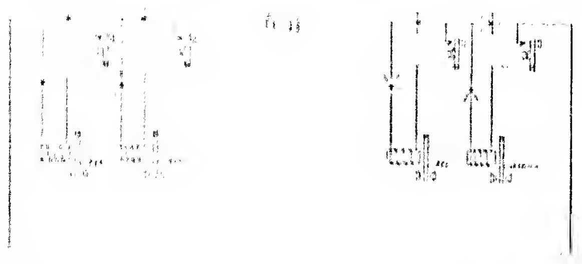

Fig. 14 Circuit Arrangement Using Rectifier for Duplex Telegraphy

necessary to give it an extra charge. This is usually a very inconvenient thing to do on account of the necessity of getting into the battery case and making the necessary connections. A small transformer and rectifier could be installed either in the automobile or on the wall of the garage with a plug on the instrument board or in some other convenient place so that the connection necessary for charging would be very simple. In such an application, the rectifier is especially practical on account of the fact that it is very sturdy and requires no attention. The charging of telephone and other storage batteries may be arranged as desired in accordance with the principles already laid down.

3. Control Apparatus. The control of electric circuits is usually accomplished by means of electromagnets. Electromagnets are more easily operated by means of direct current than they are by means of alternating current and the provision of a rectifier with each magnet makes this possible. Thus, for instance, d-c. switch magnets and circuit breaker magnets can be used on a-c. lines.

4. Telegraphy. A system of duplex telegraphy has been proposed which is given in outline in the diagram of Fig. 14. This makes it possible by the use of alternating current and a rectifier to polarize the line so that any telegraph line can be duplexed by simply adding a sending instrument and a receiving instrument and four small rectifiers at each station of the line. If the rectifiers are of the half-wave type, the operation of one sending key will transmit the upper half wave, which will be received by the sounder which is associated with another rectifier which also transmits the upper half wave. When the other sending key is used, the lower half wave is transmitted and this operates the sounder at the other end which is associated with a rectifier that transmits the lower half-wave. Such a system seems practical when one can use rectifiers that are reliable and the capacities of which are easily adapted to the purpose in question.

5. Detectors. The rectifier in its usual form is not suitable for a radio detector, but can be used in a similar way in circuits which involve larger amounts of power. For instance, if it is desired to get a current pulse through a transformer by making and breaking the current in the primary, a rectifier can be used to make the pulse uni-directional. In such cases, the rectifier serves the same purpose as a detector on a very much larger scale.

6. By-pass for Field Switches. With motor or generator field switches, provision has to be made to guard against the injurious effects that may result from the sudden release of the energy of the magnetic field. A rectifier connected between the terminals of the switch in such a direction that it opposes the flow of the direct current serves as a low resistance for the inductive surge that accompanies the opening of the switch and is very effective. A very high resistance rectifier may be used since the voltage of the field discharge is great and the energy loss in the rectifier may be made negligible. It is already in use in a number of similar applications for the protection of relay contacts.

7. Edison Direct Current Systems. In Edison direct-current systems a rectifier of this type has peculiar advantages due to the fact that it is static and can be assembled into units of any desired capacity. A large unit might be made up of a number of smaller standard units constructed so that the capacity of the rectifier may be altered as required by the load. Such a rectifier is entirely noiseless and the only moving parts are the fans or pumps necessary to carry away the heat.

8. Radio. An interesting field for rectifier manufacturers has been the radio field. Here again, the rectifiers are used as battery chargers.

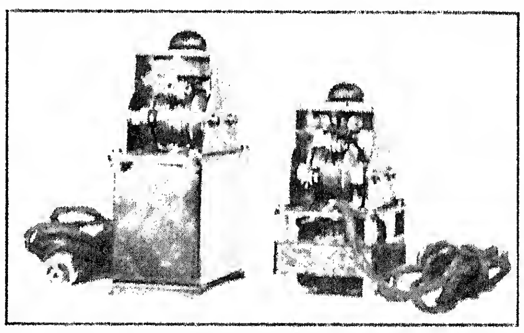

Fig. 15 "A" Battery Trickle Charging Unit

"A" batteries are very often maintained by what is known as the trickle charge method and tube rectifiers for this purpose have recently appeared on the market. With some "B" battery chargers it is necessary to disconnect the "B" battery and connect the various groups in parallel. The present rectifier can be built in the proper voltage and current capacities to charge either "B" or "A" batteries and to charge them at a

normal rate or at a trickle charging rate as desired. To charge an "A" battery at a trickle charging rate, a small transformer and a rectifier consisting of 4 to 16 copper disks may be used. Such a unit is shown in the photographs of Figs. 15 and 16. The unit may be assembled in a case together with the "A" battery

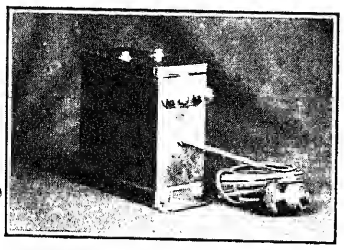

Fig. 16—"A" Battery Trickle Charging Unit

itself. Rectifiers have been designed to meet the demand for 2 ampere chargers and 5 ampere chargers. A 2 ampere charger is shown in Fig. 17.

A "B" battery charging unit for any e. m. f. up to a 115 volt "B" battery may be had by connecting the

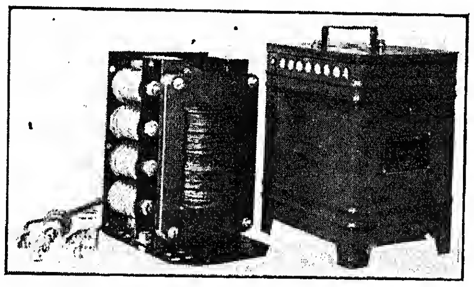

Fig. 17—Two-Ampere, Six-Volt Battery Charging Unit

rectifier with the necessary ballast reactance to the 110 volt house lighting circuit. For a 135 volt battery, it is necessary to use a transformer to step up the alternating voltage. The transformer can be built

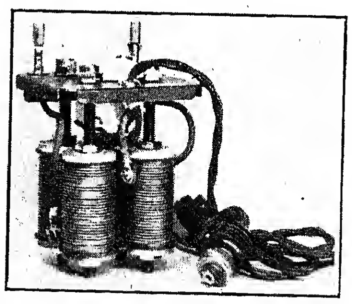

Fig. 18—"B" Battery Charger

with the necessary reactance so that the size of the unit does not need to be any greater in the second case than in the first. With such a unit, it is only necessary to reverse the switch to disconnect the battery from the receiving set and connect it to the rectifier.

The more interesting application of rectifiers in radio is probably in battery eliminators. For this purpose, the rectifiers have to be built with the necessary voltage and current capacity to supply not only the power to operate the tubes, but the power that is lost in the filter. Units have been built which give satisfactory service as substitutes for both "A" batteries and "B" batteries. Fig. 18 shows the interior of a "B" battery charger, which is the same as the rectifier that is used in a "B" battery substitute.

General Discussion of Power Units

Since the units are built up from small elements, the weight per kilowatt capacity is practically independent of the size of the unit. If we take the 1.5-in. washers that are being used at present as our basis for consideration, we find that with proper ventilation, 200 such disks are sufficient to give an output of 1 kw. Two hundred disks correspond to about four pounds of copper and the necessary metal for ventilators and supports is probably equivalent to about 16 pounds more so that the total weight per kw. capacity is about 20 pounds. This weight may be assembled in a space of approximately 400 cu. in. The capacity per cubic foot is, therefore, approximately equal to four kw.

Discussion

G. W. Janson: Schemes such as that shown in Fig. 14 have been tried at various times by communication engineers, in their efforts to increase the output of telegraph circuits. The possibilities of these arrangements have, however, been generally limited by factors other than the effectiveness of available rectifying means. However, there are probably many other valuable uses for a rectifying element having the excellent characteristics described in this paper.

Several questions have occurred to me which would be of interest to those seeking to adapt the element to purposes other than converting an a-c. supply to a d-c. supply.

What is the maximum voltage per element which may be applied before the rectifier passes a-c.? Are the characteristics of the rectifier permanently changed after that maximum voltage has been applied? Has the rectifier been used for application to loads of varying resistance and are the voltages under such conditions affected differently from those shown in the curves? Are there any polarization effects?

Another question that might be of importance is whether any time lag exists between the application of a potential to the flowing of direct current. I wondered, for example, whether the resistance ratio curves and the data on resistance at various voltages were determined by d-c. methods or by a-c. methods. If by a-c. methods, would those ratios be different for the steady d-c. state?

A. G. Oehler: When a rectifier is made of a number of elements connected in series, does the voltage or the power rectified in each unit divide up equally over all of the elements? What factors of design or what inherent characteristics limit the voltage which can be rectified by this rectifier?

George Crisson: The system of signaling described by Messrs. Grondahl and Geiger is of interest because it accomplishes duplex operation by very simple means which do not involve the problem of line balance.

Certain effects occur in this system, however, which are not encountered in the telegraph systems now in use. These effects, which are due to the fact that the velocity of propagation of a wave over a telegraph wire is not infinite, put definite limits on

the distance over which signaling can be carried on without the use of repeaters.

No reason is seen why the system should not operate satisfactorily when the length of the line is a small fraction of the wave-length. The operation of any key will cause changes in the strength of the current in the corresponding instrument at the other end of the line so that signals can readily be sent but will not affect the instruments in the second channel.

As the distance from the generator to the end of the circuit increases, the behavior of the system becomes more complex. Operating a key has less effect on the corresponding instrument at the far end, and begins to produce changes in the current of the distant instrument in the second channel. This effect is due entirely to the fact that a finite time is required for a wave to travel from the generator to the key and back. It is quite distinct from the weakening of signals due to losses in the line.

The system would become inoperable when the distance from the alternator to the key has increased to one-eighth of the wave-length, or the total length of the line has reached one-quarter of the wave-length, assuming that the alternator is located at the middle.

Assuming that a frequency of at least 200 cycles would be required to avoid operating difficulties caused by the periodic nature of the current, the greatest length of line workable by this system without repeaters would be about 200 mi. for non-load open wire lines, and a much shorter distance, in the neighborhood of 50 mi., for non loaded circuits in cable. Practically, the lengths would have to be still less to allow for a safe operating margin and for various factors not considered in this simple treatment.

This system could not be applied to composited lines without modifying the compositing apparatus, which separates the telephone and telegraph currents at each end of the line in such a way as to encroach seriously upon the range of frequencies required for the telephone.

Of course, for classes of service permitting the use of a frequency lower than 200 cycles, the workable length of the line would be increased and the difficulty of applying the system to composited lines would be somewhat reduced.

Joseph Slepian: Four to five years ago in meditating about the usual thermionic rectifier—that is, a rectifier consisting of two electrodes in a high vacuum, one electrode heated—it occurred to me that probably other types of rectifiers were based upon essentially the same phenomenon, that is, the presence of three suitable materials, two metallic conducting electrodes, and an intervening material. In the case of the thermionic rectifier the part of the intervening material is played by the vacuum.

In this combination of three materials, the electrodes are good conductors of electricity. The intervening vacuum by itself is an insulator but if electrons are somehow supplied to it, it becomes a good conductor. In other words, electrons can move freely in this vacuum if they are provided.

Now it seemed to me that it might be possible that other insulating materials than a high vacuum would have this same property, so that it might be possible to take two metals and put an insulating material in between them, this insulating material having insulating properties ordinarily not so much because it obstructed the flow of electrons but because it, itself, lacked free electrons. Now, if one of the electrodes was able to supply free electrons to the insulating material, and the other not, a rectifier would be obtained.

Of course if such a rectifier was to be practical, this insulating material would have to carry electrons rather freely, but the electrons would have to be supplied to it by the adjoining electrodes. It seemed, of course, that this intervening insulating material would have to be very thin, because you could not expect the electrons supplied to this material to move through it so freely as they will do in a vacuum. I thereupon set out to investigate the properties of thin insulating films between unlike electrodes, and for a little over two years I examined all kinds of combinations to get a very thin layer of insulating material.

I considered films formed chemically, and I got results that were frequently promising, and which led me to continue my work, but I never got anything that looked practical, or appeared to be worth following in greater detail.

Then I heard that a man from one of our neighboring companies, the Switch & Signal Co., had devised a rectifier consisting of copper and copper oxide for which great claims were made. I rather scoffed at it when I first heard about it, as I had already experimented with copper oxide. I had placed sheets of copper oxide against various metals and observed some rectification, but always the rectification was small and rather erratic.

A little time later some of these oxidized copper washers were supplied to me at the laboratory and I proceeded to test them, not expecting very much, and was quite amazed at the results. The rectification was steady to an unbelievable degree. After the experience of my two years work it seemed absolutely revolutionary. I had never seen or heard of anything like that in a rectifier of this type, and I looked into the rectifier more closely and was interested to find it had just the elements I was looking for. The ideal that I had been working for seemed to be realized in this rectifier that Mr. Grondahl had provided.

The rectifier consists of two bodies of metallically conducting material; namely, the copper and the oxide, and an intervening insulating layer. I have proved the existence of this layer between the oxide and the copper by making capacity measurements. The electrostatic capacity has such a magnitude as to indicate that the rectification takes place in a layer less than a 0.0001 cm. thick between the oxide and the copper.

It is most astonishing that a rectifying layer is obtained by such simple means as forming the oxide on the copper. It is also very astonishing that this rectifying layer is obtained only between the copper oxide and the metal on which it was formed. A piece of copper oxide by itself clamped against a piece of copper will give some rectification, but of an altogether different order and quality from that obtained where the oxide is formed on the copper itself.

B. O. Adkerson: Does the use of foils of other metal than lead, *e. g.*, aluminum and gold, change the resistance of the rectifier in the two directions? If the resistance is affected what is the amount of such change?

Fig. 6 in the paper shows the voltage-resistance characteristic curve of the rectifier between plus and minus 4 volts, and in reply to a previous discussion it was stated that about 30 volts was the maximum that one element would sustain. Does the resistance decrease continuously to zero as the negative potential is increased to this maximum? If it does not, what is the resistance at the point of discontinuity, *i. e.*, just before puncture occurs? When the rectifier is once rendered inoperative by exceeding the maximum voltage, will it automatically reform upon reducing the voltage, similar to an electrolytic rectifier, or is the element useless unless the copper washer is again oxidized?

Dr. Eccles' rectification theory, mentioned in Jolley's Alternating Current Rectification, indicated that rectification may occur at hot points of contact between or in the rectifying materials. Does the difference of potential across the rectifier, as determined by a rapid oscillograph, differ in any way from that across a pure resistance of equal ohmic value, when current is made and broken through it, *i. e.*, is there any evidence of a potential difference other than the RI drop caused by the passage of the current?

Does the instantaneous response of the rectifier, mentioned in connection with wave-meter work, mean that the time required for the rectifier to reach a steady state is negligible, as considered from a practicable point of view, or that there is no perceptible change of current with time as determined by the oscillograph? If there is a change of current what is its approximate magnitude,

is the current increasing or decreasing with time, and does the change occur in both directions through the rectifier?

L. O. Grondahl: The first question is with reference to maximum allowable voltage. The curve that gives the relation of the resistance in the high-resistance direction to the voltage shows that the resistance decreases with increasing voltage above two volts. We think of three volts in the high-resistance direction as being a normal counter-voltage for the rectifier to withstand. We are using them, however, in large units up to six volts with additional radiating surface. Within the limits mentioned it is only a question of carrying away the heat. When higher voltages are used the losses in the high-resistance direction make it difficult to carry away the heat generated.

The resistance curves in the paper were taken with direct current. There is no polarization. There is a very slight change in current in the high-resistance direction, but it is immaterial and a large part of it is explainable as due to rise in temperature. It is not in the right direction to be caused by polarization. We have tried rather carefully to find a back current such as exists in a cell that polarizes. We have not been able to find anything of that kind.

That answers the question also in regard to the various loads. The effect of varying the load is illustrated in the efficiency curve. In that case the various loads were obtained by simply changing the load resistance.

There seems to be no tendency for one unit to pick up the load and carry it to the exclusion of the other units. It divides itself exactly in terms of the resistances of the elements. As far as our experiments show up to the present time the rectifier behaves as if it were a pure resistance phenomenon.

In some rectifiers, one rectifier will pick up the load for a little while, and then another rectifier in the series will take its place so that the load darts back and forth between the elements. That does not happen here at all. The load is evenly and steadily distributed.

We have a unit in the laboratory that we have been using for eight or ten months now, supplying one ampere at 1500 volts for oscillators. It has been a reliable supply without any maintenance.

On the question of forming first of all, there is no such phenomenon as forming in connection with the rectifier as far as we have been able to determine. When I say that it operates instantaneously, I mean that the time required for the current to start and for the final condition to be set up, as far as rectification is concerned, is as nearly instantaneous as you can get it with the inductance that you have in the circuit. It depends upon the inductance in the circuit rather than upon the characteristics of the rectifier. The rectifier is a resistance pure and simple as far as its observable qualities are concerned, certainly in operation.

The change in current in the high resistance direction that I mentioned is of very small value and probably has no practical importance at all. If you have 1 milliampere high-resistance current (for instance, back leak, when the alternating current is off and the battery is discharging through the rectifier) it may grow in a little while up to 1.5 milliampere. That is something we have not yet explained. However, there is no effect similar to forming.

You can put the rectifier on direct current in either direction for any length of time, take it off and put it on in the opposite direction, and it behaves just as though nothing had happened to it. You can start it on an a-c. circuit for rectifying after it has been rectifying for a long time, and it behaves exactly the same as when you start it after it has been resting for several weeks.

The question of hot spots: if you go up to very high voltages, say 30 or 40 volts per disk so that you puncture the surface, then you find that it acts like every other dielectric—it punctures in a spot—but we have not found any other evidence of the rectification taking place in spots, or the current being carried in spots.

The lead is used as a contact on the outer surface, because it is more impressionable than other metals that are easily obtainable and makes a lower resistance contact, a slightly lower resistance contact than we get, for instance, with aluminum foil. It is not quite as low as we get with gold foil. Gold foil is inconvenient to handle and sheet lead is practical. So we use the lead. All resistance changes are continuous.

J. F. Dreyer, Jr.: I should like to ask what degree of uniformity exists in these units? Do they vary much in resistance?

L. O. Grondahl: The degree of uniformity depends entirely upon how well we are able to make the manufacturing process uniform. For our train-control work, for instance, we hold them within 10 per cent on the output. That is, those are our specification limits.

H. J. Rosenberger: Four questions came to my mind: (1) What oxide of copper is used? (2) How do you put it there? (3) How do you keep it there? (4) Does it make any difference how thick that layer is?

L. O. Grondahl: The oxide is the cuprous oxide, the red oxide of copper. It is formed in a furnace and it is formed at such temperatures and under such conditions that it stays.

The thickness is of no consequence at all except that the resistance increases with the thickness since the current has to flow through a thicker layer of oxide. Whether you have two mills of oxide or you have ten mills of oxide, you have identically the same kind of rectifier except for that increase in resistance in the low-resistance direction. The rectification takes place at the junction between the copper and the oxide or so close that we have not been able to distinguish it from the junction.

We have worked as low as 0.001 or 0.0015 in. of oxide, but for practical purposes we use 0.002 or 0.003 in.

D. E. Trucksess: I should like to know if there is any relation between the pressure on the contact and the output. I understand that after the rectifier has been operating for a while the output drops off. Can that output be increased by increasing the pressure?

L. O. Grondahl: The pressure applied seems to have an effect in that it reduces the contact resistance on the outer surface of the oxide. It is necessary to have a contact that is uniform over the whole surface as nearly as possible in order to get the low resistance.

As time goes on, there may be a slight reduction in pressure due to mechanical changes, which may be compensated for by tightening the bolt. As far as we know the pressure is important only in reducing contact resistance.

Measurement of Telegraph Transmission

BY H. NYQUIST[1], R. B. SHANCK[1], and S. I. CORY[1]
Member, A. I. E. E. Associate, A. I. E. E. Associate, A. I. E. E.

Synopsis.—Various factors contribute to impair the quality of telegraph signals. For instance, there may be interfering currents either induced in the circuit or brought in by conduction, the proportioning of the circuit elements may be imperfect or batteries and relays may be out of adjustment. The result in any case is to distort the telegraph signals so that the received signals are not a true copy of those transmitted. The paper describes methods for measuring this distortion and for analyzing the results so as to indicate the nature and extent of the impairment and its probable cause.

THE object of this paper is to describe methods of making measurements of the over-all transmission efficiency of the common types of telegraph circuit and to explain how the results may be analyzed. The most direct and practical method of measuring the efficiency of such circuits consists in determining the lengthening or shortening of the dots, dashes, and intervening spaces comprising the signals by comparing the signals delivered by the receiving relay with the sent signals. This paper will be limited to a discussion of this effect which will be called *distortion,* and a description of methods which have been devised for measuring it.

The electrical characteristics of the circuit and the wave shapes of the operating currents are not dealt with in this paper except to the extent that their effects are included in the results of the measurements of over-all transmission efficiency.

In recent years considerable work has been done by engineers of the Bell System in connection with devising and applying convenient and accurate methods and means for making quantitative tests of telegraph signal distortion. This includes comparatively elaborate and refined apparatus intended primarily for laboratory use and simpler devices suitable for field work. The technical staff has made extensive use of the new devices, and measuring sets for use by the field forces are now under commercial trial.

Various other methods have been used in the past with a view to testing telegraph transmission and the results obtained have been of considerable value. Since little has been published on this subject, a brief discussion of several older methods will also be given.

General Discussion of Telegraph Distortion

The following discussion applies directly to telegraph circuits employing only two different current values[2] thus including substantially all important long-distance wire circuits with the exception of some submarine cables which are operated with three-current values. It may also be applied to many radio telegraph circuits. Considerable modification would be required in order to adapt the ideas outlined herein to the case of circuits employing three or more different current values.

The operation of telegraph circuits by hand or machine involves impressing signals comprising parts of different length or duration at the sending end of the circuit and the reproduction of these signals at the receiving end. The interpretation of these signals depends upon the correctness of the length or duration of the individual signal parts, commonly referred to in the case of a two-element system as "marks" and "spaces" (corresponding respectively to the "closed" and "open" positions of the transmitter). Loudness or strength of the local response is practically never a factor in telegraph transmission since in nearly all cases use is made of local circuit arrangements at the terminals which provide sufficient strength and also avoid any change in strength due to variation in the line circuit. Excessive "lag," that is, time required for transmission over a circuit, is objectionable and, in the case of some printer circuits, variation in lag degrades transmission. Consideration of lag is usually not of importance, however.

An ideal or perfect telegraph circuit reproduces signals at the receiving end exactly as they were impressed at the sending end as regards length of the component marks and spaces, and any change in these lengths during transmission may be considered as lowering the quality. Therefore, the departure from perfection of the received signals, *i. e.* the lengthening or shortening of marks and spaces which occurs during transmission, is a measure of the degradation in transmission quality.

Definitions. It has been found desirable to subdivide distortion of telegraph signals into certain components. The main reason for doing this is that the components are largely due to different and distinct causes and require different treatment for their proper control in both design and transmission maintenance work. Fortunately, it is convenient to separate these components in connection with distortion measurements.

In explaining these components let us suppose a given signal such as the letter C in the American Morse code to be sent at regular intervals over a telegraph circuit and suppose that the signal is formed in such a way that each repetition is substantially perfect at the transmitting end. If the distortion of each of the unit marks or dots of a large number of successive signals

1. Dept. of Dev. and Research, American Telephone and Telegraph Company, New York, N. Y.

2. See *Certain Factors Affecting Telegraph Speed,* H. Nyquist, Trans, A. I. E. E., Vol. XLIII, 1924, pp. 412-22.

Presented at the A. I. E. E. Winter Convention, New York, N. Y., February 7-11, 1927.

is measured at the receiving end and tabulated, it is, in general, found that the distortion differs not only from dot to dot in a given repetition of the signal, but also that it differs from signal to signal for a given dot. Let us obtain the average of a large number of distortions for a given dot and consider each individual distortion as being made up of two components, one the average and the other the individual departure from the average. The average distortion of a given part of a large number of successive signals will be called the *systematic* distortion. The individual departure of one distortion from the average will be called the *fortuitous* distortion.

It is found of great value to subdivide the systematic component of the distortion still further. To understand this subdivision, assume that we are dealing with a telegraph system in which markings and spacings are sent by means of currents which are equal in magnitude but opposite in sign. It is, of course, possible with such a system to transmit the marking by means of negative current and the spacings by means of positive current, or vice versa. The change from one method of transmission to the other is accomplished by interchanging the positive and negative batteries at the transmitting end and at the same time interchanging the connections to the marking and spacing contacts of the receiving relay.

Now let us assume that the systematic distortion is brought about by the fact that the positive battery at the transmitting end is stronger than the negative battery. Further, let us assume that the circuit is such that this will result in lengthening of the marks when positive current is used for transmitting marks. Then, when negative current is used for transmitting marks, shortening the marks by substantially the same amount will result. When the systematic distortion is of such a nature that interchanging the functions of the two current values employed changes the sign of the systematic distortion but not its magnitude, the distortion will be referred to as *bias,* inasmuch as it indicates a lack of symmetry in the circuit.

Now assume a similar telegraph system in which the battery voltages are equal but which gives rise to distortion due to the fact that the current at the receiving end of the circuit is slow in building up. If the current does not have time to reach its final value on the short impulses, the first dot following a long space may be shortened. In this case it is obvious that interchanging the functions of the positive and negative current does not alter either the sign or the magnitude of the resulting distortion, the first dot of the C signal being shortened whether it is formed by means of positive current or negative current. If the systematic distortion is such that it changes neither sign nor magnitude on interchanging the functions of the two current values employed, it will be called *characteristic* distortion.

In general, it will be found, in measuring the systematic distortion, that neither of the two simple conditions considered above exists by itself. When the functions of the two currents are interchanged, it is nearly always found that the magnitude of the systematic distortion is changed but the sign may or may not be. This phenomenon may be described in a simple manner by saying that both bias and characteristic distortion are present and that the bias is reversed but that the characteristic distortion is not. In other words, it is convenient to say that the total systematic distortion, when the circuit is normal, is given by the expression

$$C + B$$

where C is the characteristic distortion and B is the bias and that with the reverse condition the total systematic distortion is given by the expression

$$C - B$$

The separation of the two components is then easily effected by simply adding and subtracting these measured values of the systematic distortion and dividing by two.

We are now in a position to give a definition of the components of the systematic distortion for the general case. Let us call the systematic distortion measured with the circuit normal S_1 and with the circuit altered so as to interchange the functions of the two current values employed S_2. Then the *characteristic* component is defined as $(S_1 + S_2)/2$ and the *bias* is defined as $(S_1 - S_2)/2$.

It should be noted that, in practically all cases, individual factors which cause distortion do not produce pure bias, characteristic distortion, or fortuitous distortion but rather a combination of these. One reason for this is that the effect of a particular factor depends on the extent to which the wave shape has been affected by other factors. Furthermore, distortion produced by a given factor in a particular repeater section depends on the impressed signal combination and this combination is, of course, changed by any distortion experienced previously; this is of importance mainly in connection with circuits made up of a number of repeater sections. As a result, the amount of one component of distortion as determined by the method outlined above depends to a secondary extent on the amount and sign of the other components. Distortion-corrrecting devices such as the Gulstad vibrating circuit[3] also tend to prevent linear addition of increments of distortion. It will be apparent from the foregoing that in order to obtain accurate data on total distortion, measurement should be made over the entire circuit with all components present.

In practical field work it is most generally desired to obtain a measure of the maximum total distortion which may be expected to occur at fairly short intervals. This maximum distortion is reached or exceeded when

3. Described in *Metallic Polar Duplex Telegraph System for Cables,* Bell, Shanck and Branson, A. I. E. E. TRANS., Vol. XLIV, 1925, p. 316.

comparatively large characteristic and fortuitous components combine with bias in such a manner as to cause a comparatively large total distortion. Since bias is the most readily corrected or neutralized distortion, it is nearly always determined separately.

Many different signal combinations have been used in transmission measuring. The Morse letter C has been used for the most part since this was found to be a fairly severe combination from the standpoint of characteristic distortion. Miscellaneous signals such as occur in actual operation are, in general, preferable to anything else for the measurement of total distortion and are, therefore, used in some methods. For the measurement of bias, the use of "reversals" (a stream of dots and unit spaces) is convenient and gives good approximate data.

Distribution of Different Values of Distortion. It is of interest to note that the distribution of distortions of different magnitude is generally in fair agreement with the normal distribution curve of the theory of probability. This has been shown by results obtained in tests on a number of representative telegraph circuits in the Bell System. A distribution curve showing the quality of telegraph transmission of a particular circuit may therefore be constructed by measuring the total distortion of a number of parts of signals, obtaining the average distortion A, and the probable deviation d from the average. The latter is obtained from the following formula:

$$d = 0.6745 \sqrt{\frac{\Sigma r^2}{N-1}}$$

where N is the number of measurements, r is the difference between the distortion obtained in a particular observation and the average distortion A. The distribution curve may then be plotted from the formula given in Fig. 1.

Fig. 1 shows a typical curve plotted from the results of tests of a particular circuit at a manual operating speed (dotting rate about 12 per second). The basic idea of this distribution curve is that within a particular range of distortion (that is, on the horizontal axis) the probability of the distortion of any particular signal impulse falling in this range is indicated by the area under the curve in that range. Half of the area under the curve is included between the vertical lines drawn at distance d on each side of the vertical line passing through the peak of the curve, it being equally probable that a given impulse will have a distortion within and without this range.

If the distribution of distortion is in accordance with the normal distribution law, the two parameters A and d completely determine the grade of transmission. A circuit with good transmission has small average distortion and a high narrow curve whereas a circuit with poor transmission has large average distortion or a low flat curve or both.

The definition of perfect telegraph signals and the method of specifying the distortion or departure of signals from perfection could be formulated in other ways than that followed in the preceding discussion. However, it is believed that the criteria which have been set forth are very good for manual operation and are fairly good in connection with present printing systems and circuits[4]. As regards the latter, for complete information it would be desirable to determine not only the distortion as defined above but the relative displacement of marks and spaces because synchronism is involved in the operation of these systems.

Effect of Distortion on Operation. A large quantity of data has been collected in connection with tests of different telegraph systems and tests which have been made solely for the purpose of determining the effect

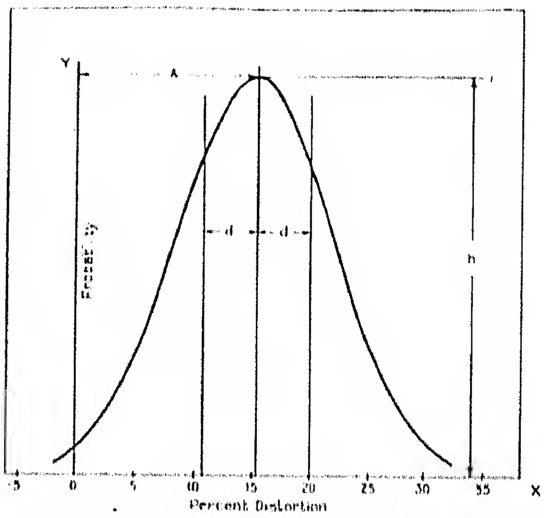

FIG. 1—PROBABILITY CURVE DERIVED FROM TELEGRAPH DISTORTION MEASUREMENTS

Scale of ordinates is so chosen that area under curve is unity. To find probable percentage of all marks or spaces whose distortions fall within a range of one per cent, read off corresponding ordinate from curve and multiply by 100. A = average distortion. d = probable deviation from the average distortion. $y = \frac{h}{\sqrt{\pi}} e^{-h^2(x-A)^2}$

of different amounts and kinds of distortion upon manual and printer operation. The effect of distortion will be discussed only very briefly here, however.

It is thought that the limit which distortion may reach without seriously impairing service is about 35 per cent., as a round average figure, for either manual or printer circuits as used in the Bell System. In order for telegraph operation to be satisfactory, it must, in general, afford communication with very nearly 100 per cent accuracy. In the case of printers, there is no effect whatever until distortion becomes large enough to cause errors. In manual operation, however, the strain on the receiving operator due to distortion, as well as the effect upon accuracy of reception must be taken into consideration.

Methods and Means of Measurement

Several methods of observing telegraph transmission quality, which have been employed in the maintenance of commercial telegraph circuits and in the design and development work of the Bell System, will be described below. Generally speaking, methods 1 to 4, inclusive, are older methods in which standard telegraph apparatus is used in connection with making certain observations and accordingly are discussed only briefly. Methods 5, 6, and 7 are newer methods employing telegraph transmission measuring apparatus specially designed for the purpose and will be treated more fully.

The more elaborate and refined methods have been used to advantage in connection with development work on d-c. and carrier telegraph systems including balancing artificial lines and arrangements for minimizing distortion. They have likewise been employed in designing compositing arrangements by means of which telegraph circuits are derived from wires used simultaneously for telephony. In the case of the d-c. metallic telegraph system,[5] it is believed that it would not have been practicable to evolve a satisfactory design without the use of these or equivalent methods.

The determination of the distortion of telegraph signals as defined above consists essentially in the measurement of comparatively small intervals of time, *i. e.*, very small fractions of a second. For comparatively low-speed operation, that is, at manual speeds and somewhat higher, a reasonable limit of sensitivity of apparatus for measuring differences in time intervals is of the order of about one thirty-thousandth second for refined laboratory tests. For general field work, a sensitivity of the measuring apparatus of about one thousandth second is usually sufficient. These sensitivities are found to be well within the unpredictable variations in circuit performance from time to time.

Measurements of distortion by means of the methods described herein have given results which furnish a good criterion of the quality of telegraph circuits, data thus obtained being, in general, reasonably consistent with observations by highly trained telegraphers in the case of manual circuits, and with printer performance in the case of printer circuits. It will be appreciated that these data, being practically independent of judgment on the part of the observer, are considerably more accurate and dependable than those obtained by older methods in the case of manual circuits. As regards printer circuits, some inconsistency is to be expected, for reasons which were brought out in the discussion of distortion. However, experience to date indicates that relations between the results of measurement of distortion and printer performance are fairly consistent and the new methods should be of considerable value for use in connection with printer circuits.

1. Listening Tests. On manually-operated circuits, the quality of transmission may be observed by means of listening tests. In making such tests, a good sender should send signals at the distant end of the circuit while a competent operator at the receiving end listens to a sounder. The receiving operator then forms judgment as to whether the signals are biased or unsteady and whether transmission is satisfactory or not. Unsteadiness, of course, indicates the presence of considerable characteristic or fortuitous distortion or both. It is very convenient to make these observations since no special apparatus is required. In many cases it can be done without interfering with the normal operation of the circuit.

Experience has indicated, however, that there is considerable uncertainty in connection with such observations since they depend upon personal judgment. Skilled operators with considerable experience in passing judgment on telegraph signals often disagree and a particular operator does not form consistent opinions from time to time. It is, of course, impossible to detect small distortions or differences, as is required in connection with development work. In lining up circuits for service by means of listening tests, improper adjustments may be made in order to overcome faults of the sender or to suit the tastes of individual receiving operators.

2. Meter Observations. Ammeters and voltmeters which are not sufficiently fast to follow all the individual signal impulses faithfully are used to a considerable extent for detecting bias and unsteadiness of circuits when a steady stream of dots and short spaces, or reversals, is sent over a circuit. A measure of the bias is obtained by taking the difference between the meter reading for biased signals and the reading for unbiased signals. The presence of fortuitous distortion is indicated if the meter needle vibrates unsteadily or if sudden deflections occur occasionally. This method is particularly useful in maintaining multi-section circuits, especially those operated at high speeds. It is usually necessary to use the meters in local circuits rather than directly in the line and to take certain precautions to avoid misleading results.

3. Tape-Recorder and Similar Methods. A tape recorder, such as that used in the Wheatstone system of telegraphy, giving a graphic record of telegraph signals has been of considerable use in telegraph transmission investigations made by Bell System engineers but it has been almost entirely superseded by improved testing apparatus. Tape records properly taken and analyzed furnish complete information on the signal distortion (as defined above) and displacement of marks and spaces. The process is complicated and very laborious, however, the results not being available for a considerable time, and the accuracy with available apparatus is not great. However, a quick but rough idea of the quality of transmission may be obtained by merely inspecting the tape records.

In using the recorder, it is preferable to impress a perfect, regularly recurring test signal at the distant end

5. See Note 3.

and take two tapes, one with normal signals and the other with "inverted" signals, that is, with marking and spacing interchanged. A number of signals may then be measured and the components of distortion may then be computed.

Tape recorders have been used in connection with making transmission observations on working telegraph circuits also. Two recorders are employed, one at the sending end of the circuit under test and the other at the receiving end. The effect of transmission over the circuit can be ascertained by comparing received marks and spaces with the corresponding sent marks and spaces.

It has been found practicable with some refinement of standard apparatus to obtain an accuracy of about ± 3 per cent at a speed of 15 dots per second with recorders, corresponding to ± 0.001 second.

A recording voltmeter has been employed to advantage in determining the stability of transmission over telegraph circuits. In doing this, a continuous record is made of received signals while reversals are sent over the circuit. The record will show not only interruptions of material extent but gradual changes in bias.

Other instruments, such as Morse recorders, oscillographs, and "undulators," have also been employed for making records to show the quality of signals.

4. Tests With Printers. The start-stop and multiplex printing telegraph apparatus,[6] which is in general use in this country, is adaptable to simple manipulation which gives a very good indication of the quality of transmission for printer operation. A test which is commonly made is a determination of margin of orientation. Another test which is used in some cases is called a determination of bias margin.

In order to explain these tests, certain basic principles involved in the operation of these systems will be briefly outlined using a typical system for illustration. In the typical system, each printer operation requires five units of line time, five impulses being sent, one after the other, from segments on the sending "distributor" and received in the same sequence on corresponding segments of a distributor at the receiving end. The brushes of the sending and receiving distributors, of course, rotate in approximate synchronism. The receiving segments are shortened so that only the middle portion of each incoming signal unit is used for operating the selecting arrangements and, therefore, distortion must exceed a certain amount before there is any effect whatever upon the accuracy of the received message. A phase or "orientation" adjustment is provided so that each segment may be traversed by the rotating brush so as to receive a signal from the line at the proper time. This permits the obtaining of orientation margin by rotating the ring of receiving segments a short distance, first one way and then the other, until errors appear in the printed copy.

6. See Note 4.

In order to obtain a measure of the quality of transmission of the line circuit, the orientation margin is first determined locally and then a similar determination is made with signals transmitted from a distant station. As the printer may be assumed to be operating on substantially perfect signals on the local test, the difference between the margins found in the two tests is a measure of the distortion of the line circuit.

In making a test of bias margin, the printing apparatus is first tested locally; then with the most favorable orientation setting, the signals are biased in one direction and then in the other until errors are noted in the printed record. Similar tests are then made with the distant station sending over the line circuit. Bias may be impressed at the receiving end, in which case the difference between the range which can be impressed without causing failure and the local bias range is a measure of the excellence of the signals as normally received over the circuit. When bias is impressed at the sending end of the circuit, the corresponding difference is a measure of the amount of distortion with which signals could be repeated into the line without causing failure; this test is, therefore, of most value in checking up parts of long circuits.

For printer circuits, this method has the advantage that measurements are made with apparatus identical with that used in operation and the results are readily interpretable in terms of performance. Good data on total distortion for use in connection with printer operation may be obtained with miscellaneous signals. By noting how failure occurs for various signal combinations in the neighborhood of the limits of the range, some information may also be obtained as to the components of the distortion.

5. Bridge Methods of Measuring Systematic Distortion. In this subdivision there will be described arrangements which have been employed advantageously for a number of years in making accurate measurements in connection with development work. These devices are in the form of bridge arrangements in which galvanometers give direct indication of the amount of systematic distortion. Simple computations from readings made before and after reversing certain connections give data on bias and characteristic distortion. These devices do not measure the total distortion and are therefore not well suited to use in connection with transmission maintenance.

As these arrangements are more accurate than any others which have been available, they have been very useful in showing the effect of small changes in circuit elements. With these devices, it is possible to make design tests on single section circuits, whereas, with less refined methods, it would be necessary to use a number of sections to obtain values of the distortion which could be measured.

One of these arrangements requires synchronism between the sending and receiving ends and is, accordingly, generally used in looped tests; that is, where

both sending and receiving apparatus is located at one point. Another arrangement, which is considerably simpler, does not require synchronism and can be used for either looped or straightaway tests.

A. Synchronous bridge arrangement. The synchronous arrangement for measuring systematic distortion employs a differential method in which signals received over the line are compared with substantially perfect signals in a circuit of the Wheatstone bridge type.

The basic principles of this device may be understood from Fig. 2. As indicated, relay 1 is operated by the incoming or distorted signal and relay 2 is operated by a

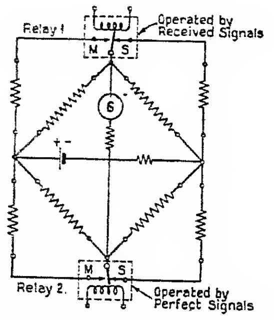

FIG. 2—SYNCHRONOUS DISTORTION-BRIDGE ARRANGEMENT

perfect signal which is sent locally. If the armatures of these two relays move exactly together, there will be no deflection of the galvanometer inasmuch as the four outer resistances all have the same value and the four inner resistances are also equal to each other. It will also be seen that if both relays repeat perfect signals, but with a phase difference, the average current through the galvanometer will be zero. (There is no net effect of armature travel time if it is the same for both relays.) If a particular mark repeated by relay 1 is distorted systematically, there will, however, be a preponderance of current in one direction or the other through the galvanometer every time this mark occurs. Now, if a switching device be provided to close the galvanometer circuit only shortly before the beginning of this mark and open it shortly after its end, a slow-moving galvanometer will indicate directly the sign and magnitude of the distortion, provided the bridge is properly proportioned. Measurement of normal and inverted signals and simple computation will, therefore, afford data on bias and characteristic distortion of this part of the signal and similar procedure will give corresponding data for the other parts.

This device has been used for very accurate measurements of the effect of duplex unbalance and some other kinds of interference by sending the interfering current from a distributor running at a speed slightly different from twice that employed with the bridge and noting the maximum deflection of the galvanometer as it swings slowly back and forth. The bridge is readily adaptable also to the measurement of relative displacement of signal parts or lag, as well as distortion, which may be desired, for instance, in connection with printer operation.

Several bridges of this type have been built which are capable of indicating differences in distortion of about one thirty-thousandth second. A multiplex printing telegraph distributor has been adapted to the sending of signals and performing the selecting operations.

For a detailed description of these arrangements, it is suggested that reference be made to U. S. Patents Nos. 1,435,328 and 1,548,059.

B. "E" signal bridge. This arrangement has the advantage of comparative simplicity and portability and also of being usable for straightaway measurements of systematic distortion. It consists of a simple Wheatstone bridge circuit so arranged that the average current through the meter is proportional to the distortion when an "E" signal having a certain ratio of marking to spacing is used. The accuracy is substantially the same as that of the synchronous bridge arrangement.

In applying this method, an "E" signal with, for example, a space four times as long as the mark is sent repeatedly at the distant station and the bridge arrangement shown in Fig. 3 connected to the receiving end so that the bridge relay repeats the incoming signals. When the tongue of this relay is on the marking contact *M*, the galvanometer current is in one direction and of strength 4; when the tongue is on the spacing contact, it is in the opposite direction and of strength 1; the average is, therefore, zero. A resistance is connected from the tongue of this relay to the right corner of the bridge so as to avoid any effect of time

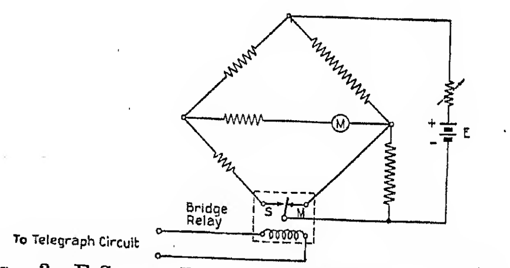

FIG. 3—E-SIGNAL DISTORTION-MEASURING BRIDGE

required for the tongue to travel from one contact to the other. The average current through the meter will be such as to cause it to indicate directly the magnitude and direction of distortion of the unit part of the "E" signal when proper voltage is used.

It is of interest to note that results obtained with the "E" signal have been nearly as satisfactory as those obtained with more complex signals such as the Morse C.

6. Speed-of-Failure Measurement. The speed at which total failure (100 per cent. distortion) occurs is of interest in connection with telegraph transmission

work. The speed of failure must, in general, be materially higher than the operating speed to provide a margin for variations and in order that the circuit may handle signals which are considerably distorted before being impressed upon the circuit.

The "speed-of-failure meter," the essential features of which are shown in Fig. 4, is a convenient arrangement for obtaining a measurement of the breakdown speed of circuits with a regularly-recurring signal such as the Morse letter C. It may also be used for determining the speed of a regularly recurring signal. As will be seen from the figure, the condenser C is

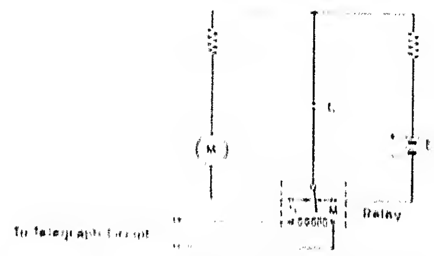

Fig. 4—Speed-of-Failure Meter

charged by the battery E while the relay armature is on marking contact and is discharged through the galvanometer M when the armature is on spacing contact. The time constants of the circuit with the armature on either contact must be small in comparison with the duration of greatly distorted dots and spaces sent at the speed of failure. Then, if a recurring signal is operating the relay at a certain comparatively low speed, the number of impulses passing through the meter is directly proportional to the speed and therefore a slow-moving meter may be made to indicate speed directly.

In measuring the speed of failure, the speed is gradually increased from a low value while the indication of the meter is noted carefully. When the speed reaches the breakdown point, the deflection of the meter, which had been increasing gradually, is suddenly reduced. Although the deflection will then increase further for a time as the speed is increased (until another part of the signal fails), there is no difficulty in noting the breakdown speed with fair accuracy.

7. *New Method for Convenient Measurement of Total Distortion.* This method, which has recently been devised, allows the quick, convenient and accurate measurement of the total distortion of regularly-recurring signals, including both fortuitous and systematic effects. To accomplish this the problem was approached in a different way from that followed previously, the plan being to provide arrangements which would give a response only when the total distortion of signal parts under observation exceeded a particular amount determined by the observer. As has been brought out, since the distribution of distortions of different value is generally in reasonable agreement with the normal curve of probability theory, a few measurements by this method serve to give fairly complete information regarding transmission performance of a circuit.

Two types of transmission measuring sets have been designed for use in the new method, one of these being a simple arrangement intended primarily for field work and the other a more elaborate device suitable for laboratory tests. These sets are arranged so that a condenser is charged during each mark (or space) and a vacuum tube arrangement provided to give an indication whenever the condenser charge exceeds a predetermined amount. In this way, the amount of distortion which is exceeded with a certain frequency, or the frequency with which distortion exceeds any particular value, may be determined. In addition, the sets are arranged for the measurement of bias separately. Synchronism between sending and receiving apparatus is not required so that straightaway as well as looped tests may be made. Since the principles of operation of the two arrangements are nearly alike, the operation of the simpler type of set only will be taken up in detail.

A. Measurement with field-type set. The principles of this set for measuring total distortion of marks and spaces will be described in connection with Figs. 5 and

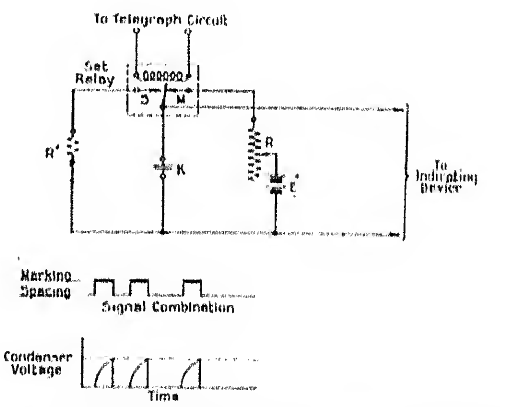

Fig. 5—Circuit for Measurement of Marks

6, respectively. Fig. 5 shows a charging and discharging arrangement which produces a voltage across the condenser K, the value of which depends upon the duration of the mark.

Suppose that the relay is operated by an undistorted normal "C" signal, such as is illustrated in the figure. During each mark the condenser K will be charged, as indicated at the bottom of the figure, to a value which depends on the voltage of the battery E and the value of resistance R. It will be practically discharged through the low resistance R' during each space. By suitably proportioning K and R, the voltage across the condenser K can be made to assume, during the time of a mark, any value less than the voltage of the battery.

Now, if one of the marks is distorted, the condenser voltage will be greater or less than that for an undis-

torted mark, depending upon whether the mark is lengthened or shortened. If, for instance, all of the marks are lengthened, the voltage at the conclusion of each mark will be greater than that for undistorted marks.

The voltage which the condenser attains during a distorted mark may be adjusted to the value for undistorted marks by changing the value of resistance R, the amount of change being a measure of the amount of distortion.

As is well known, in a circuit of this type, the voltage

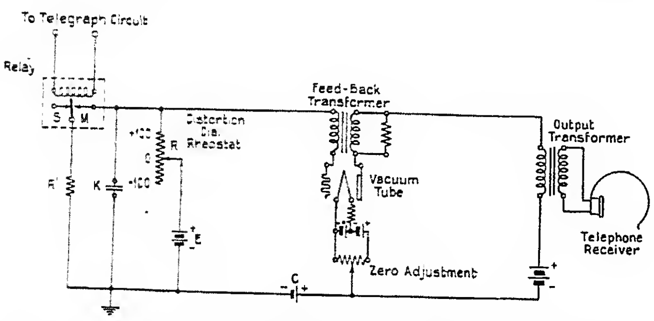

FIG. 6—FIELD-TYPE SET FOR MEASURING TOTAL DISTORTION ARRANGED FOR MEASUREMENT OF SPACES

of a condenser of capacity K, after being charged for time t through a resistance R, equals $\left(1 - e^{-\frac{t}{KR}}\right)$ times the battery voltage, e being the base of Naperian logarithms. If there is a certain percentage increase (or decrease) in time t, the condenser voltage may be brought back to the original value by a corresponding increase (or decrease) in R. Therefore, the change in resistance, expressed as a percentage of the original resistance, is the percentage distortion.

Fig. 6 shows the arrangement of the circuit for the measurement of spaces and includes the essential features of the indicating device. It is seen that condenser K has been connected to the marking contact and the resistance R' to the relay armature, so that the condenser will be discharged during the marking interval and allowed to charge during the spacing interval. The duration of the space thus determines the amount of charge during the spacing interval. The resistance R may be used to control the rate of charge of the condenser and the percentage distortion of spaces determined in the same way as described above in the case of marks.

By reference to the part of Fig. 6 which shows the indicating device, it is seen that the input or grid circuit of the tube is connected across condenser K with a grid-bias battery C in series. The grid-bias voltage is of such value that the plate current is zero until the voltage of condenser K reaches that for an undistorted dot at which time the plate current suddenly increases. This is due to the feed-back effect which is obtained by coupling the input and output circuits of the tube together by means of a transformer. Therefore, the circuit commences to oscillate at an audible frequency whenever the potential of the grid reaches a certain value. This oscillation is allowed to persist for only a short time with the result that a click is heard in a telephone receiver connected in the output circuit whenever the voltage of the condenser exceeds that for undistorted marks.

The arrangements described above are suitable for the measurement of total distortion of marks and spaces of almost any recurring signal combination. In case the signal contains only unit signal parts, as for instance, when measuring the marks of a "C" signal, the distortion indicating dial is set at a position where occasional clicks are present, say several per minute, this value of distortion being taken as the representative maximum lengthening. Now, as the dial is moved towards the negative part of the scale, the clicks will become more and more frequent until a position is reached where clicks are missing only occasionally, this being taken as the representative maximum shortening. When measuring spaces of the "C" signal, undesirable noises are present in the receiver due to the presence of the two long spaces. In some cases this causes difficulty in measuring at high speeds but is not particularly bothersome at manual speeds. If desired these long parts may be measured by adding a lumped resistance in series with the rheostat so that the voltage across the condenser for undistorted parts of the new length is restored to the original reference value.

This set is also arranged to measure directly percentage bias when reversals are used as the test signal, the circuit arrangement for this purpose being shown by Fig. 7. A bridge circuit, containing a meter, is connected

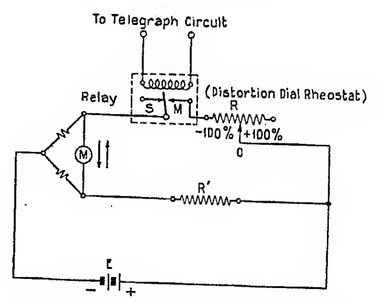

FIG. 7—CIRCUIT FOR MEASUREMENT OF BIAS

to the receiving relay. Equal and opposite currents flow through the meter when the relay armature is on the spacing contact S and marking contact M, respectively, provided that resistance R is one-half of resistance R' and resistances r are small. If the relay is adjusted to repeat unbiased reversals, the average current through the meter will be zero and the meter needle will vibrate through a small amplitude about the zero mark. With biased reversals, the average current through the meter is no longer zero, but it can be brought back to zero by adjusting resistance R. The meter will always indicate zero when resistance R has been adjusted to correspond to the amount of bias, the percentage

change in R being equal to the percentage bias in terms of an undistorted dot length.

It will be recalled that this relation also holds for resistance R when measuring total distortion so that only one calibrated rheostat is necessary. This rheostat is designed to cover the range from plus 100 to minus 100 per cent., with resistances corresponding to 5 per cent distortion for each step. This is sufficiently close for most field work. Intermediate values may be roughly estimated, however.

Before making a series of measurements, the set is calibrated with substantially perfect reversals. In doing this, the relay is adjusted to repeat the signals unbiased and the vacuum-tube circuit is adjusted so that clicks are just produced in the receiver for about half of the dots. The latter is called the zero adjustment and is accomplished by a slight variation in the grid-biasing potential.

In making a measurement over a circuit the bias is first measured, then the marks and spaces of both normal and inverted Morse "C" signals are usually observed to determine the representative maximum to taldistortion. If desired, a rough idea of the value of the characteristic component may be obtained by measuring the total distortion on both "C" signals and reversals and taking the difference, since in the latter case there is practically no characteristic distortion present.

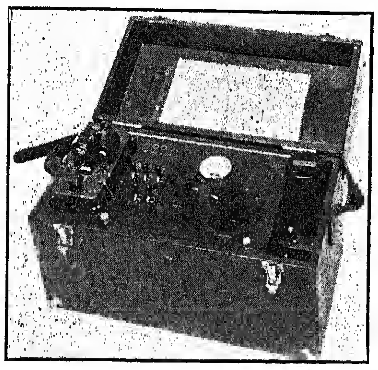

Fig. 8—Field-Type Set for Measuring Total Distortion

Fig. 8 is from a photograph of one of the field-type measuring sets. As may be seen both a neutral relay and a polar relay are provided so that either may be used as the receiving relay. The distortion-indicating dial, meter, zero-adjusting dial, switching keys, and jacks are mounted on a panel which may be locked. Underneath the panel are mounted the necessary batteries, resistances, condensers, transformers, and vacuum tube. A Western Electric 215-A tube which requires only small currents is employed. Accordingly, it is possible to employ a dry cell to energize the filament, and small B batteries. The set is entirely self-contained with the exception of a source of biasing current for the polar relay when receiving with it in an open-and-close local circuit.

B. Laboratory type of measuring set. The essential features of the laboratory type of measuring set are illustrated by Fig. 9. The condenser C_1 corresponds to condenser K of the field-type set and the variable resistance R_1 in its charging circuit corresponds to the distortion dial. Although R_1 might be used for the distortion dial in this case, it has been found more desirable to use a potentiometer P for this purpose. This potentiometer is connected into the charging circuit of condenser C_2 and permits of varying the applied voltage, and consequently, the value of charge taken by this condenser.

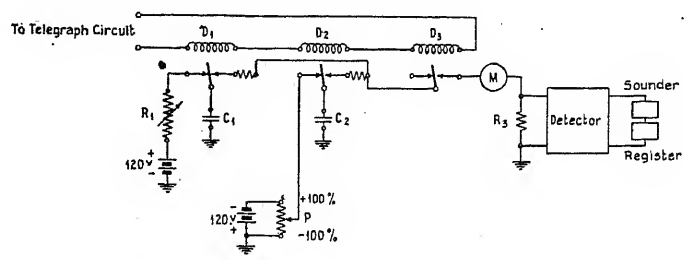

Fig. 9—Laboratory-Type Telegraph Transmission Measuring Set

Schematic Circuit Diagram.

For a given battery voltage the amount of the charge stored on condenser C_1 depends upon the length of the mark (or space), but that stored on C_2 depends, for practical purposes, only upon the setting of potentiometer P. At the end of the mark, the two charges are first combined so that they tend to neutralize each other and the residue discharged through the meter M and resistance R_3. These operations are performed in the proper sequence by the relays D_1 to D_3, inclusive. The potentiometer calibration holds true for any particular speed of signaling, provided the resistance R_1 is adjusted to the proper value for that speed.

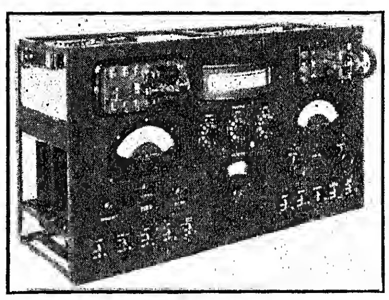

Fig. 10—Laboratory-Type Set for Measuring Total Distortion

To measure average distortion of a recurring test signal the potentiometer is adjusted until the meter M indicates zero, under which condition the charges of the two condensers are on the average equal and neutralize each other. By taking readings with normal and inverted signals, the bias and characteristic distortion may be calculated as explained previously. If an "E" signal is used, good results will be obtained

in this manner. However, with other signals the results being average values may be misleading, as positive distortion of one impulse tends to offset negative distortion of others. If reversals are used for the signal, it may be assumed that there is no characteristic distortion and the measurement will give the bias.

To measure total distortion, the detector shown connected across R_3 is used instead of the meter, this detector being responsive only to positive discharges through R_3. Whenever such a charge is impressed across R_3, the detector oscillates momentarily causing operation of the sounder, or register associated with it.

Measurement of total distortion is carried out in much the same manner as in the case of the field-type set. For measurements of maximum lengthening, the charging battery is so connected that condenser C_1 is given a positive charge, while for measurements of maximum shortening, the battery is reversed so that C_1 is given a negative charge. By means of the register, data may conveniently be obtained for plotting distribution curves of distortion.

The complete set as shown in Fig. 10 contains numerous switching arrangements to adapt the set to various conditions of measurement. It also includes a speed-of-failure meter. Incidentally the set is provided with an arrangement which can be used to suppress dashes and long spaces so that measurement may be made of miscellaneous printer signals.

The distortion dial is graduated in 2 per cent steps and intermediate values may be estimated. In the measurement of bias and characteristic distortion, the set may be readily adapted to the detection of much smaller differences.

Conclusion

A number of methods have been described for measuring the transmission quality of telegraph circuits. Which method to use in a particular case depends on the circumstances. For the purposes of transmission maintenance, the need has existed for a convenient method of fair accuracy for measuring the total distortion. In this connection it is believed that the method and means described under 7-A above offers considerable promise. Considerable use has been made of this type of apparatus by the development and engineering staffs of the Bell System and experience indicates that it will probably be of considerable value for the following purposes, particularly in connection with manual systems: (1) Obtaining quantitative data with a view of determining whether or not telegraph circuits are satisfactory for service, (2) Making routine checks of telegraph transmission, (3) Lining up circuits for service, and (4) Locating and diagnosing troubles. In the case of printer circuits it should be of most use in connection with item 4.

Discussion

J. H. Bell: The old method of evaluating the quality of telegraph signals was by running a tape at a particular speed and measuring each dot and each space and comparing with the length of a perfect dot. That required a good deal of time to carry out. The experimenter in the laboratory, after making each change in his circuit, had to measure his tape before he could proceed any further.

With these newer tools we can change a coil or a relay and at the same time listen to the effect upon the circuit, so that the tools make for much quicker development work than hitherto.

The telegraph circuits in this country have a great many repeaters, and, as you will find in the paper, the maximum allowable distortion between terminals is 35 per cent. That does not mean that 35 per cent is an allowable distortion in one section. The distortion is cumulative from section to section, so that the permissible distortion in one section must be kept down to say, 4 or 5 per cent.

The old method did not permit of measuring 5 per cent distortion with any degree of accuracy, as pointed out in the paper; about plus or minus 3 per cent was the best that could be done. That was due to the variations in the speed of the tape running through the Wheatstone receiver.

In the older days when the Wheatstone was the system for carrying heavy traffic, it was perfectly satisfactory if one got all the dots, and was able to distinguish between the dots and the dashes; the human factor could then come in and make up the discrepancy and translate the tape without any difficulties.

However, today with the growth of machine telegraphs, it is necessary that the amount of distortion be kept down to a definite limit, and these new tools will certainly be a great aid in carrying out our experiments. Even in hand-operated systems, I question whether any operator can detect a few per cent distortion.

H. W. Drake: A rather significant statement is made on the first page of this paper, which leads me to ask a question. The statement I refer to is that "in the case of some printer circuits, variation in lag degrades transmission. Consideration of lag is usually not of importance, however."

The question I wanted to ask is whether these admirable means which have been devised in the Bell System for measuring transmission include the possible measurement of this variation in lag.

The reason for asking that question is the fact that I am aware of a good deal of work that is being done by the commercial telegraph companies, and this matter of determining variation of lag has been one of the important factors in that work. I think that I would not be stretching the case to say that this paper is probably in the nature of a progress report and that the authors would be the last to have it taken as the final statement of what can and must be done in the measurement of telegraph transmission.

H. Nyquist: We have successfully used both the synchronous distortion bridge arrangement shown in Fig. 2 and the Wheatstone recorder in the measurement of lag and its variation. The field type of measuring set is not readily adaptable to this kind of measurement.

THE subject, telegraph traffic engineering, covers a field so wide that to compress it within the limits of a single paper necessitates an arbitrary limitation of the points to be discussed. For this reason there is here presented an outline of only the following four points:

1. Wire layout.
2. Traffic routing.
3. Office layout.
4. Operator assignment.

WIRE LAYOUT

As the economic conduct of any business activity is dependent upon a system of adequate, accurate, and up-to-date records, so the economic use of a large telegraph wire plant requires a somewhat elaborate scheme for recording the kind and amount of use made of the various facilities as well as for directing changes to be made in such use. The Western Union Telegraph Company has over a million miles (1,600,000 km.) of wire used for the handling of commercial telegrams and for other telegraph company activities. This figure does not include the mileage of wire owned but used by the railroad companies under contracts nor does it include the conductor mileage in underground and aerial cables used in city-wide distribution. This mileage of wire can be divided as to usage, as follows:

Wire used as	Miles of wire	Number of msgs. carried per month
Automatic trunks	266,000	20,100,000
Morse trunks	165,000	4,450,000
Way wires	296,000	3,270,000
Spare and protection	174,000	
Dispatcher and test	30,000	
Other uses	92,000	
	1,023,000	

"Other uses" cover wires in the service of disseminating quotations of stocks and commodities either by Morse or by ticker; wires leased to firms and especially to Press Associations for their use in Morse or automatic service, the so-called "private wires;" and wires given over to some small scattering uses, battery, clock, telephone tie lines, and the like.

In reading the foregoing table one must guard against taking the figures in the right hand column as representing the messages filed with the company by the public. The figures are quoted to indicate the relative density of load on the circuits of different sorts and a given message is counted again each time it is relayed from one circuit to another. That company's report to the Interstate Commerce Commission showed for 1925 a total of 146 million messages filed. It will be noted from the table how vastly more economical is the use of wire in automatic service. There a density of 76 monthly messages per mile of wire is achieved while in Morse trunk service 27 is the prevailing figure and on way wires only 11 can be counted on. Yet over 29 per cent of the whole wire plant is given over to way service, chiefly as the result of adherence to the policy of providing universal telegraph service.

The traffic engineer should be responsible for the amount and general location of wire used and for the economic assignment of circuits to these wires. The material, method of erecting, and the detailed location of pole lines and wires are properly the consideration of other departments but these, broadly, must be designed to provide what is required in the way of operating circuits. To this end there must be established a section of the traffic department whose duty it is to maintain a record of wires and of assignment of circuits to those wires, and long experience has shown that it is entirely impractical to maintain such a record unless the same section is given authority to designate the assignment of all wires and to insist that field forces recognize and conform to its orders. This section receives from divisional headquarters in the field suggestions as to improving operating arrangements and is itself continually busy with investigations looking toward improved layouts.

Monthly reports of the volume of traffic handled on each circuit terminating in all important offices are received. These reports show the loads, preferably by half-hourly periods, throughout a typical day and segregate the business into full rate, day letter, and night letter traffic. With these data and a knowledge of the practicable operating speeds of various circuits the circuit layout engineer can determine how best to utilize the wires at his command and can justify to that authority which appropriates the money, his requests for additional new wire construction. He daily issues orders in a well defined form, copies of which are sent to every field office which may be interested in the changes. The orders designate changes in circuit assignment together with the date upon which they are to be made effective. These changes are thereupon indicated on the chart of wires which he maintains as his primary record. This chart, with a line for every wire, shows the route followed, all towns being indicated and notations made as to all switchboards at which each wire is cut in either for operation or for test. The material and gage of the wire are shown and at each junction office the cross connections

Presented at the A. I. E. E. Winter Convention, New York, N. Y., February 7-11, 1927.

are indicated. These latter are customarily in lead pencil in order that alterations may readily be made as orders for circuit layout changes are issued. The chart for the million miles of wire before mentioned is 65 feet (19.8m.) wide and 24 feet (7.3m.) high and, of course, has to be maintained in sections.

In determining upon advisable layouts many facts must be taken into consideration and these vary with the type of circuit involved.

Taking up first the simplest of the circuits, the way wires, we can define as such all circuits that have intermediate offices or "drops" between the terminal stations. Almost invariably they are operated "single Morse," that is by the opening and closing of a circuit in which unidirectional current may flow, though in rare cases where the circuit is very long duplex operation with its greater reliability due to use of current of one polarity for "marking" and of the other polarity for "spacing" is used between the relay office and some repeater point at which a "half-set" connects it to a single Morse wire on which are located all the operating drops.

The volume of business which may be handled on a given way wire is to a considerable extent dependent upon the operating ability of the personnel at the various offices and particularly upon the experience and the judgment of the operator customarily working this wire at the relay office. Then, too, in an effort to give universal service provision must be made for handling business from offices so small that it obviously cannot be in itself profitable. For these reasons the provision of way wires is largely a matter of determining the most economical way to give service under particular conditions rather than a determination of the economy of giving such service. Broadly speaking, it is found that with a number of small offices, say ten or twenty on a way wire, a load of about 150 messages per day is all that is consistent with a satisfactory speed of service. Naturally where distances are great, as particularly in the western part of the country, and the way wires of necessity are very long, a somewhat greater density is enforced before relief is given. An ordinary way wire operated "single Morse" with current supplied generally by motor generators at each end of the line, can comfortably be operated up to about 150 miles (240 km.). Many circuits exceed that length but it is the tendency to so locate relay offices that wires may be shortened to about this figure. The longest way wire in the Western Union plant today is from Denver, Colorado, to Farmington, New Mexico, 497 miles (800 km.), with an intermediate single line repeater at Alamosa. Arrangements are now under way for the installation of equipment at Alamosa to permit relaying at that office this and adjacent way wires, thence handling the business to Denver on an automatic circuit.

If iron wire is used, the possible limit of mileage in a circuit depends upon the amount of deterioration and as the older wires are customarily put into way service it is not unusual to find cases where such circuits run up to 18 ohms per mile (11.2 ohms per km.), though new No. 8 gage iron would measure about 12.5 ohms. Where the abnormal resistance of an iron wire is found to be largely in the joints, conditions may be improved by soldering, brazing or welding as suggested in the paper presented by Mr. Stanley Rhoads (TRANS, A. I. E. E., 1921, Vol. XL, p. 301). Naturally, the use of No. 9 gage copper, averaging about five ohms per mile (3.1 ohms per km.), improves conditions greatly but insulation plays its part and even with the best of wires it is found that satisfactory service cannot in general be maintained on a way circuit of over 300 miles (480 km.) in length without repeaters.

As the load on a way wire grows, relief may be provided by constructing a new wire from the relay office to a point about midway of the load thus giving room for approximately 100 per cent growth. Quite often, however, the major portion of the load of a congested way wire will be from an individual office in which case the new construction may be placed between that town and the relay office thus establishing a trunk, naturally much underloaded at first, but which, it may be hoped, will gradually grow in usefulness until the day comes when the load justifies duplexing it. Occasionally, as a territory develops, it becomes necessary to establish new relay offices in order to avoid an uneconomical arrangement of many long way wires. The form of an engineering study of the features involved in determining upon the propriety of such a step might alone easily suffice as material for a paper the length of this.

The next general class of wires comprises the Morse operated trunks. With the present development of the printing telegraph, the establishment of new Morse operated trunks is indeed rare except in the manner just above indicated where a way office becomes sufficiently important to have an exclusive wire. Since several printer channels but only one Morse circuit may be put on a wire and, too, since it is easier to secure and quicker to train automatic than Morse personnel, it is not surprising that the duplex Morse trunks are diminishing with the growth of the automatics. The present field for duplex Morse trunks is largely confined to those offices which are maintained in connection with grain, cotton, and other commodity exchanges. In these situations where the messages are short and where the operators are especially selected very substantial loads may be secured. But better loads could be carried by automatics, and we may confidently look forward to the time when, with an improved technique and with customers' prejudices swept away, all important trunks, including those to exchange offices, will be operated automatic.

Broadly speaking when a duplex Morse trunk load grows to over 300 messages each way per day, the limit for a satisfactory speed of service has been reached and it is time to consider measures for relief. Generally it will be found more economical to install automatic

equipment, with its attendant maintenance charges but greater capacity, than to construct new wire. Particularly is this so if the offices involved already have such maintenance in connection with other circuits.

The single Morse trunk, the outgrowth of the way wire as previously described, occupies a wider field. Even here the evidence of trial installations suggests that a single channel printing mechanism of simple structure and substantial operation is, or shortly will be, available with economic advantages over Morse operation so that we may reasonably look forward to the time when manual Morse operation will have disappeared from all towns large enough to warrant a trunk circuit for an outlet and which enjoy 24 hour electric light service to provide the necessary operating power.

A load of 300 messages per day, counting both directions together, is about all a single Morse trunk may be expected to move with a satisfactory speed of service. Relief in general would be secured by duplexing the wire, requiring a more elaborate power plant to supply the two polarities needed by this method.

In taking up the third and most important class of circuits, the "automatic" trunks, it may be well to point out that the word universally used in the industry is somewhat of a misnomer. Really what is meant by "automatic" circuit is a circuit operating printing telegraphs. As a perforator operator does the sending and a receiving operator arranges the blanks in the machine or gums down the tape as the case may be, checks the number of words and calls for the necessary corrections, the only human operation that has in fact been eliminated is the actual typing up on the receiving end. The productiveness of the labor under the two systems is, however, marked. An experienced automatic operator works at between 55 and 60 words per minute while the average output per Morse operator is between 12 and 15 words.

The tendency toward automatic operation on trunk circuits is to be noted, the largest company handling about 80 per cent of its trunk line traffic by this means. In present usage the relation between practical line speeds and customary operator speeds sets a limit of three channels per circuit, these being duplexed so that six messages can be handled simultaneously, three eastbound and three westbound. However, four have been operated in many instances and the indications are that further improvements in the art will result in increasing to at least four and possibly to six channels in the majority of cases. It appears that the average automatic operator can be safely expected to perforate at the rate of 60 words per minute, a word averaging 5 characters and a space. The five unit code used in automatic telegraphy uses $2\frac{1}{2}$ cycles per character so a channel speed of 60 words per minute corresponds exactly to a speed of 15 cycles per second. Therefore a three channel circuit has a line speed of 45 cycles. The present practise indicates that this speed may be maintained on wires up to about 1000 miles and involving probably three repeaters. Longer circuits are operated two channel at line speeds of from 25 to 30 cycles, and such circuits can be and are operated over the greatest distances covered. Specifically, the longest automatic land line circuit regularly operated is one of the New York-San Francisco wires, which is 3779 miles (6100 km.) along the route followed with 13 repeaters located at Washington, Parkersburg, W. Va., Cincinnati, St. Louis, Little Rock, Texarkana, Tex., Dallas, Sweetwater, Tex., El Paso, Tucson, Ariz., Yuma, Ariz., Los Angeles, and Fresno, Cal.

In all of these longer automatic circuits at least one and perhaps two of the repeaters are of the rotary regenerative type.

It is possible, by suitable installation of apparatus, to drop off one channel of an automatic at any repeater point, or to intercept one or more channels and work them both ways. Thus the Boston-Cincinnati circuit is equipped for three channel operation one channel working between those cities and two channels cut at Pittsburgh giving Pittsburgh two channels to Boston and two to Cincinnati. Extensive use is made of this ability in situations where the traffic is somewhat lighter than would justify the use of an exclusive wire. For instance, the business of Dayton for New York or of Newark for Chicago would not economically justify a direct wire though ample to support one-third of a wire. So a three channel circuit is set up between Dayton and New York, two channels being cut at Columbus, whose loads happen to fit the situation, giving one Dayton-New York channel, two Dayton-Columbus channels and two Columbus-New York channels. The Newark situation is taken care of by cutting through a channel of one of the Chicago-New York circuits to one on the New York-Newark wire, giving two outlets each way from New York and one through circuit Newark to Chicago.

Perhaps enough has been said under this heading of "wire layout" to give some conception of the involved factors to be taken into consideration in administering the wire plant. With many existing wires on many routes, with varying circuit limitations as to lengths and loads, with alternative possible methods of operation, with different existing and potential relay offices to care for a given territory and with the possibility of combining channel loads on wires in different combinations, it is evident that it is a real problem of economic engineering to properly assign circuits. With a wire plant in commercial service carrying annual charges of perhaps thirty million dollars an improvement of but one per cent in average efficiency would, in an ever growing business, provide a sum of $300,000 per year, enough to pay for a considerable engineering staff to achieve that one per cent saving.

Traffic Routing

When, as elsewhere described, direct trunks have been established between all of the cities whose inter-

change of business either originating or relayed is sufficient to warrant such connection, it is evident that, in general, a number of possible routes will present themselves over which might be handled the business between any two offices which are not directly connected. The economies which can be achieved by judiciously selecting these routes are found greatly to outweigh the cost of the office force at headquarters necessary to determine the facts and to suitably instruct the field. Several considerations affect the choice of these authorized routes; the most important, likewise the most obvious, is that the fewest possible number of relays must be involved. This for the double reason that each relay increases the labor costs and at the same time degrades the speed of service.

Another, and quite important feature, is the relative percentage of full load carried by the various trunk groups involved. For example, a message filed at A and destined to Z may be handled with one relay through either M or N. Now, the trunks from A to M and from A to N may be equally loaded and both may have ample room for the proposed A–Z message. The operating force at A therefore, unless instructed, might choose either M or N as the outlet. If, however, the trunks from M to Z are already running to capacity while those from N to Z have a wide margin for increase then, obviously, the A–Z message should be routed through N. It has been found that due consideration of this factor may postpone for a considerable period, sometimes several years, the construction of additional wire to relieve congested trunk groups as, for instance, between M and Z in the quoted instance.

A less controlling ground for selection may be the method of operating, because the cost per message is cheaper on the automatic circuits than on the Morse circuits. Lastly, relaying through one office may be cheaper than relaying through another office because the cost per message handling in the first is lower than in the second. This difference may be due to the size of the office, to a more fortunate load factor due to more even fall of traffic throughout the hours of the day, or possibly even to closer operator assignment reflecting a superior grade of management. These differences, however, will be quite small and as a rule the other reasons for selecting a route will have determined the matter before this last mentioned point comes into consideration. It is probably a fact that in a perfectly ideal plant the relay point for business between A and Z should be located geographically half way between those offices. Practically, this thought is given little or no weight in determining routing instructions. It is, however, made a universal practise to route from Z to A through the same relay office as was used from A to Z. A theory was advanced and, in fact, some years ago a slight effort was made toward putting it into effect, that always provided the number of relays was not increased, a message should be routed on its first sending to the office geographically nearest its destination. The idea was that there was more probability of ample facilities and less probability of interruption on all of the available routes between points geographically near together than between points more widely separated. This plan, of course, insures that relayed traffic between A and Z would generally take a different route eastbound from that used westbound. Actually, this scheme is unsound in theory and impractical of application. Under it, it will be found impossible in all or even most cases to keep the eastbound and the westbound loads on a given trunk route equal which is obviously desirable from a wire economy standpoint, else the more heavily loaded side will require the construction of new wire for relief before this relief is needed in the opposite direction. Then, too, so much of the telegraph business is between regular and active customers that the peculiar form and phraseology of their messages becomes more or less familiar to the operating forces who are therefore in a position more accurately and readily to handle them. Evidently, then, to have the eastbound and westbound business between such firms relayed in the same office presents some slight advantage.

Following the considerations set down above the engineer charged with the responsibility of authorizing routes from each point to every other point in the country can readily reach his conclusions on the basis of the records of direct trunks and of their loads which have already been described. Then there remains the matter of issuing instructions to the field.

The earliest route guides consisted merely of a list of the telegraph offices, a separate list for each state, with a statement after each entry of the office which acted as relay for it. The inadequacy of such an arrangement is evident, for the card would show that Gorman, Md., was relayed by Pittsburgh while the office at Billings, Mont., would be wholly uninformed thereby as to whether to send the message to Helena, Denver, or Minneapolis, his only three outlets. Then, in the larger offices, the local forces made up route guides of their own, taking as a basis the "tariff book," which is the telegraph directory, and lists all the telegraph offices by states, entering the name of the relay point to which they should send messages for each of the listed destinations. This was faulty because decision as to route lay with the local people whose knowledge of the conditions was not complete and also it offered a very unsatisfactory arrangement for ease of consultation.

The most modern method, which has some five years' experience to justify it, consists of issuing from the home office in New York routing instructions for every office of sufficient size to warrant three or more trunk outlets. These instructions are in the form of lists printed on narrow slips much the size and shape of a newspaper column which can be slid into suitably designed metal leaves mounted on the wall or on racks in the operating

rooms. Several duplicate copies may be displayed if necessary. They are prepared specifically for the office in which they are used and they tell the local forces what they are to do with each message rather than what happens to the message at points beyond their reach. That is to say, if the route clerk at Billings has a message addressed to Gorman, Md., on one of these instruction sheets headed "Maryland" he finds the entry "Gorman" and after it the direction, "Minneapolis." The Billings operator then sends the message to Minneapolis and has no further interest in how it is routed.

In the Western Union system there are 87 offices at which such route guides are displayed. The tariff book lists 65,000 names of places in the United States. Not all names are listed in any one guide, for about three-quarters are eliminated by the expedient of determining for each state which outlet covers the greatest number of places, then listing only the other places with the direction that those not listed be routed to that outlet. For instance, most Maryland points are relayed at Philadelphia, Baltimore, or Washington, all of which cities are best reached from Billings through Denver but fifteen towns, including Gorman, are relayed by Pittsburgh which has a direct trunk to Minneapolis. Therefore Billings' route guide for Maryland consists of a statement that all points go to Denver except the list of names that go to Minneapolis. So, though Maryland has 1400 listed offices, the Billings guide carries but fifteen of them.

To prepare these instruction lists a somewhat elaborate organization is employed. Linotype slugs are made for each entry on a linotype machine in the executive offices at headquarters and these are held in galleys especially shaped, the galleys being filed in metal racks also designed for the purpose. Changes are continually being made and when any change is made either in trunk routes or by reason of new offices being added to the list, such changes are made up on slugs which are put in the galley in lieu of or in addition to those already there and as many copies are struck off as may be necessary. These are made on a proof press which is the most satisfactory way of taking a few copies from type slugs carried in galleys rather than in chases. These instruction slips are then mailed to the respective offices. A record is kept of them and it is required that the receiving office remove the slips which they are to replace and mail the old slips back to New York. This not only serves as a receipt for the new slips but is almost certain evidence that the local forces have not erroneously removed a perfectly good slip and put the new slip which really belongs elsewhere, into its place.

A considerable office force is needed to effect this procedure. The benefits realized are those of more efficient use of wire plant, reduced number of relays, and improved speed of service due to elimination of misroutes. While it is difficult if not impossible to prove the monetary saving, it seems beyond question an advisable expenditure to those who have had an opportunity to compare the routing of business before the advent of this method with that of the present time. Since all the linotype slugs for all of the instructions for all of the offices are kept permanently on file in order that reprints may readily be made when changes in individual items occur, it is obvious that a considerable amount of type metal is involved. For the 87 offices mentioned, a total of about 1.3 million names are carried involving some 45 tons (41,000 kg.) of type metal.

Some provision must, of course, be made for routing over unusual channels when confronted by unusual conditions. A telegraph company has always to contend with inoperative circuits due to wire troubles, sometimes more, sometimes less, but always in some part of the country to such a degree as to exceed the possibility of restoration by spare wires paralleling those interrupted. Then, too, extraordinary files of traffic occur which when scheduled for a trunk group of limited carrying capacity may well overload it. To take care of these two classes of emergencies, those of wire failure and those of extraordinary file, a department is maintained centering in New York with branches in several of the important telegraph centers, known as the Dispatching Bureau.

The Dispatching Bureau is the only authority recognized as supervening over the authorized routing instructions. The Dispatching Bureaus are equipped with wires picking up all of the more important centers of the country and used solely for dispatcher circuits. A dispatcher is hourly advised of the traffic conditions of each of the important offices in his territory. He is advised both as to the number of messages on hand and the filing time of the oldest. He is also informed of all circuit failures which it has not been possible to make good with spare paralleling facilities. With this information at hand he is in a position to and he does instruct the offices as to temporary routings to reduce congestion which may have arisen. Having knowledge of the conditions on all groups he is able to avoid the earlier unfortunate practise of having the office *A* send on the *N* trunk business destined to *Z* and authorized to go to *M*, because his *M* trunk was overloaded or in trouble when at that particular time the *N Z* trunk, unknown to him, was already badly congested or out of service. The dispatcher is also authorized to divert a wire from one assignment to another assignment even though it leaves the first assignment short. This is a function which cannot safely be left to the local forces because of their natural ambition to keep their own offices clear even at the expense of taking down a long through wire to make good a short local wire. The installation of the Dispatching Bureaus has proven of great benefit in expediting the movement of traffic under abnormal conditions and of increasing the useful distribution of wire when storm conditions prevail.

Office Layout

If we are to separate the engineering of a telegraph company into various parts among which are traffic engineering and fundamental plan engineering, we find that the matter of determining operating room layouts falls within both of these classifications. Practically, it works out that in the larger offices being newly established and planned for continuing service through a relatively long period of years, that part of the engineering force which has to do with the estimates of future growth and fundamental plans undertakes a major part of the office planning. Even in this case, however, the details of the initial equipment are arranged by, or at least are approved by, those specifically responsible for the traffic engineering.

Prior to the general use of printing telegraphs we had the "quad room," so-called, which really more often was merely one end of the operating room, in which were located the duplex repeating sets, the duplex terminal sets, the quadruplex sets, such repeaters as there might be, together with the main switchboard and the loop board. Now, with the high proportion of printing telegraph circuits, the so-called "automatics," this older arrangement has been departed from in a measure. In a large modern office we have a terminal room, usually on a floor separate from the operating room, in which are located the main and loop switchboards, the repeaters, both relay and rotary, and the Morse terminal equipment, whether single, duplex, or quadruplex. The terminal apparatus for the automatic circuits including the main line relay and the duplexing equipment in general present practise, are carried to the operating room floor and respectively located on the distributor tables appurtenant to each automatic circuit. These distributor tables are set at the head of the line of alternate sending and receiving positions making up the two or three channels worked on that circuit and while other arrangements might be possible, the desirability of this layout is so great that the floor plan of the operating room is customarily forced to conform to this arrangement. The Morse operating positions, either single or duplex, and carrying only local circuits from the quad room, present an easier problem and may be placed around the room as conditions permit although, of course, for the best handling of physical messages within the office, proper grouping is desirable.

In the normal operating room we would expect to find the following sections:

a. Automatic trunks
b. Morse trunks
c. Way Wires
d. City lines
e. Tube center
f. Routing center

The equipment for recording and delivering to customers over the public telephone and for operating the telephone circuits to branch offices which are so served, is usually in a "phone room" separate from but near to the operating room and connected therewith by some type of message conveyor, either belts, tubes, Lamson carriers, or gravity chutes.

As previously suggested the automatics will all be arranged in rows. At the head of the row is the distributor table with the artificial line for duplexing, the main line relay, the phonic wheel motor and the tuning fork that drives it, coupled to the rotating brushes and the segmented face plate which constitutes the distributor, and sundry miscellaneous apparatus. Then in line come the tables at which sit the four or six operators needed to man the two or three channels, all facing in the same direction. These are invariably arranged in alternating perforating and printing positions, in such order that the *A* channel perforator is to the right of the *A* channel printer. Two such rows are placed back to back with a "pickup" belt between. These belts, open on top and continuously moving, take the received messages as they are removed from the printer (or from the gumming desk if the position is equipped with the newer tape printer rather than the older page printer) and carry them to the ends of the rows where other mechanical conveyers take them to the routing center. An aisle is left between parallel rows as near to 5 feet 6 inches in width as the floor plan of the building permits.

The Morse positions are also aligned in a similar manner though their arrangement is much more flexible as the only limitation as to adjacency is that for duplex operation the sending position be immediately to the left of the receiving position. Quite generally a pair of duplex positions are so equipped that they can be used to table two single Morse wires. These rows, like the automatics, are arranged back to back and have a pickup belt between them.

In handling commercial business on way wires it is not the custom for way offices even on the same way wire to handle messages directly one to the other, partly because railroad operators generally have other duties and it is easier for one to unload his traffic on the main office which is always there rather than to try to raise the man at the other small office; partly too, because a main office relay copy is desired for check control to protect the company's revenues.

An experienced main office operator covering a way wire will become familiar with the train schedules, meal hours, and other facts regarding the offices and the operators with whom he works and he can turn this knowledge to good advantage with considerable conservation of line time when he is trying to dispose of business to these points. Evidently it is not conducive to economy to spend many minutes calling on a wire to raise an office which is closed for lunch or where the operator is out arranging baggage to put aboard an approaching train.

Improved operating efficiency at the main office on way wires is achieved through the use of "concentrator

units" a device which is nothing more nor less than a small switchboard in which the line terminates and on which a lamp lights if a prearranged code is sent on the wire by any of the outer offices. These outer offices may communicate with each other or with, in many cases, the head railroad office, without calling in the telegraph company's main office operator. The concentrator units are so situated that four operators, two on each side of the table, may at any time reach any of the eight lines terminated in the concentrator by plugging into the jack associated with the corresponding signal lamp, jacks and lamps being multipled on the two sides of the unit. Arrangements are also provided, either in the loop board or immediately adjacent to the concentrator unit, whereby any given line can be taken out and tabled individually during the busy hours of the day if the load during those hours warrants the entire attention of one operator.

It is still the general practise to run "number sheets" on all circuits which is to say that between the main office and each office on the line a series of numbers is run and after the transmitting of each message one of these numbers is crossed off at both the main office and the distant office. These series of numbers appurtenant to any one wire are in general kept upon a single number sheet. The message itself bears the same number. At the end of the day the numbers are compared between offices and the whole is intended to guard against lost messages. Were it not for these number sheets obvious economies could be secured by terminating all of the way wires in one switchboard, multipled if necessary, and handling the traffic very much as calls are handled on a telephone switchboard, but the impracticability of moving the number sheets around between the various operators involved, according to present practise, limits the concentration to units as before described. Upon these units a simple rack is used to hold the number sheets belonging to the wires terminating therein and the operator who for the moment is working with an office on a specific wire reaches for and puts before him the number sheet of that wire and makes the necessary notation thereon.

Of course not all way wires are in concentrators and some are put in concentrators during slack hours but given individual positions during busy hours. The arrangement of these Morse positions in the room does not differ from that of the Morse trunks.

The "city lines" are the short single Morse wires to branch offices throughout the city. They are worked on positions quite the same as the way wires.

The growth of these various methods of reaching branch offices is interesting. Originally, of course, Morse was used entirely but beginning some fifteen years ago, the telephone was introduced. Its advantage lay partly in the fact that it is faster than Morse even when all proper names and questionable words are spelled out, "S for Sugar, M for Mary, I for Ida, T for Thomas, H for Henry, Smith," etc., and the message then repeated back. Even more advantage resulted from the greatly widened field from which branch office personnel could be selected, an important consideration in view of the fact that quite generally besides transmitting messages, they have to meet the public, keep accounts, and generally represent the company. For all the substitutions of phone for Morse on city lines and automatics on the trunks it is nevertheless true that the number of available operators for manning the remaining Morse wires is decreasing chiefly because of the failure of the younger generation to learn the code and enter into this profession.

In their turn the telephone city office lines are now giving way to the short line printer because of the somewhat greater accuracy and the considerably greater output which may be achieved by this means.

Pneumatic tubes have been used for moving messages between main and branch offices for many years. Roughly, a speed of 1000 feet per minute may be expected and not more than a five minute run may be allowed without unwarrantably degrading the speed of service. From this it follows that in general, branch offices cannot be served by tube if more than a mile from the main office. The installation costs of tubes are quite high but their operating costs are extremely low as compared with any other method. For that reason great savings can be made by means of tubes in an office with a sufficient number of messages per day depending upon the distance and upon other conditions. After tubes have once been installed, then growths of several hundred per cent can be taken care of without any appreciable increase in cost. In general it is found economical to use tubes to offices where the loads are in excess of from two hundred to six hundred messages both ways per day.

It is beyond the scope of the present paper to describe the methods used in moving messages from one part of the operating room to another as is necessary in connection with the relay and delivering functions. Suffice it to say that for this intra-office routing it is found, in general, best to pick up business of all sorts from the incoming wires and carry it automatically to a single "route center" located as near the center of the operating room as conditions will allow. At the route center a slow moving belt carries the business before the requisite number of route clerks who dispatch it to the "drops" nearest the proper outgoing wires. Largely this is done by belt conveyers but sometimes the route clerks lodge the business in pigeon holes whence it is taken by "routing aides" by hand to the outgoing wire or perhaps it is dispatched by Lamson carrier or by tube. In any case "routing aides" move the messages from the "drops" to the outgoing operator positions.

The pneumatic tubes are grouped at a "tube center" generally immediately adjacent to the route center. Where the number of tubes warrants, instead of having the clerk who inserts the carriers into the tubes load the messages into the carriers, the carriers are all loaded at

one location and distributed to the tube heads by a conveyer belt. The carriers being variously colored, the tube attendants readily insert them into the proper tubes. On very busy tubes an automatic device is employed which insures that successive carriers are not despatched in less than the permissible time interval and yet conserves tube capacity by assuring that when business is on hand it is sent just as promptly as is consistent with proper carrier speed in the tubes. According to the fall of traffic one or several messages may be enclosed in a single carrier. The tubes are 2¼ inches in diameter, the carriers of course less, and good practise indicates that not more than a dozen messages should be inserted in a single carrier.

The matter of delivering telegrams direct to the patron and receiving them direct from him over a public telephone system presents many angles. The success of a widespread application of this method depends of course upon the attitude the public takes toward it. This attitude in turn may be affected both by the physical conditions and by the development work carried on by the telegraph company's publicity forces. For instance, in a manufacturing town where the telegraphing is largely conducted by the offices of the mills and the mills themselves are naturally scattered at some distance from the center of the town, the telephone pickup and delivery is looked upon with considerable favor. In other districts where branch offices are located within a few steps of all of the biggest users, considerable resistance is felt toward an effort to make telephone deliveries. There is no question that telephone delivery direct to the customer is more expeditious than branch office and messenger boy handling and since speed is practically the sole incentive for using the telegraph, the telephone seems to be the logical method of effecting delivery and the public prejudice against it can, in large measure, be attributed simply to habit, and can be overcome to some extent by proper publicity work. As extremes of these conditions might be pointed out, on the one hand, the city of New Haven, Connecticut, where 55 per cent of all telegraph deliveries are made over the public telephone and on the other hand Manhattan Island where no effort is made to deliver by telephone any telegrams to addresses south of 59th Street.

Operator Assignment

Operator assignment studies are predicated to such a considerable extent upon certain fundamental facts regarding telegraph traffic that an outline of these features seems to be essential to an understanding of this problem.

After a message is filed at a branch office a certain amount of time is required to complete the primary record concerning this message before it can be sent to an operating position for transmission. Similarly, when a message is received at the main office on any circuit and this message is destined for retransmission by the main office to another office a certain amount of time is required to get this message through the distributing center and deliver it at the proper sending position. This time interval is known as the "office drag" and is a variable depending upon the size and type of the office.

When a message arrives at a given circuit for transmission to the distant terminal, other messages may be on hand awaiting transmission. All the traffic for this circuit is then sorted by classes in filing time order, the earliest full rate message being transmitted first.

The message last received will therefore be subject to some delay before it is transmitted and a decision as to how long it may be so delayed before it is transmitted is in order. If we assume as permissible an average delay of not more than five minutes we may find that with the given load one operator can handle all the traffic within the time limit. On the other hand, if the average delay is fixed at one minute it may be necessary to use no less than four sendings to handle the same volume of traffic.

The latter figure will obviously result in a tremendous increase in the cost of handling this traffic and in determining the time limits within which all traffic must be transmitted after it is received in an office, the company's policy must be based on the relation between the cost of the desired speed of service and its value to the patron, as reflected in the volume of traffic which may be expected as a result of this speed of service.

Having decided upon the average and the maximum delay to be maintained we may now proceed to develop the load which we may reasonably expect an operator to handle. At this point we find that if an operator working on a single channel between two offices is given such an amount of traffic as will cause her to work more than 43 minutes out of an hour, the desired speed of service cannot be maintained and it becomes necessary to cover a second sending position.

As the load increases the second operator absorbs more and more of the excess and we find that we can still maintain the speed of service up to the point where each of the two operators is busy for 52 minutes out of the hour. Assuming a channel capacity of 60 messages per hour we can expect to handle 43 messages per hour on a single channel to a given office but when two channels are in use to this office up to 52 messages per hour can be transmitted on each channel without degrading the speed of service.

This increase in available work time per operator continues as the number of operators in the group increases up to the point where 10 channels are in use, when approximately 100 per cent of the operators' time is usefully employed and each channel is working at the full capacity of the apparatus. As automatic trunk groups are largely of two or three channels one cannot normally expect to get 100 per cent capacity from the equipment even during the busy hour. It is only in such large groups as the Chicago-New York circuits where fourteen duplex channels are provided

that the capacity of the equipment and the time of the operators is fully utilized. In times of stress, of course, by arbitrarily degrading the speed of service through increasing the time limits, the available operator work time is increased to such an extent as to clear up abnormal accumulations of traffic without increasing the operator staff.

Further limits are placed on the amount of traffic which can be handled over a given channel or channels, by the safe operating speed at which the circuit can be worked. By safe operating speed is meant a speed which can be maintained day by day without introducing too many errors or interruptions.

Detailed analysis of the circuit load reports which record the volume of traffic filed for transmission on each circuit or circuit group during each half hour of the day, shows that not only are there wide fluctuations in the amount of traffic to be handled in any half hour period, but there are variations due to the day of the week as well as seasonal changes. Estimates of the traffic to be handled tomorrow or next week, and the operator requirements based on this traffic must of necessity recognize these variations.

Analysis of the actual messages flowing regularly over a given circuit shows that the number of characters in the average message is practically a fixed quantity for each class of traffic handled on the circuit, but this average length is not the same for all circuits.

Having decided upon the operating speed of the circuit in words per minute and knowing the average length of the message to be handled on it the theoretical capacity of the channel in messages per hour can easily be determined. From this theoretical capacity we must deduct allowances for

a. Lost channel time due to temporary wire and equipment failures.

b. Operating or apparatus errors which necessitate the correction of messages which have already been transmitted.

c. Errors which the operator is conscious of having made and corrects before the complete message is transmitted.

When these deductions have been made it is possible to state that under the given conditions a certain number of channels must be manned to handle the estimated volume of traffic.

It will be noted that up to this point we have apparently assumed that the operators can work at any circuit speed. The fact is that while Morse and phone operators are in general limited only by their ability and not by the circuit characteristics, the automatic operator is limited by the speed at which the channel operates. Several thousand stop watch observations on perforator operators indicate that the present maximum operating speed of 65 words per minute on automatic circuits is not only well within the range of the average operator but that this rate can be sustained without undue fatigue.

In actual operating room practise, it has been found desirable to locate all the trunk circuits in one group, all city circuits in a second group with a third comprising the way circuits. Interchange of operators from one position to another within the given group is facilitated by a further division of the three major groups into automatic, Morse, and telephone operating sections, and the operating staff is in general assigned by methods.

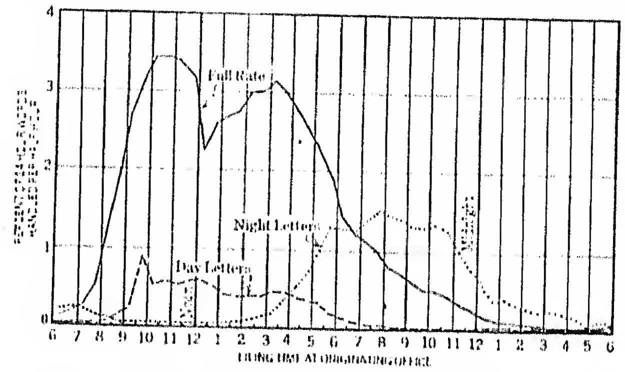

Fig. 1—Load Curve—Entire Telegraph Plant

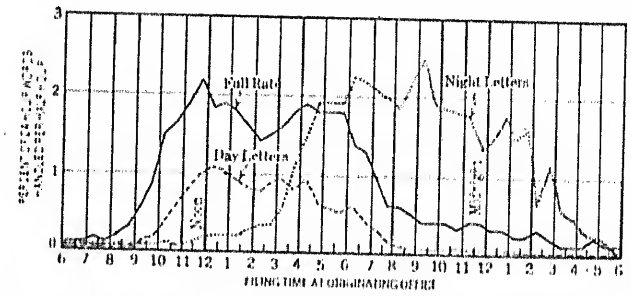

Fig. 2—Load Curve—Atlantic Coast to Pacific Coast

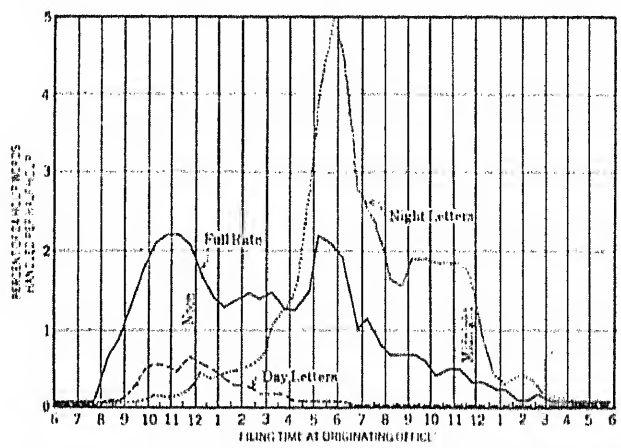

Fig. 3—Load Curve—Pacific Coast to Atlantic Coast

An operator's tour of duty is nominally eight hours, but as each operator receives a fifteen minute rest period after she has been at work approximately two hours, and a second fifteen minute period about midway of the last four hour working period, both of which are on company time, their actual working period, is only 7.5 hours. Advantage is taken of the relief periods to minimize the effect of fatigue, particularly on the automatic circuits by alternating the kind of work. If an operator begins her tour of duty at a sending position she will be assigned to a receiving

position after the first relief period. Upon her return from the lunch relief she will again be assigned to a sending position.

Reference to the load curve for the entire telegraph plant shows that while the traffic is heaviest during ordinary business hours, *i. e.*, 9:00 a. m. to 5:00 p. m., there is a considerable volume remaining to be handled up to 10:00 and 11:00 p. m. and the beginning of any operator's tour of duty is naturally determined by the shape of the load curve on each individual circuit.

As examples of extreme deviation from the average are given graphs of the eastbound and the westbound file of business between cities respectively on the Atlantic coast and the Pacific coast where the difference in standard times and the greater absolute savings to the patron make the use of the deferred services more extensive.

While the shape and position of this load curve is generally the same for a given circuit minor variations occur which serve to set these peaks ahead or behind the normal time position. Our obligation to give service requires us to anticipate these changes and the positions are covered in advance of the time when the change in load is expected to occur.

With the information already available it is a relatively simple matter to assign the operators in such a way as to provide for handling the full-rate traffic filed during the business day. Ordinarily, additional staff would not be assigned during the day hours to handle deferred traffic because the staff needed for full-rate traffic has sufficient idle time available to permit of handling the deferred traffic during these idle periods if the transmission of the deferred file is sufficiently delayed. Naturally we cannot delay this traffic to such an extent as will prevent the delivery of these messages before the close of the ordinary business day but in general this does not occur.

During the latter part of the afternoon and evening we are confronted with a falling load but as it is necessary to bring on a certain number of operators at this time to replace those whose tour of duty has just been completed and as it is manifestly unfair to release them without an opportunity for a full day's work, the falling full-rate file is supplemented by the night letter file in such a way as to keep this staff busy until after midnight when only a few operators are required to handle the balance of the file.

A complete assignment of the staff required for the entire 24 hours may now be made for each of the circuits or circuit groups. The total number of operators required to handle the traffic on all circuits including relief operators may then be determined and to this total is added a sufficient number to provide for operators who are either late, or fail to report, those on vacations, etc.

Roughly, and subject to considerable variation, in specific instances, the total number of operators needed in an office to conduct operations throughout the 24 hours, to cover vacation and sickness reliefs, absentees and those tardy, can be taken as 2.8 times the number of operating positions covered during the busiest half hour of the day.

Discussion

J. H. Bell: There is one question I would like to ask Mr. Mason. On page three this statement occurs: "an experienced automatic operator works at between 55 and 60 words per minute while the average output per Morse operator is between 12 and 15 words per minute."

I question whether those two are comparable. My recollection is that it is much easier to operate a Morse system by hand at about 20 words per minute, and human nature being as it is, I rather think that the operator would prefer to operate about 20 words per minute rather than 12 or 15. I would like to know whether 55 to 60 words per minute is the output of the automatic operator?

H. Mason: The point is well taken. The way it is stated in the paper the figures are not literally comparable. I agree that a Morse operator might work at 20 words as well or perhaps better than he would at 12, but our actual output is of the order of from 12 to 14 words per minute. In the case of the automatic operators 55 words per minute represents an average performance but not the output. The human nature feature comes in here. The operator is perforating against a machine. That machine is set to go at a given speed, generally about 55 words per minute. She must keep up with that machine or the auto control stops the transmission in a way evidencing her failure.

I am not prepared to say that the performance throughout the country is universally as high as 55, but individual operators can perforate at double that speed and we have no mechanisms which would take that rate of perforating. A recent figure shows the average output per Morse operator hour to be 28 equated messages, while that of an automatic operator is 62 equated messages. These figures reduce to approximately 15 words per minute and 32 words per minute respectively.

J. H. Bell: Reference was made to the delivery of telegrams. Nothing was said about the messenger service. I would like to mention that in one of the British journals I read that they have started a new method of delivering telegrams. Instead of having the boys go out with each message that comes, they have divided the town into 25 or 30 separate routes. A boy leaves every five minutes from the telegraph office and he takes all the messages along one particular route. That makes for a slight increase in delay in delivery of some messages, but it brings the average delay much more uniform.

H. Mason: In the company which I represent the line of organization is not such that the messenger delivery problem comes under the control of the engineers for which reason I am not so well fitted as would be some other, to discuss this question. I do not think, however, that anywhere in our service is such a method as is suggested by Mr. Bell used.

We do have routes and send boys over them with messages just for those routes in-so-far as the delivery of night letters in the early morning is concerned, and also full-rate messages for which we have instructions, as we have in some cases, not to make delivery until the customer's office is open.

However, other than that, so far as I know, we do not at the present time indulge in the suggested practise but our full-rate meassages are taken out practically as they fall. That does not mean that the messenger boy always goes out with one, quite often he has two or three, but he is not definitely held until several come for that zone.

The matter of deliveries of the day letters may be held up. For instance, if it is several blocks from the office, the delivery clerk may very well hold up a day letter waiting for some preferred business to come along, and send it out with the same boy, but not as a policy.

Developments in the Manufacture of Copper Wire

BY JOHN R. SHEA[1]

and

SAMUEL McMULLAN[1]
Non-Member

Synopsis.—This paper covers interesting developments in the manufacture of copper wire and contains a description of a copper rod and wire mill designed to meet the new requirements. It also includes a brief survey of the copper rolling and wire drawing art at the time the investigation was started; a summary of tests made in varying the practise in rod rolling and wire drawing, and an outline of the work done by the Bell System engineers in developing and designing new types of wire drawing machinery. The economies in floor space and plant investment due to the use of more compact and higher-speed machinery are outlined. Some of the outstanding features in plant arrangement which contribute to more efficient operation are discussed in the concluding pages.

RAPID developments in the various branches of the communication business are constantly leading to important investigations in line with more efficiently and economically meeting the increasing demands of the service. In this connection, one of the more recent and very interesting investigations indicated the possibility of effecting substantial improvement in the process of manufacturing copper wire. Accordingly, a comprehensive study of all the factors concerned was undertaken which resulted in the construction of a rod and wire mill at Chicago, Illinois, embodying many unique and improved operations, a schematic layout of which is illustrated in Fig. 1.

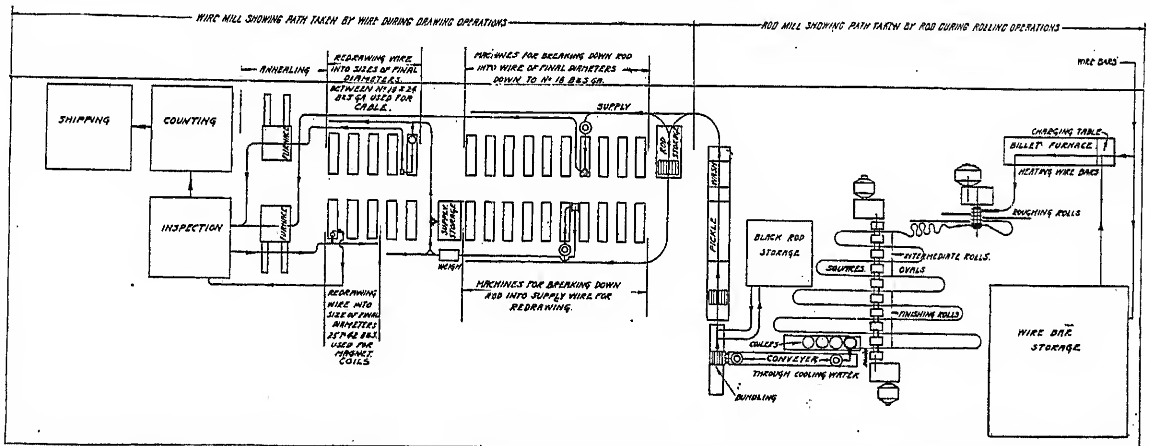

FIG. 1—SCHEMATIC LAYOUT OF WESTERN ELECTRIC CO.'S COPPER ROD AND WIRE MILL AT CHICAGO

At the outset the sources of copper and its transportation were studied and it was found more economical to ship wire bars to Chicago for conversion into wire than to locate a wire mill near some of the large refineries and ship wire to the factory. It was also considered that this plan would reduce the investment in wire during the process of manufacturing cable and telephone apparatus.

ROD ROLLING MILL

The rod rolling mill equipment consists of a billet heating furnace, a roughing mill, an intermediate mill, a finishing mill, coilers, conveyers, and pickling tubs. The mills are water-cooled and equipped with a downdraft exhaust which carries the fumes produced during the rolling operation to an air washer where the copper dust is removed before the air is discharged.

The 225-pound wire bars as received in cars from the refineries are unloaded onto skids in the train shed and transported by an electric truck to the charging end of the billet heating furnace. Here they are transferred in groups of six by a hoist to the charging table, where a compressed-air pusher moves them along through the furnace which holds 120 bars. The bars are brought up to the required temperature for rolling as they move through the furnace, which is heated by fuel oil. When the bars reach the opposite end of the furnace they are withdrawn at about 1600 deg. fahr. with a pair of tongs through the discharge door and pushed into the roughing mill one at a time. These tongs operate on a trolley suspended from a beam, which is in line with the first groove of the mill.

The roughing mill consists of three motor-driven rolls, one above the other. The bar, after passing through the first groove between the top and middle roll, drops upon feed rolls set in the floor and is returned through the second groove, between the middle and bottom roll; then raised into position and passed through the third groove, which is in the same rolls as the first pass.

1. Both of the Western Electric Company.

Presented at the A. I. E. E. Winter Convention, New York, N. Y., February 7-11, 1927.

Five passes are made in this manner until its cross-section is reduced sufficiently for it to enter the intermediate mill. As the bar enters the roughing mill it is 54 inches long and about 4 inches square. When it leaves this mill it has been rolled into an oval cross-section and is about 124 feet in length. Formerly the last pass on this mill was handled manually, and recently a mechanical repeater has been added as illustrated by Fig. 2.

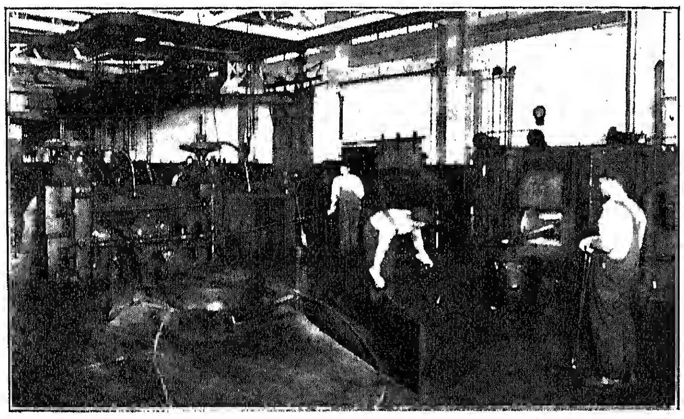

FIG. 2—VIEW OF ROUGHING MILL SHOWING REPEATER ON LAST PASS

From the roughing mill the bar goes to the intermediate mill and is passed through the first pair of rolls. As it emerges an operator catches the end with a pair of tongs and passes it back through the next pair of rolls. The increased length between each pass at the intermediate and finishing mills is allowed to run out in a loop on a sloping iron covered floor on each side of the rolls. This catching and returning is repeated at each set of rolls until the original copper bar finally emerges a round, quarter-inch rod about 1200 feet long. This last pass goes through a guide pipe into a coiler, Fig. 3. The reductions in cross section are illustrated by Fig. 4. An appreciable amount of copper oxide scale is carried off with the cooling water, and deposited in a reservoir from which it is later salvaged.

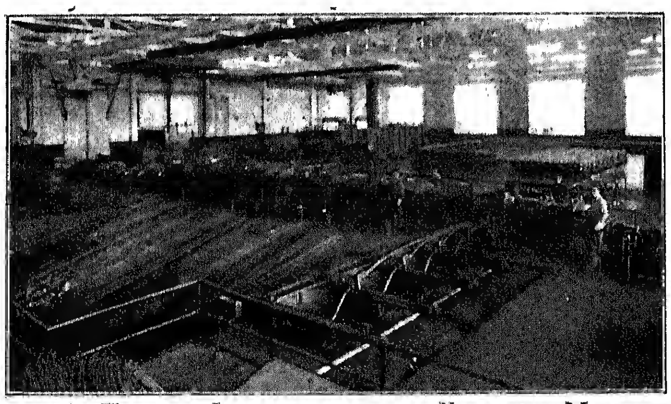

FIG. 3—VIEW OF INTERMEDIATE AND FINISHING MILLS AND COILERS

The coils are automatically unloaded from the coilers on to a conveyer, which carries them through cooling water in a tank underneath the floor. Eighty-two seconds after entering the roughing mill the bar is a coil of ¼ in. rod ready to proceed on its way to the pickling tanks. The mill has a capacity of 70,000,000 pounds annually on a 48-hour per week basis.

While the diagram and illustration of the intermediate and finishing mills indicate for simplicity that the rod follows only a single path, in actual operation sufficient material is kept in the mill practically to maintain at least two rods in the finishing mill. This is illustrated graphically by that part of Fig. 5 which covers the finishing mill. Referring to line A-A^1, 11 reductions are being made in this mill at the same time, two for each of the first four pairs of rolls and three on the final rolls. At this period in the cycle of operation 800 hp. is required.

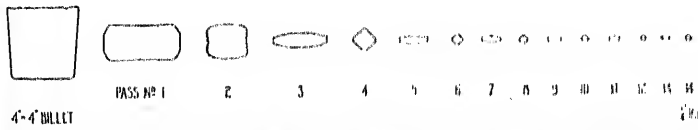

FIG. 4—ROD MILL REDUCTIONS 4-IN. X 4-IN. BILLET TO ¼-IN. ROD

When the rod mill was started eighteen passes were in use by several of the most modern mills. A sixteen pass arrangement was adopted for the new mill, in which the metal was subjected to a greater amount of work in the earlier passes when it was hot. Later, as a result of further study, fourteen passes were adopted. Fig. 6 illustrates graphically the per cent reduction effected at each of the above passes. The reductions plotted as the abscissa are in terms of reduced area in cross-section at each pass and the passes reading from left to right are plotted as ordinates.

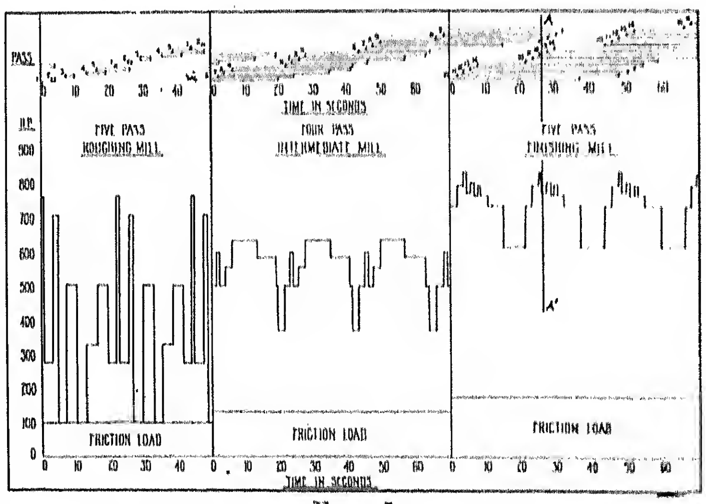

FIG. 5

It is obvious that careful planning must be done in changing the number of passes in a mill in order not to exceed the safe working capacity of the mill rolls and stands. Such calculations have been made using roll-

ing mill formulas[2]. Based on the more sturdy mill installed at the Chicago plant the first four passes of the eighteen pass arrangement would operate at about 82, 100, 105, and 90 per cent of the safe working load of the mill. These same passes calculated on the basis of the sixteen and fourteen pass arrangement operate at 86, 87, 90, 85 and 96, 96, 90, 90 respectively. This

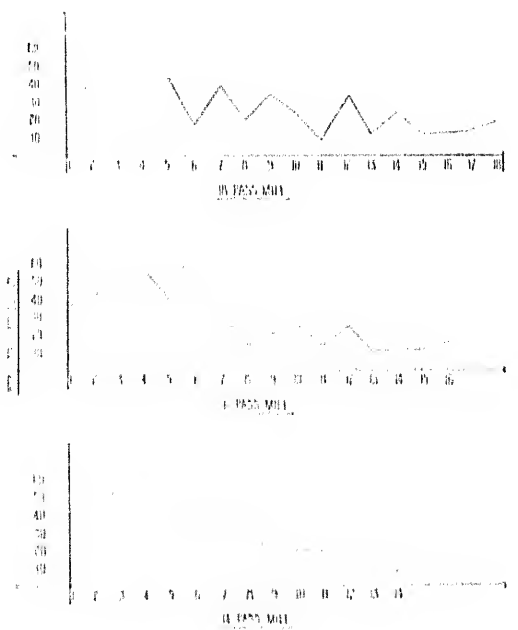

FIG. 6

indicates that a further reduction may be made in the number of passes in the mill provided other features are improved; *i. e.*, roll adjustment.

Relation Between Working and Physical Properties

It has often been stated that the more passes (*i. e.*, the more gradual working) given the copper, the better the physical qualities of the rod. Actual tests (see Table I) made on representative lots of ¼-in. rod fail to confirm this impression.

TABLE 1

Lot	Number of passes	Elongation per cent	Tensile strength lb. per sq. in.
1	18	35.8	33,752
2	18	40.0	31,445
3	16	37.1	32,408
4	16	41.0	32,100
5	14	42.0	32,301
	Average of 5 lots	39.5	32,243

The averages indicate that a fourteen-pass rod is superior in elongation, and better than the total average in tensile strength.

Cleaning of Rod

When the coils emerge from the tank through which the rod coiler apron conveyer passes, they are cool enough to handle and after being tied with wire, several are lifted together by a monorail crane, and placed for thirty minutes in a pickling tank containing from 5 to 10 per cent free sulphuric acid, in order to remove the black oxide caused by oxidation of the hot copper in the air during rolling. The solution is maintained at approximately 120 deg. fahr., and the copper content varies from one to three grams per 100 cu. cm. Experiments have shown a difference of less than 10 per cent in pickling time between the minimum and maximum acid used, the greater solubility being obtained from the weak solution. Actual results obtained were checked with Sidell's Table of Solubilities (see Fig. 7). While a variation from the minimum to maximum acid concentration does not materially affect the pickling time, a variation in temperature has a decided effect as may be seen from Fig. 8.

Electrolytic Plant

Fig. 9 shows a plant in which the copper is reclaimed from the pickling bath at about the same rate as it is absorbed. This is accomplished by electrolytic deposition according to principles worked out and practised in the large refineries which produce electrolytic copper.

The electrolytic system operates best with a minimum

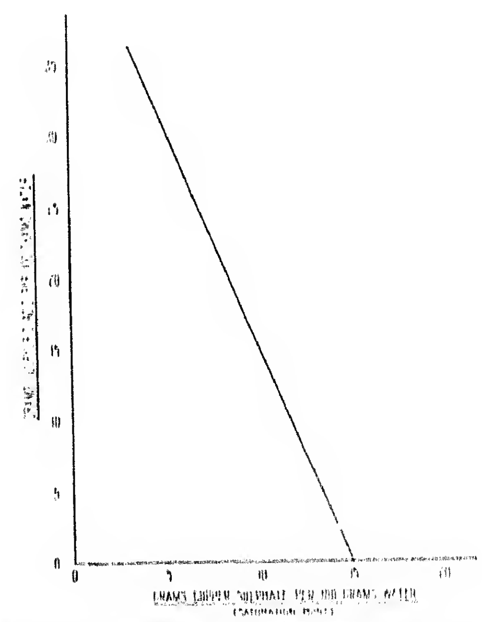

FIG. 7—SOLUBILITY CURVE OF COPPER SULPHATE IN A SULPHURIC ACID SOLUTION (TEMP. 25 DEG. CENT)

Reference Table of Solubilities by Sidell, *Chem. & Met. Eng.*, Vol. 21, p. 181-2, 1919.

content of about 1 per cent copper and 5 per cent acid and a maximum of 3 per cent copper and 10 per cent acid. The copper and acid contents are kept as low as practicable to minimize "carrying out losses"[3] during the pickling operation. About 775 pounds of acid, and 430 pounds of copper are recovered per day

2. "Pass Limitation in Rolling Mill Practice," *Machinery*, July, 1918.
"The Theory and Practise of Rolling Steel," Wilhelm Tafel.

3. Pickling solution carried out when coils are removed from tank.

from the electrolyte. The anodes are operated at a current density of five amperes per square foot with a rate of deposition of about 0.00261 pound of copper per ampere-hour.

The heat generated in the plating tanks under normal operating conditions maintains a minimum

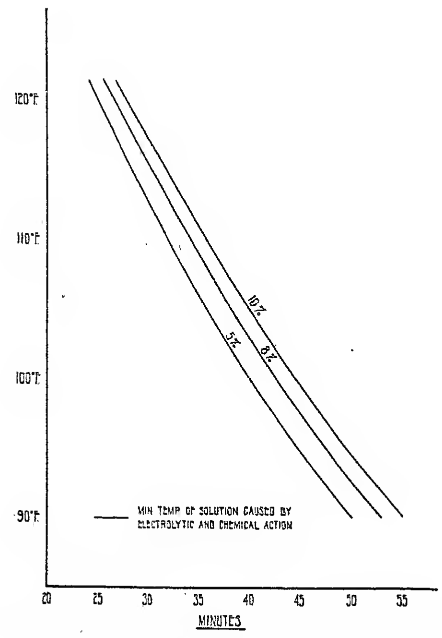

FIG. 8—RATE OF PICKLING AT PRACTICAL ACID CONCENTRATION

Max. temp. without excessive evaporation and fumes

temperature of about 90 deg. fahr., throughout the acid system, and the maximum temperature is obtained through steam heating coils in the pickle tanks. Faster pickling would result from the use of higher temperatures but experience has shown that the additional steam and

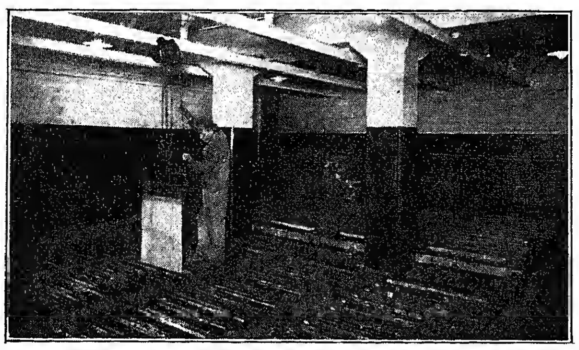

FIG. 9—ELECTROLYTIC RECOVERY OF COPPER FROM ROD MILL PICKLING SOLUTION

gas released above 120 deg. fahr., results in unsatisfactory operating conditions.

The coils of rod after pickling are thoroughly washed with lake water[4] at a pressure of about 70 pounds per square inch to remove loose copper dust and acid, and then immersed in an alkaline fat solution to neutralize any trace of acid and to provide a protective coating against oxidation until converted into wire.

WIRE MILL

The coils, after being pickled and washed, are carried by monorail cranes to the wire-drawing machines where they are converted into wire of the desired size. The dies used in the heavy wire drawing machines are pulled into place at the starting end of the coil of rod on a die

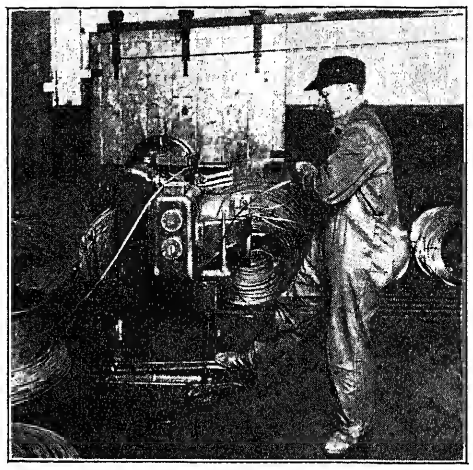

FIG. 10—HEAVY WIRE DIE STRINGER

stringing machine (Fig. 10). The coil, with dies strung into position, is then placed in a heavy wire-drawing machine.

The heavy gages of wire, such as line wire, are drawn with one set-up on a heavy wire-drawing machine;

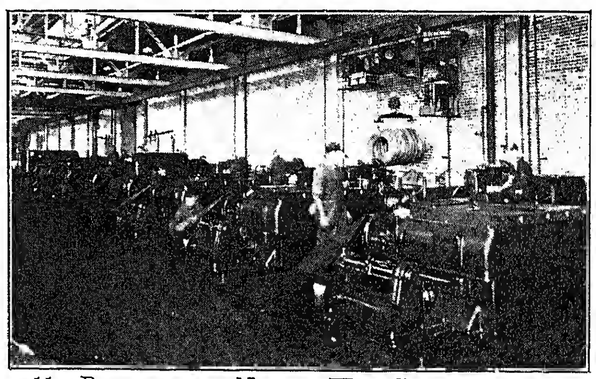

FIG. 11—BATTERY OF NO. 1 WIRE-DRAWING MACHINES

medium sizes, used in lead covered cable, are made by taking the wire as it comes from the heavy machine and redrawing it on the intermediate machine; and finer sizes, commonly known as magnet wire sizes, are produced by redrawing intermediate sizes.

The present capacity of the wire mill is approximately 42,000,000 pounds annually, and the sizes range from 0.165-in. line wire to 42 B. & S. (0.00247-in.) gage magnet wire. Provisions have been made in the construction of the building and its foundations so that the mill may be expanded in capacity when needed.

The No. 1 or heavy wire-drawing machine shown by

4. Lake water is relatively free from mineral salts which would corrode the rod and affect the wire drawing compound.

Figs. 11 and 12 draws line wire, heavy toll cable sizes, and supply wire for the loop cable wire machines. This ten-die machine with its auxiliary equipment and operating area occupies a floor space of 270 sq. ft. and runs at 1500 to 2000 ft. per min. as compared with 470 sq. ft. for a commercial nine-die machine running about 1000 ft. per min.

A battery of these machines costs much less than an installation of commercial machines of the same capacity,

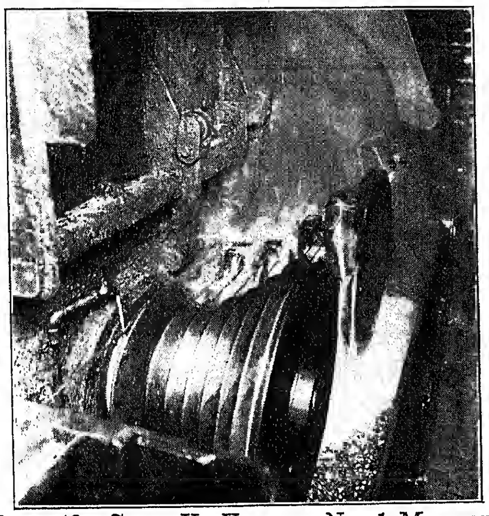

Fig. 12—Close-Up View of No. 1 Machine

and in addition, effects a considerable economy in floor space.

The commercial types of ten-die intermediate machines for drawing cable wire require about 130 sq. ft. of floor space as compared to 90 sq. ft. for a twelve-die multiple head machine. The former is a single-unit machine and the latter a four-unit machine operating at twice the speed and capable of producing

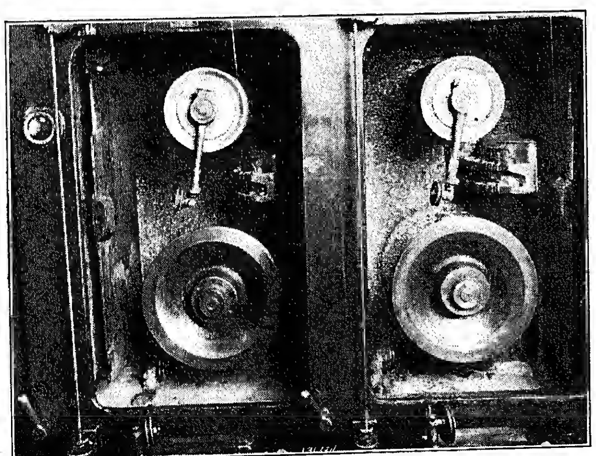

Fig. 13—Close-Up View of Units of No. 3 Wire-Drawing Machine

about five times the output of the commercial equipment. This new multiple unit machine costs more than regular equipment, but considering the four units, the cost is materially less per unit, and very much less on an output basis.

The magnet wire-drawing machine is a high-speed twelve-die multiple head machine of eight wire drawing units, occupying 90 sq. ft. of floor space including the operating area. A close-up view of two heads of this machine is shown in Fig. 13. Fifty-one sq. ft. of floor space are required for a single unit (one head) commercial machine of the same die capacity. The saving in investment in this case is even greater than for the heavy and intermediate types of machines. The use of these compact machines and overhead monorail equipment for transporting material instead of using trucks with large aisles has permitted the installation of the wire drawing mill in less than one-fourth of the building area which would have been required if commercial equipment had been purchased.

General Plant Features

The present connected load of the motors in the rod and wire mill is about 6000 horse power for which it was necessary to enlarge the factory power plant.

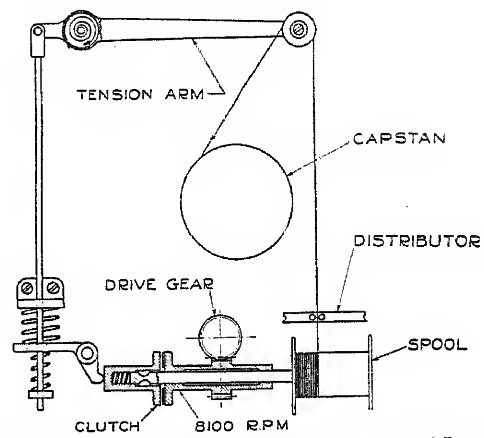

Fig. 14—Automatic Tension Mechanism of No. 3 Wire-Drawing Machine

A 700-ft. tunnel connects the power plant with the rod and wire mill in which are laid pipes for carrying hot and cold water, steam, gas, and air and lead covered power cables.

The basement under the rod mill houses the electrolytic equipment, control boards for the roughing and intermediate mills, pumps for cooling water, and exhaust fans connected with an air washer for removing the fumes from the rod mill. A tunnel which passes beneath the intermediate and finishing mills connects with a room which houses the drives for the four rod coilers, the coiler control boards, the finishing mill control board, and the main power panel. In the wire mill basement are six large tanks which hold the compound used to lubricate and cool the wire-drawing dies. This compound is supplied under pressure to the wire-drawing machines on the floor above and returns by gravity.

All the wire-drawing machines are controlled by push buttons mounted on the machines, which connect with compensators in the basement. The 100-hp. motors

driving the large wire-drawing machines are mounted in a tunnel and are connected to the machines above by chain drive.

This arrangement permits accessibility for maintenance of the electrical equipment with a minimum of interference to production, prevents the wire-drawing operators from having access to the electrical equipment and reduces accident hazard to a minimum.

Developments in Wire-Drawing Equipment and Methods

The rod and wire mill just described was designed following a comprehensive survey of wire-drawing

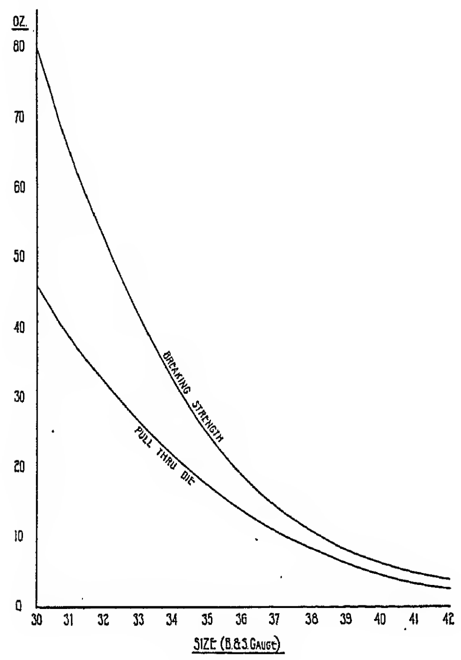

Fig. 15

processes and equipment used in this country and abroad. In connection with these studies, extensive laboratory investigations were undertaken relative to the characteristics of different types of commercial machines especially from the standpoint of operating efficiency, investment, and floor space requirements. As a result of these investigations, it developed that marked improvements could be effected if wire could be produced commercially at higher machine speeds and with more compact machine equipment.

While the design of the drawing mechanism in the new machine was very important, it was also essential that the finished wire be taken up on spools instead of coils. After considerable experimental work, a sensitive take-up device was developed to permit spooling at a constant drawing speed.

This spooling mechanism is illustrated by Fig. 14 in which the spool spindle is driven by a slipping clutch member controlled through a tension arm, on which an idler pulley is located over which the wire passes on its way from the drawing capstan to the take-up spool. The take-up mechanism rotates the core of an empty spool at a speed synchronous with the speed of the wire as it leaves the drawing capstan. As the spool fills and the speed tends to increase, the wire on the tension arm tightens and compresses the tension arm against a spring adjusted for the proper gage of wire. This in turn reduces the pressure of the clutch driving the take-up spindle permitting the spool of wire to readjust its speed.

This device is extremely sensitive as illustrated in the drawing of No. 42 B. & S. wire at 2000 ft. per min., in which case the control arm must be adjusted to operate between 90 and 150 grams, since the pull required is 87 grams and the breaking strength of the wire is 170 grams. This device is so flexible that it can be adjusted to a drawing tension of from 9 pounds for No. 25 wire to 3 ounces for No. 42 wire. Fig. 15 illustrates its operating range on wire sizes No. 30 to No. 42, showing the gradual narrowing of the limits as the sizes decrease. A larger machine used for drawing loop cable wire from No. 18 to No. 30 B. & S. gages contains a similar mechanism.

The use of this sensitive device and a clutch which

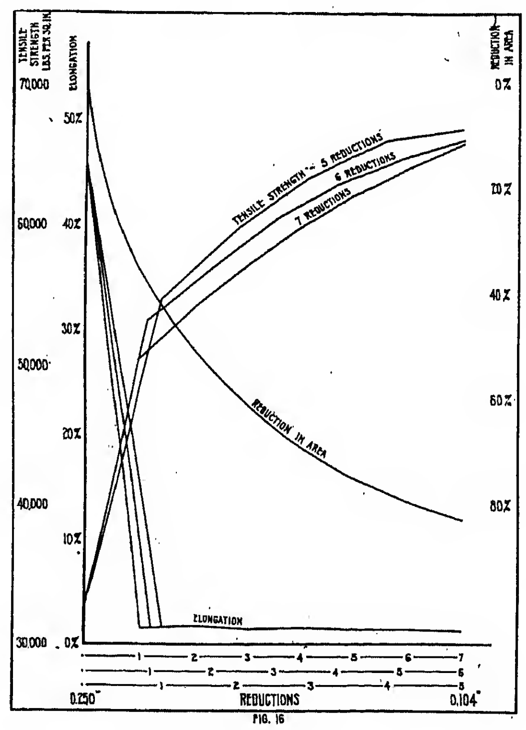

Fig. 16

would slip without overheating as the spool filled, together with improvements in the wire drawing compound and the shape and quality of the diamond dies later described, permitted the drawing of wire at speeds ranging from 2000 to 3000 ft. per min.

Wire Drawing Compound

At low speeds it was discovered that the compound for lubricating wire-drawing dies required little attention but as the speeds were increased the necessity for close analytical control was evident. The compound con-

sists of an emulsion of soap, tallow, and water, the percentage of the soap and tallow being varied depending upon the size of wire and type of machine on which it is used.

It is important that the degree of emulsification[5] be carried far enough to break the tallow into particles about one micron in diameter, so that the material will stay in suspension in the water. If the tallow content is increased beyond a certain point it holds

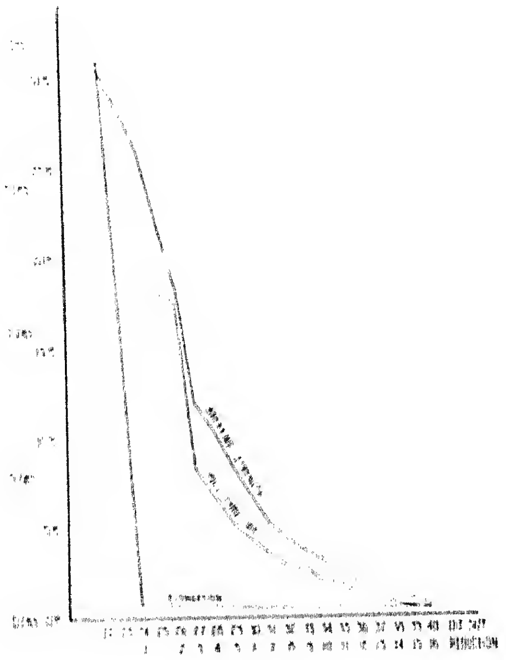

Fig. 17

in suspension in the solution a large amount of the copper dust which flakes off in a very fine state during the wire-drawing operation and this clogs the dies and causes breakage during the wire drawing. Ordinarily this copper dust settles out of the solution while in the large cooling tanks and a considerable amount is salvaged in this manner.

Effect of Drawing on Copper

Tests were made to determine if the drawing of the smaller cable and all magnet wire sizes[6] in Brown & Sharpe (A. W. G) steps was obtaining the maximum reduction possible per die. These tests showed it was feasible to make much heavier than A. W. G. reductions at the first draft when annealed wire or soft copper rod was being drawn. It also showed that the elongation[7] of the rod or annealed wire was rapidly reduced to the drawing minimum after the first pass, and remained at that point throughout the process.

Fig. 16 illustrates the effect of a five-die reduction on elongation and tensile strength. It may be seen that the elongation drops very rapidly at the first die when a reduction in area of about 42½ per cent is made, and the tensile strength increases rapidly because of the cold working of the metal.

This same figure shows the tensile strengths obtained when five-, six-, and seven-die reductions are used to produce line wire of 0.104 diameter from the same supply. Here the elongation loss is about the same in each case, but the tensile strength is greater with the heavier reductions. The five-die arrangement is satisfactory according to the results shown on the curve, but the heavy reduction at the first die often results in rough or slivered wire. The six-die arrangement, therefore, gives the greatest factor of safety. The seven-die arrangement is less satisfactory since the elongation and tensile strength in the finished wire are so close to the requirements.

The use of A. W. G. reductions for the finer sizes of cable and magnet wire provides flexibility, since a change in the size of wire can be accomplished simply

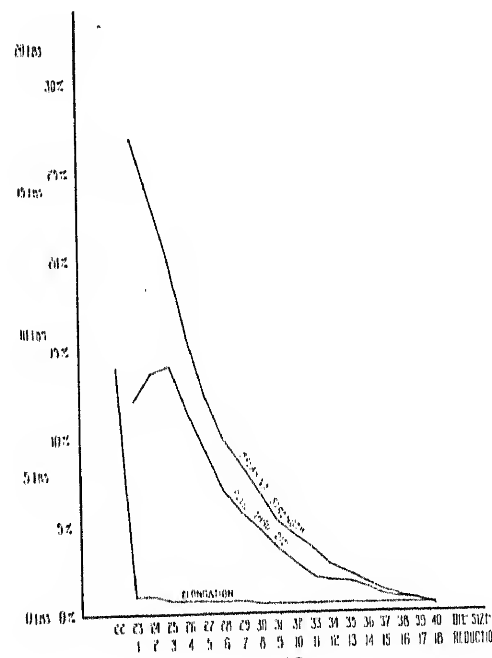

Fig. 18

by increasing or reducing the number of dies used. Tests were conducted to determine the gain by using heavier reductions and annealing the wire before redrawing, and Fig. 17 shows the increased reduction possible at the first die when the metal is plastic. In this test, an annealed No. 22 gage wire of 31 per cent elongation was reduced to No. 24, two gages, in one draw. The soft copper permitted a double reduction at the first die, but the elongation dropped during the operation to less than 1 per cent; the second reduction on this test was from No. 24 to No. 26 gage and the pull

5. "The Theory of Emulsions and Emulsifications," W. Clayton.

6. A. W. G. ("American Wire" or "Brown and Sharpe" gage) reductions are not used in converting the rod to line wire; these are generally specified in B. W. G. and N. B. S. gages.

7. See Figures, 16, 17, 18, and 19 showing the elongation of the rod or wire dropping to about 1½ per cent at the first die reduction and remaining practically constant.

required for this pass practically coincides with the breaking strength of the wire. Wire drawing under such conditions is impractical because the annealing operation is much more expensive than drawing hard wire from No. 22 to No. 24 in two passes.

Fig. 18 illustrates the results obtained when drawing annealed wire with A. W. G. reductions. The large margin of safety between the pull required and the breaking strength of the material again disappears after two reductions. Fig. 19[8] illustrates practical

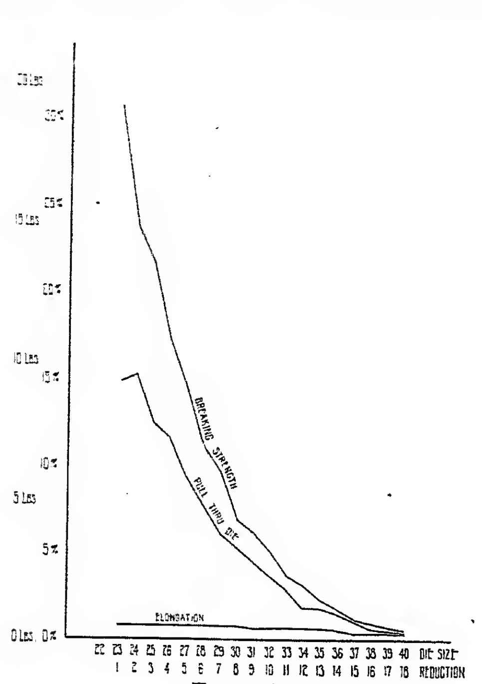

FIG. 19

drawing conditions adopted for drawing wire to finished sizes without annealing during the process.

Chilled Iron Dies

The dies used for drawing heavy wire are cast with a tapered hole from chilled cast iron and reamed to the desired size. When the die wears too large for a particular size of wire, it is reamed to a larger size and used in that manner until the dies goes above the maximum size used. These dies, shown in Fig. 20 are used for drawing line and heavy gage wire for which the cost of diamond dies would be excessive. Many alloy steel dies have been tested as substitutes for chilled iron dies for copper wire drawing, but so far have failed to replace them, due to excessive cost. For the wire sizes smaller than No. 16 down to as fine as No. 42 B. & S. diamond dies as described below are used.

Diamond Die Study

It was necessary to make an extensive study of the manufacture of diamond dies because dies through which wire could be satisfactory drawn at low speeds failed to draw to gage and without excessive breakage of the wire as the speeds were increased. At this time practically all commercial diamond drilling was done in Europe, Belgium being the hub of the diamond cutting industry and the art was new to this country. The diamonds generally used for wire drawing dies are obtained from South Africa[9], Australia, and Brazil, and made into diamond dies in Europe.

In view of the difficulty of obtaining dies for drawing wire at high speeds and the large investment in dies required for the proposed wire mill, it was decided to undertake a laboratory investigation of the manufacture of diamond dies suitable for drawing cable and magnet wire.

It was found that the dies suitable for high-speed wire drawing required a differently shaped approach, a better polish, and a shorter land[10] than used for low-speed drawing. In addition the origin of the stone, the shape of the diamond and its setting are all very important because of the internal strain to which the die is subjected during the drawing operation.

It has not been possible to definitely establish any

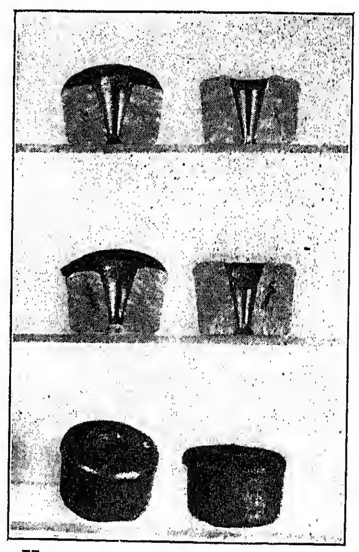

FIG. 20—DIES USED FOR DRAWING LINE AND HEAVY-GAGE WIRE

quantitative relationship as to the effect of high-speed drawing on the wear of dies except that about the same number of million feet of wire may be expected from a properly lubricated die irrespective of the drawing speed. Under such conditions, the high-speed die naturally runs a shorter time, but length of life is not

8. Slight irregularities in the curves are due to variations from the mean in the diameters of the dies used during the tess.

9. The South African and Australian diamonds are the more suitable for wire drawing. There are two types of the former, the smooth brown premier which is not suitable for dies because of its tendency to crack and split, the other commonly known as the Jager, a product of the Jagerfontein mines. These stones, very irregular in contour and light gray to black in color, are most suitable for dies. The Australian diamonds are gray to brown to almost black in color and can be distinguished from the Jager. Many of the Brazilian diamonds are a dark gray similar to graphite in color and not being translucent are difficult to inspect for seams, cracks, or inclusions.

10. See Figure 21.

the important factor; tonnage of a satisfactory quality with a minimum plant and labor investment is the prime consideration.

Fig. 22 shows a diamond before drilling, a stone drilled and lapped, ready for mounting, and a die in

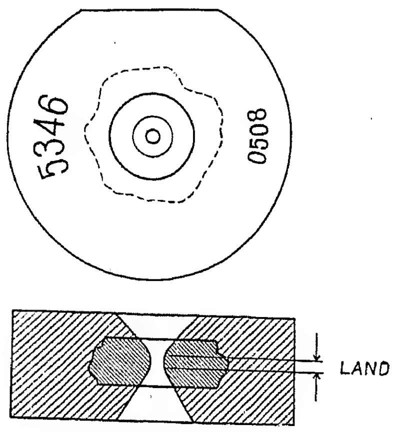

FIG. 21—DIAMOND WIRE DRAWING DIE

the final mounting ready for use. Fig. 21 gives an outline of the shape of the working surfaces of a wire-drawing die.

ANNEALING

Hard copper wire is obtained by using the wire as it comes from the wire drawing machine. This same wire may be softened by annealing, or medium-hard wire can be produced by annealing hard wire at such a point in the drawing operations that the final draws will give the desired degree of hardness[11].

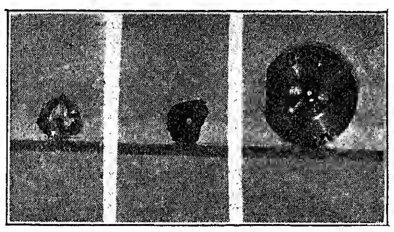

FIG. 22—SHOWING DIAMOND BEFORE DRILLING, DRILLED AND LAPPED READY FOR MOUNTING, AND DIE READY FOR USE IN FINAL MOUNTING

In a recent commercial type of annealing furnace, Fig. 23, wire may be bright annealed, but it requires a drying operation in order to remove the water through which it passes in leaving the furnace. The retorts of these furnaces are water-sealed and filled with steam to exclude the outside atmosphere, which would discolor hot copper. To obtain bright wire, it is passed under water into the retort to exclude the air and is generally taken out and cooled under water or in an atmosphere of steam or gas, which excludes oxygen until the wire is relatively cool.

11. "Experiments in the Working and Annealing of Copper," F. Johnson, *Journal Institute of Metals*, Volume XXVI, No. 2, 1921.

A special steam-seal annealing furnace for small spools of wire was developed on an experimental basis

C. LOW SET—OXYGEN 0.12 PER CENT

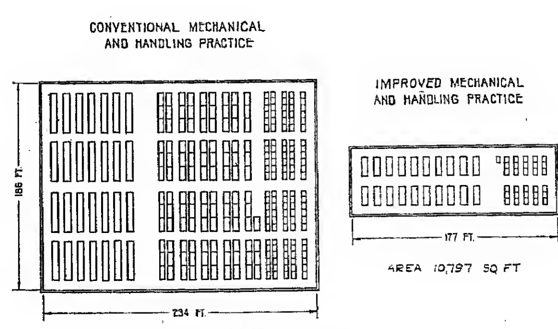

FIG. 26—DIAGRAM OF WIRE-DRAWING PLANT

from which the wire was obtained bright annealed and free from moisture. In this furnace the spools were submerged in water to displace the air, raised into the charging end which was under water, thence to the muffle to be heated and then along a cooling tube to the discharge opening. Air was excluded from the retort and cooling chamber at the discharge end by means of a steam jet.

The success of the small furnace led to the construction of a larger machine (Fig. 24) for annealing cable wire on spools. The spools are placed in perforated metal baskets which are charged into the furnace at a specified time interval, pushing each other through the retort and along the cooling tube to the discharge end.

Inspection of Raw Material and Finished Product

Wire bar made from electrolytic refined copper is used as a material in the manufacture of wire. This material is practically free from silver and other elements which ordinarily exist in the ore, and which have a detrimental effect on the electrical or physical properties of the finished product. A small percentage of silver[12] seriously affects the annealing qualities of the wire. Traces of other impurities have a very detrimental effect on the wire drawing properties. During the refining process, the molten bath is oxidized in order to carry off the foreign material in the form of slag, and it is very important that the oxygen content be later reduced to a very small point if bars of proper set are desired. Fig. 25 shows three photomicrographs of wire bar containing varying amounts of cuprous oxide[13]. Ordinarily the surface condition on top of the bar is a good index of the oxygen content. If the bar is level set or slightly convex on top, it is usually a satisfactory material. If it is low set or concave it usually contains a large amount of copper oxide, which caused the metal to shrink in solidifying[14]. When excessive shrinkage occurs it has an adverse effect during the rolling operation.

The finished wire is inspected for dimensional limits, tensile strength, elongation, and surface condition. Limits for 42 B. & S. gage wire 0.002475 are 0.00245 minimum and 0.0025 maximum.

Conclusion

The establishment of this industry as a part of the plant at Chicago represents the combined effort of a large number of inventors, engineers, designers, and mechanics. While the actual plant was built within a comparatively short period, the advances which have been made in the art represent several years' effort. Briefly, the development of compact and high-speed wire-drawing machines has required a much smaller investment in buildings and equipment as compared with a plant of the same capacity using commercial equipment. A comparison of the relative floor area, based upon the conventional and the improved types of wire drawing equipment, is illustrated by Fig. 26. The supervisory force in charge of the operation of this new mill must be given a considerable share of the credit for its successful operation.

A-C. Elevator Motor Drive

BY E. B. THURSTON[1]

Fellow, A. I. E. E.

Synopsis. *There are very few data available on the problems of using alternating current when applied directly to a motor on an elevator. It is apparent, also, that eventually there will be no d-c. power transmitted for elevator service.*

Because of these facts and the size of this industry it seems that such data should be available. A paper covering the entire field in detail would be excessively long and it is therefore the aim of this paper to cover the subject in a general way, giving such outstanding facts as are felt to be of most interest at this time.

It is hoped also to correct a false impression that is sometimes found to exist that an a-c. elevator is not practical for car speeds above 850 ft. per min. Without question, this understanding was correct six or seven years ago but it is desired to call attention to the fact that for the past five years many a-c. elevators have been installed with car speeds in excess of 500 ft. per min. and today some are operating as high as 700 ft. per min., and nothing has appeared to indicate that there is a limit of car speed other than for any other type of control.

A brief outline of the necessary requirements of the elevator machine is given because as yet the development of a-c. elevators has depended upon the success of this unit.

The desirable characteristics of the motor are given somewhat in detail, the important ones being positive speed control, elimination of exposed and sliding contacts, speed ratios of at least 6:1, a rotor of low kinetic energy, quiet under operation, allowing torque characteristic changes, smooth control of speed changes, liberal temperature range, high power factor, a maximum torque capacity, and maximum practical starting torque per ampere.

The desirable characteristics of the controller which permit high speed elevator operation with economical and reliable service and a minimum number of shut-downs, may be outlined as follows: Full magnetically operated but with a minimum number and types of magnets, types of magnets that guarantee against magnetic hum or chatter requiring no oil immersion and giving a constant pull. The controller parts in general should be as interchangeable as practical, with oilless bearings and a minimum of auxiliary parts and contacts. As a whole, the controller and its wiring must be simple and easily understood.

The principles of control allowing the high-speed elevator operation are rapid but smooth acceleration and retardation, a forced slowing down of the elevator by the motor irrespective of the operator and allowing the simultaneous or overlapping braking action of the slowing down and stopping means.

The brake magnet must be one guaranteeing against magnetic hum or chatter, giving a constant pull, and must be positive and rapid but not violent in action.

The curves which were taken by power companies serve to show the high power factor and a minimum of line disturbance.

Introduction

STATISTICS show that the elevators of the larger cities actually carry more passengers than the horizontal transportation systems. Furthermore, there is probably no industry so vital to the public and of corresponding size with its equipment and principles so little understood by the engineering profession. Naturally they are justified in asking for more reliable data.

Referring to published papers on elevators, we find there are a few on elevator service, d-c. elevators, etc., but without question there is need for more information on these and similar subjects. Upon searching for papers with information about a-c. elevator equipment, its history and problems, it is found there are so few available that it would be very difficult to get a fair understanding of this phase of the industry.

Far from a general understanding of the present art of a-c. elevators, we hear such expressions as these: "They are all right for low-speed elevator service;" "They cannot be operated smoothly;" or, "A-c. magnets and motors are too noisy to use for passenger service." These and similar expressions serve to show that it is easy to forget that new developments are possible.

Today, it has been proved illogical in connection with any development to say "It cannot be done," although this statement has been made in connection with high-speed a-c. elevators.

When we stop to realize the tremendous change from direct to alternating current in general applications, and other developments that have been made in recent years, it is natural to expect that the elevator industry has progressed accordingly. It is felt, however, that this industry did not keep pace with developments in general previous to 1920, with the result that since that time the developments have been tremendous, especially with alternating current, in order to bring this industry to its present state.

The fact that passenger a-c. elevators are operating at 700 ft. per min. and have been proved practical and reliable should make information regarding their development interesting to electrical engineers.

It is not the purpose of this paper to cover the subject in detail but rather to give a general discussion of the more important problems with the hope that other papers with more details will follow.

History

About 20 years ago there was developing a demand for direct-connected a-c. elevators, especially from many of the larger manufacturing concerns. This was due to their plants operating on alternating current and to the production basis of manufacturing.

A large percentage of this demand was for the higher capacity with car speeds of 100 to 200 ft. per min., which at that time was considered high speed for freight service. This presented many problems that had not been met before.

The single-speed, slip-ring type of motor, being the only one considered practical for elevator service, was

1. Haughton Elevator and Machine Co., Toledo, Ohio.

Presented at the Winter Convention of the A. I. E. E., New York, N. Y., February 7-11, 1927.

used and proved quite satisfactory for the demands of service at that time. Due to continual starting, stopping, and reversing, the major problems were those of preventing the rotor working loose and the burning and rapid wearing of the slip-rings.

The brake problem was considered the most serious and difficult. Many devices were developed with none having all the desired features.

The mechanically operated brakes gave the best operating service but were not by themselves considered safe. The magnet-operated brakes were very violent in action and noisy. A brake that proved quite popular and reliable was a dual type, using the mechanically-operated principle for the service and a magnetic-operated emergency brake for safety.

At this time a-c. elevator controllers were mostly mechanically operated, magnetically-operated controllers not having been developed to a reliable stage.

About 15 years ago the high resistance squirrel-cage motor began to find favor and was used for service requiring the lower horse powers. This type of motor at first met with considerable opposition, probably more because of its name than any other one thing, although there were many motors of this type manufactured with characteristics such that objections to their use were well warranted.

At this time these squirrel-cage motors were started directly across the power lines, requiring only a very simple controller, with the result that an elevator of this type was found to be the most reliable obtainable.

Its operation limited its application, however, because of the high instantaneous starting current drawn from the line, and its too sudden starting of the car. It is now apparent that to have added a resistance starter or its equivalent would have overcome these objections, but we must not forget that at that time one of the chief objections to the slip-ring type of motor was that it required a starting device, and there was no real satisfactory and reliable magnetic starter available for elevator service. Thus the high-resistance, squirrel-cage motor across the line elevator gained its reputation for reliability.

About 10 years ago the fact was apparent that the a-c. elevator for all car speeds and service was inevitable. While passenger elevators were at this time available for car speeds up to 300 ft. per min., they could not be considered as satisfactory for reliability, smoothness and noise. It was necessary, therefore, to plan for a large amount of research and development work.

The equipment offered at this time generally used a 3:1 motor speed ratio and a motor composed of a single stator and rotor with slots sufficiently large in each to permit two insulated and independent windings. This required not less than five slip-rings. Although it is difficult to accelerate a slip-ring motor smoothly and rapidly with varying loads, it is even more difficult to retard from a higher to a lower synchronous speed, smoothly. It was also found impossible by any known method to reduce the motor noise sufficiently to make it satisfactory for all elevator service.

Experience indicates that it is impossible to accelerate an elevator at high speed with a slip-ring motor rapidly and smoothly with varying loads except by what might be called a dual acceleration.

Let us suppose that we have an elevator fully loaded; to accelerate it in the up direction will require approximately the maximum torque available and a controller resistance may be used that produces maximum torque at standstill. This resistance may be cut out by any known method, either series relay, speed control, or definite time, and this operation will be satisfactory.

When starting the fully loaded elevator in the down direction, however, the load is tending to drive the motor in that direction and its maximum torque added to the load tendency to start gives too violent an action, so it is necessary to use additional resistance for a smooth start under all loads. With this additional resistance it is impossible to utilize the full available torque of the motor when used in connection with the series relay or speed control method of acceleration.

If we now use a definite time control for acceleration, it must be set slow in order to lift full load and not short circuit the resistance too rapidly, causing the motor to stall. This results in too slow an acceleration when lifting load, if the resistance is such as to give smooth operation when lowering the load. The only way found to insure the desirable results was by the use of a rapid definite time control acceleration for all surplus resistance down to that which produces maximum torque at standstill and from this point by series relay or speed control.

With this type, it was found that with fairly rapid and smooth acceleration it was possible to insure lifting a 25 per cent greater load with a given motor.

This, however, increased the cost considerably, made the controller more difficult to keep in adjustment, and still used slip-rings.

During the next five years there were what might be termed radical developments, the results of which allowed the installation early in 1922 of the first a-c. elevators running above 500 ft. per min.

With these developments and further experience the range of speed has been raised to 700 ft. per min.

Definition of A-C. Elevator

In order that there may be no misunderstanding as to the type of equipment considered when the term, a-c. elevator, is used, it should be defined as an elevator with alternating current applied only directly to the elevator motor, controller and brake with no conversion.

Machine

In the development of a-c. elevators for the higher car speed service, there were four vital units to be con-

sidered, each a complete problem by itself—the machine, the motor, the controller, and the brake.

It was immediately apparent from known principles of a-c. motor construction that a suitable geared elevator machine designed for the high car speed service must be produced before much headway could be gained with the other units.

It was not, nor is it now, practical to produce a gearless type, a-c. motor that is satisfactory for elevator service. The geared type elevator machine for the higher car speed service had been more or less neglected because a gearless type d-c. motor had been developed for this class of service.

It soon became evident that the geared elevator machines, designed primarily for the slower car speed service, would have to be re-designed for the higher car speeds and would require refinements for passenger service that had not been available theretofore.

Some of these important refinements were: a more sturdy machine throughout, more accurate machine work especially in connection with the gear, antifriction bearings for the thrust of the worm shaft, antifriction bearings for the drum shaft, and gears which would be perfectly adjustable under load and running conditions of the elevator.

The reason for the more sturdy machine and accurate workmanship is to reduce vibration that may produce noise objectionable for this class of service. The antifriction bearings are necessary to increase the efficiency and the adjustable gear to give the proper running position. As further explanation for the adjustable gear, it will be appreciated that it is impossible to babbitt a gear in place and insure having the correct gear tooth contact under operating conditions with the load of car and counterweights on the machine.

Inasmuch as the slower and moderate speed passenger elevators do not always warrant as high a degree of refinement as the higher speed passenger elevators, it is desired to confine the remainder of this paper to a-c. elevators with car speeds greater than 350 ft. per min.

The Motor

The a-c. motor being used today for the higher speed passenger service represents the result of the accumulated experience of the last 15 years. It has been a very gradual and conservative development.

It is at once evident that the motor must have more than one speed and these speeds must be positive and practically constant whether the motor is running as a motor or is driven as a generator. A direct-connected elevator motor is always required to operate under both conditions, and any motor which varies much in speed with load variations must be eliminated.

Accordingly, the induction type of a-c. motor is the only one that has been found suitable for elevator service and giving the positive multi-speed control.

As was stated in the history, the slip-ring type of induction multi-speed motor was preferred until about 1919 at which time the multispeed high resistance squirrel-cage motor was indicating advantages.

Past experiences gave a basis for arriving at what was essential for a motor in order to produce what would be considered a satisfactory a-c. elevator for all service and speeds. Tests indicated that so far as is known the single stator with two independent windings and a high resistance squirrel-cage rotor does fulfill more of the requirements than any other type available.

The more important of these requirements are outlined and explained as follows:

First, it must be practical to manufacture motors of at least 6:1 speed ratio and still have a motor of practical size to install on the elevator machine. As far as is known, 3:1 ratio was the maximum for slip-ring type motors. Squirrel-cage motors of from 25 to 150 h. p. with 6:1 ratio have been in regular elevator service for over five years.

Second, the motor must be as small as possible, especially the rotor. This is necessary in order to keep the kinetic energy at a minimum and allow rapid acceleration and retardation with a minimum of power consumption and starting current. It is apparent that the single stator squirrel-cage motor would be best fitted for this requirement.

Third, it must be possible to design a motor sufficiently quiet in operation to allow its use in hospitals, hotels, apartments, office buildings, and private residences. Because of the insulated polar windings in the stator and the rotor, the slip-ring type of motor requires slot combinations such that it is impossible to reduce noise sufficiently, while the squirrel-cage motor allows practically any slot combinations.

Fourth, the motor must allow torque characteristic changes at the installation. This is necessary because it is practically impossible to determine the exact requirements in advance, and if it were possible, it would be impractical to design a motor for each application. These changes can be accomplished in either the slip-ring or squirrel-cage motors after the general motor characteristic requirements are known.

Fifth, the motor must allow a smooth and positive control of speeds, whether accelerating or retarding, and still not require an excessive number of switches or a complicated and expensive type of controller. This is necessary in order to obtain simplicity and reliability. As outlined in the History, the squirrel-cage motor is best suited for this requirement.

Sixth, all sliding and exposed contacts should be eliminated. This is very essential because of the operating conditions and requirements. It is a generally recognized fact that the squirrel-cage type of motor is the most reliable.

Seventh, the motor must have sufficient radiation to permit the handling of maximum elevator service without abnormal temperature rise. This is one of the most important problems of design in connection with

high-resistance squirrel-cage motors for elevator service. It is possible to change the heating of a motor on elevator service a large per cent by changing its characteristics. It should also be recognized that standard commercial motor parts cannot be adapted to all elevator service. One of the most important facts to consider when designing a motor for elevator service is that its average running speed is usually less than one-half its full rated speed. This results in less than one-fourth the volume of air that a constant running motor would have. And last its radiating surface must be carefully considered.

Eighth, it is very important to have a relatively high running and starting power factor. The reason for this is to reduce to a minimum the power line disturbance when starting or lifting maximum loads.

Ninth, a motor should be capable of producing the maximum starting torque that is practical to obtain with given mechanical dimensions. This is necessary in keeping the kinetic energy at a minimum and increasing the acceleration and retardation efficiency.

Tenth, the motor should produce the maximum practical torque per ampere in starting. What is meant by this is that it should produce the maximum starting torque obtainable without increasing the frame size. This is also necessary to obtain the most efficient acceleration and retardation. In this connection attention is called to the fact that it is more important to have efficient acceleration and retardation than efficient full speed operation in order to obtain the most economical elevator service. This fact is also very forcibly shown in connection with d-c. elevators.

Exhaustive tests under actual operating conditions were necessary to develop a motor that would give these requirements. The facts found by these tests resulted in the development of a new motor of entirely new characteristics and one that was very different from any commercial motor available.

Controller

Next to the development of this motor the important problem was the development of a controller that would give certain required characteristics and could be adapted to control this motor as required.

The important requirements for a satisfactory and reliable a-c., high-speed elevator controller are outlined as follows:

First, it should be full magnetically operated. This is self-evident because it would not be practical to operate at high speeds with a mechanical control.

Second, it should have a minimum number of magnets. This is necessary for simplicity and reliability.

Third, the magnets should be interchangeable, as far as practical. This is essential for reliability and low maintenance.

Fourth, it is very necessary to insure continuously against magnetic hum or chatter. This is because of magnetic noise being so objectionable in connection with elevators. In view of this it seemed essential to use a polyphase magnet of a non-sealing type although this was a radial departure from previous practise.

Fifth, it was very desirable to use a type of magnet that did not require oil immersion, because oil around a controller has always been found objectionable.

Sixth, the magnets should be such as to give a constant pull throughout their range of action. This is necessary in order to eliminate auxiliary retarding devices and yet insure against too violent an action in closing the switches.

Seventh, to insure low maintenance and reliability in operation, the units, contacts, and parts should be interchangeable to the extreme.

Eighth, all bearings should be oilless to prevent the collection of dust and to insure long life with a minimum amount of attention.

Ninth, experience indicates that a series or speed control of acceleration does not lend itself to elevator requirements; therefore a minimum number of dash pots or retarding devices should be used and, if dash pots, they should be large, sturdy, and oilless to insure against variation in their retarding action under all conditions of service, care, and atmospheric changes.

Tenth, there should be a minimum of auxiliary contacts. This is required to insure against frequent or long shut-downs, because experience has always proved that small or auxiliary contact troubles more often do not indicate themselves and therefore are very difficult to locate, the result being long interval shut-downs while locating the fault. Attention is called to the fact that it is not the cost of a replacement contact of an elevator as much as the time out of service, that is most important.

In the interest of reliability, then, there may be mentioned: sturdy construction, minimum number of magnets, minimum of auxiliary contacts, a minimum of power contacts for service rendered, and contacts that give long life.

After considerable research it was found that a polyphase rotating-magnetic-field rotary type of magnet would give the above requirements. It was found that using this type of magnet, however, would make the controller somewhat more expensive to manufacture than with other known types; nevertheless experience has proved that this increased first cost was more than justified by the results obtained.

Further, it is interesting to note that this type of magnet made possible other desirable features. It has inherent phase reversal protection, inherent phase failure protection, allows the locking of the switch contacts in the off position, allows the forcing open of contacts by power should they mechanically stick closed, or vice versa, and gives the car control switch control over two separate and independent circuits.

Incidentally, this type of magnet allows a very simple

system of wiring which is not what was originally anticipated.

Figs. 1 and 2 are front and rear views of a controller using this type of magnet, and show the simplicity of wiring and the interchangeability of parts.

Principle of Control

After the development of the controller, the next and probably the most vital considerations to decide were the principles of control.

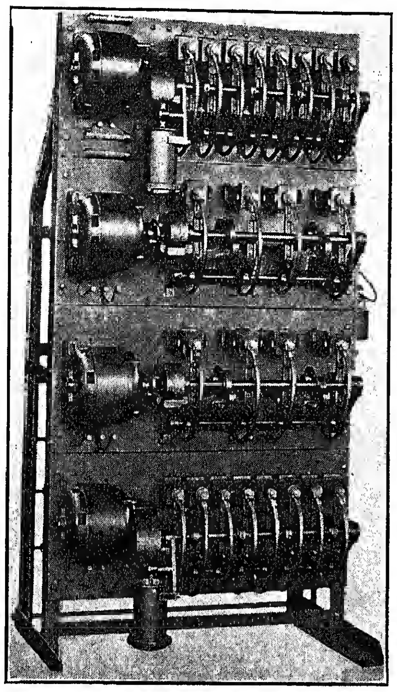

Fig. 1—Front View of A-C. Elevator Controller

It was evident that in entering a new field of application (because it is believed there were no a-c. elevators in operation with car speeds above 400 ft. per min., prior to 1920), there were many problems to overcome. The principal and most important one of these was safety, which led to conclusions that proved very important.

When it is desired to stop quickly, the neutral or reverse position of the car control switch should produce this result, or in other words when traveling at full speed and immediately moving the car control switch to the neutral or reverse position, all of the normal stopping means must act together. This principle was old with d-c. elevators but had never been available with a-c. elevators. This result or its equivalent is essential for smooth, rapid, positive, and safe operation of a-c. elevators at the higher car speeds.

It will also be appreciated that this equipment has no run-away charactericitics, because there is no generator action from an induction motor when disconnected from the power line. Should the power fail, all devices will immediately return to the stop position regardless of the load, speed, or direction.

It was also found desirable for the control to be such as to tend to increase the power factor of the motor, thereby aiding in reducing any line disturbance under operating service to a minimum. It is probably of interest to know that many of these elevators are operating very satisfactorily in buildings having a common transformer for lights and power, and experiencing no trouble from light flicker.

The Brake

It is rather generally understood that an elevator magnet brake is applied by a compression spring or by gravity and released and held released by a magnet while the elevator is operating.

The major problem is the development of a suitable a-c. magnet that will give reliable operation and still be such that it will be suitable for all classes of work. The important necessary requirements are outlined as follows:

First, it must insure against a magnetic hum or chatter under all conditions of service, such as low voltage, want of adjustment, collection of dirt, etc.

Second, it must be one that does not require oil immersion for cooling or reducing noise. Further objections to the use of oil immersion are its effect in varying brake operation with atmospheric changes and the liability of getting oil on the brake drum.

Third, it must insure against the violent action so common to a-c. magnets.

These requirements prompted the following: that it should be polyphase, non-sealing, giving a constant pull, and be reciprocating in action.

After considerable research a magnet was developed that fulfilled all of the above features.
